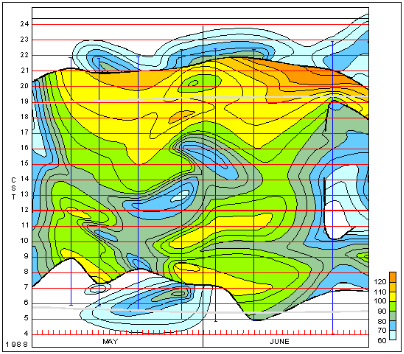
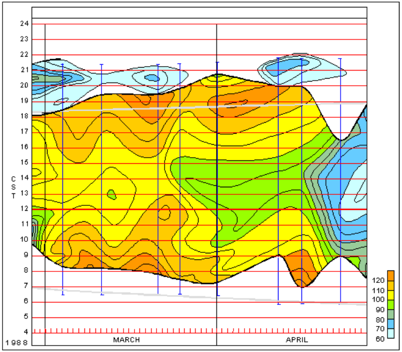
Late Afternoon, Mid-February to Mid-March - Western Australia and beyond, and Southern Malaysia: Predominately 20M.



This map shows the period of March and April, 1988. In it you see the strong morning and evening signal (in browns) and the midday sag in yellow to green. On the right the signal for the record of 22 April becomes poor, (blues). This was an active day with geomagnetic disturbances disrupting the propagation. Also in this map you can see typical evening sporadic low-level propagation after the main opening has ended, especially in early March.

In contrast to the above "winter" view, the following map shows the doldrums of summer. It is for the period of May and June, 1988. I characterize the propagation in summer as generally longer duration, but with lower signal strength and much greater day to day variability. It is not unusual to have a good strong opening for an hour or two in the evening, but



0700-1000 Local, Early to Late Summer - Eastern and Southern Africa, and Indian Ocean: 20, 15, 17, 12, and 10M (17 through 10M depending on Solar Flux).

0800-1000 Local, Early Fall - Western Australia and S.E. Indian Ocean: 20M

0500-0700 Local, * December - Malaysia, Indonesia, and S.E. Asia: 40M

Sunset to 1 Hour Before, Fall to Mid-December - Middle and Eastern Asia: 40M

0700-0800 Local, Mid-December - Middle East: Predominately 20M

Sunset to 1 Hour Before, Mid-December - Northern Middle and Eastern Asia: 20 and 40M (20M depending on Solar Flux).

* Sporadically as late as early March

If one is lucky enough to be on the receive end of a ducted medium frequency signal due to an IBGW or two, a change in the vertical and/or horizontal electron gradient will allow the RF to drop out of the duct at your QTH. Galactic Cosmic Rays also play a role in where an RF signal drops out of the duct.

A note, high solar activity in the form of increased ionization created by ultraviolet and X-ray radiation, can fill in the E Valley/F Layer ducting region with medium frequency absorptive ionization and interfere with the E Valley/F Layer ducting mechanism. In a sense the E/F layer duct is shut down and the medium frequency RF signal can only propagate between the E layer and land/ocean surface, at a higher angle and with more signal loss. This closing of the duct can be reciprocal on each end of the propagation path or one way only. (((((When closing of the duct occurs the advantage of a low angle vertical radiator is lost, with a higher takeoff angle horizontal dipole making the contact still possible, albeit maybe weaker.)))))

Medium frequency radio waves possess elliptical polarization, with the signal splitting into ordinary and extra-ordinary rays. These rays can propagate in or out of phase, more often out of phase. The out of phase extra-ordinary ray represents a 50% power loss on the receive end of a propagation path.

As follows is a recent experience I had in Florida with this propagation mode on 160 meters.
I began listening for DX on 160 meters at 5:00 pm EST this evening February 05-06, 2006. I was watching the OH2AQ spot and the stations in ME to VA were working stations in Europe and Africa. I could hear the stateside stations real well but not a peep out of any DX.

Then right at my local sunset which was at 6:15 pm EST it was like flipping a switch as all the DX stations just showed up. It was a classic example of the E Valley-F Layer ducting mechanism propagation mode with the duct opening up right over Florida as the ionized layers changed height with the arrival of the gray line terminator.

Once the DX showed up I heard oodles of CW DX stations including VQ9LA and 6W/G4WFQ who were 55 on the receive loop. MM0SJH, G3FPQ and I7RIZ showed up on phone between 1841 and 1849 kc and they were 57. I didn't bother to work anything this time as the only countries I heard

Seasonal Variations

The record presented in the previous section represented a nearly "ideal" winter record. I found that winter openings were generally dependable with a distinct jumps in the morning and drop in the evening, and good strong reception all day. 06 October, 1989 was another good day. It is possible to "map" the data from week to week in order to visualize how the propagation openings change with time. The following chart shows a map of signal strength contoured against time. Local Central Standard Time is on the Y-axis and calendar time on the X-axis. Each day starts at the bottom and moves up, the next day starting again at the bottom next to (to the right of) the prior one so the calendar flows to the right. Additionally, the Gray curves running along the upper and lower portions of the map indicate local Houston sunrise and sunset respectively.

is an asymmetry to the opening as well with a longer period of strong signal in the evening than in the morning. I attribute this to the geometry of the Houston-Ft. Collins circuit with Ft. Collins being to the west. By the time the F layer ionizes in the morning at a point halfway between Houston and Ft. Collins, the lower D layer is already ionized, conversely, in the evening there is still a couple of good hours remaining for the F layer after the D has dissipated.

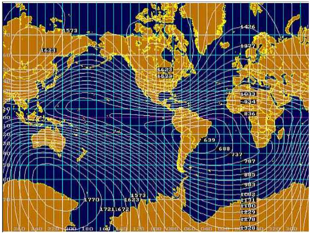
Base level, (S0) on this record is 58, the solar flux that day was quite high at 239 and the geomagnetic field was quiet. The resulting record is pretty close to ideal which is actually quite unusual. In all, the project ran for nearly four years from just after sunspot minimum to past sunspot maximum and resulted in nearly 200 weekly records. The next section provides additional views giving a flavor of the variability possible, and why.

that I've never worked were VQ9LA and 6W/G4WFQ and I couldn't break the pileups with 100 watts.

9.) Electron Gyro Frequency Absorption-

Unfortunately medium frequencies fall within or very near the electron gyro-frequency which is in the approximate range of 630 to 1630 kHz and of course the AM broadcast band and 160 meter band is very close to these electron gyro frequencies. There is a direct correlation between the strength of Earth's magnetic field lines and electron gyro frequencies.

Basically, the electron gyro frequency is a measure of the interaction between an electron in the Earth's atmosphere and the Earth's magnetic field. The closer a transmitted medium frequency carrier or sideband wave frequency is to the electron gyro frequency, the more energy that is absorbed by the gyro (spinning) electrons from that carrier wave frequency. This is especially true for medium frequency signals traveling perpendicular to the Earth's magnetic field, meaning high latitude NW and NE propagation paths. Unfortunately this form of medium frequency signal absorption is ALWAYS present.



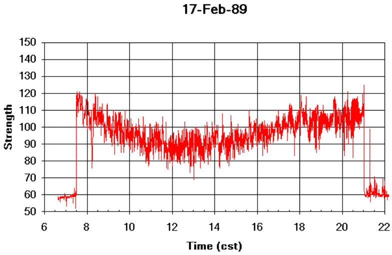
Electron Gyro-frequency Map From Prop lab Pro Software

10.) Medium & High Frequency Radio Signal Propagation Path Skewing-

Medium & High frequency radio signal propagation path skewing occurs due to changes in the "horizontal" electron gradient. Put in simple layman's terms the transmitted RF signal will "always" seek to propagate along the path with least absorption, which almost always means via a darkness path.

As an example a medium frequency signal (say 1830 kc) transmitted from Norway to New England, which is via a polar great circle path, will be directly absorbed most of the time by the Aurora Oval, with the remaining signal skirting south and then west on the darkness path via the E layer, arriving in New England from say the SE rather then the expected NE path.

Another example is a high frequency (say 28400 kc) signal transmitted from Florida that arrives from the SE at Clipperton Island (FO/TX5), which is located in the Eastern North Pacific Ocean near 11 degrees north latitude and 110 degrees west



The above record shows a fairly "classic" response for a 15 hour run. In all my runs regardless of duration I collected 3200 samples only. That was an expedient to simplify the programming, keep the record within the memory limits of a Commodore 64, and have a simple multiple of the high-resolution screen's 320 pixel width. For a nominal 15 hour run that translates to about one record each 17 seconds which is more than sufficient for the project. In addition, I actually sampled continuously between saves and read the average of many readings for each saved record. Even then, there is considerable fading and short second to minute scale noise which accounts for the "grassy" surface.

Note also two important features of the record, the very sharp discontinuities at the beginning and end of the "opening", and the general sag or lower strength of the signal at mid-day. More on the discontinuities later, the sag itself is due to increased absorption by the lower D layer at it reached full ionization near midday and dissipates by the afternoon. There

Daily Record

My study utilizes the WWV time standards beacon at Ft. Collins, Colorado. That transmitter emits at 2.500, 5.000, 10.000, 15.000, and 20.000 MHz. I monitor the 15 MHz signal which provides a strong signal at my station in Houston, Texas. 10MHz openings last longer into the night but would be useless for flare detecting at that time as the sun has set! I use a Yaesu FRG7700 receiver which is not terribly expensive and extremely stable once it has warmed up.

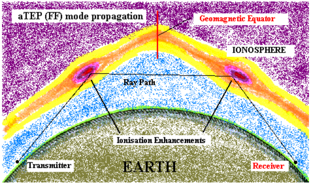
The interface between the receiver and computer uses a voltage to ohms converter which proved very acceptable but, being a resistance device, was susceptible to temperature induced drift. In Houston that was generally only a problem in the spring or fall where large changes in day to day temperature are typical in the Gulf of Mexico's battle against the continent for dominance of the climate of the region. I made occasional calibrations as necessary to the interface and kept the base level within a narrow range. The following list gives the correspondence between the digital signal strength readings presented on the charts and the radio's S-meter output:

S-meter	Computer
S0	60
S3	79
S5	90
S7	101
S9	112
+10db	132
+20db	157

record of 17 feb, 1989

longitude. This relatively short path contact gives the appearance of the double hop Sporadic E (Es) propagation mode, which frequently occurs during a low point in a solar cycle, when actually it is a skewed F2 layer propagation mode.

A general east-west band of high (25000-35000 kc) maximum usable frequencies (MUF's) exist north and south of the geomagnetic equator http://www.spacew.com/www/realtime.gif . These bands allow for the existence of the north-south propagation mode called Trans Equatorial Propagation (TEP). In any event the contact between Florida and Clipperton Island was made via the horizontal gradients that existed in the band of high MUF's north of the geomagnetic equator.



Side View Of High MUF Bands North & South Of The Geomagnetic Equator

By the way skewed propagation paths are the norm rather than the exception on medium frequencies, especially past approximately 3200 miles.

11.) Geomagnetic/Ionosphere Storm-

A worldwide disturbance of the Earth's magnetosphere and or ionosphere, induced by direct connection to the Sun's Interplanetary Magnetic Field (IMF), distinct from regular diurnal variations. Basically it's a precipitation of electrons trapped within our magnetosphere, as the electrons collide. The end result is a reduction of the MUF of the F2 layer. (See definition #3. Equatorial Ring Current). (See definition #4. Coronal Mass Ejection). (See definition #5. Coronal Hole). (See definition #6. Solar Filament).

Geomagnetic Storm Levels

Planetary K Indices	Geomagnetic Storm Level
K = 5	G1 Minor
K = 6	G2 Moderate
K = 7	G3 Strong
K = 8	G4 Severe
K= 9	G5 Extreme

Active K = 4
Unsettled K = 3
Quiet K= 0, 1, 2

A= 100-400 Severe
A= 50-99 Major
A= 30-49 Minor
A= 16-29 Active
A= 8-15 Unsettled
A= 0-7 Quiet

h = 230 KM
F2
F1
E
D
a = 72 d
v = 15.000 MHz
Nec => 2.59 x10^5
Ft Collins
<-- ~1400 KM -->
Houston

Graphical presentation of the relationships between the frequency, ionosphere electron density, and propagation incident angle measured from vertical are given in the expression:
Nec = 1.2 x 10^4 v^2 cos^2 a ...(from Tascione, 1988)

For the given circuit parameters:
v = 15.000 MHz
a = 72 d ...(h = 230 KM)

Then the Critical ionosphere density from the formula is
Nec = 2.59 x 10^5 cm^-3.

For densities lower than that value the signal will pass out of the ionosphere into space. For densities above that value the signal will continue to propagate, but with increasing absorption on this circuit.

"critical" density needed to return reflections. The relationship between the three parameters (Nec = electron density (cm^-3), v = frequency, and a = incident angle measured from vertical) is given by the following expression, (Tascione, 1988):

Nec = 1.2 x 10^4 v^2 cos^2 a

It should be noted that this expression is for the critical situation only. Where the angle is approximately known based on the circuit geometry and the frequency is known precisely, the density calculated will be the lowest density that, below which, no return (reception) will be possible. A radio wave of a given frequency therefore will continue to travel upwards into an ionosphere layer until it reaches the elevation where the density rises to the "critical" level (Nec) and the wave will be turned back to earth.

For most HF radio communication the main reflecting layer is the F layer situated between 200 to 300 KM altitude. The D and E layers are generally too weakly ionized to be of much importance except during the day over shorter distances. Ionization, although falling, persists through much of the night in the F layer as well. Intense ionization of the F layer causes it to warm and split into a second, higher, level during the day, returning to a single layer at night. There are also seasonal variations on the theme. The E layer, about 100-150 KM up, can persist into the night to some extent and in addition there are occasional "clouds" or masses of E level ionization which can drift causing sporadic radio openings when the right geometries exist. The D layer at about 80 to 90 KM is only useful for propagation during the day recombining quickly after sunset. In the negative sense, it absorbs signals passing through it to or from the F layer.

Solar Radiation Storm Levels

Flux Level of > 10 MeV Particles	Solar Radiation Storm Level
10	S1 Minor
102	S2 Moderate
103	S3 Strong
104	S4 Severe
105	S5 Extreme

Medium Frequency Radio Blackout Levels

Peak X-Ray Level and Flux	Radio Blackout Level
M1 and (10-5)	R1 Minor
M5 and (5 x 10-5)	R2 Moderate
X1 and (10-4)	R3 Strong
X10 and (10-3)	R4 Severe
X20 and (2 x 10-3)	R5 Extreme

((((Note! Unfortunately elevated Kp indices of as little as a 3 will create absorptive conditions for medium frequency signal propagation on higher propagation paths)))).

Initial phase of a geomagnetic storm is that period when there may be an increase of the middle latitude horizontal intensity.

Main phase of a geomagnetic storm is that period when the horizontal magnetic field at middle latitudes is generally decreasing.

Recovery phase of a geomagnetic storm is that period when the depressed northward field component returns to normal levels.

By the way effects of the solar wind on the magnetosphere decreases as we approach the Summer/Winter solstice and increase at the Fall/Spring Equinox. Why? Basically it's the orientation of Earth's magnetic field with respect to the Interplanetary Magnetic Field within the Solar Wind. When solar material and shock waves reach Earth their effects may be enhanced or dampened depending on the angle at which they arrive. http://science.nasa.gov/headlines/y2001/ast26oct_1.htm?list101234.

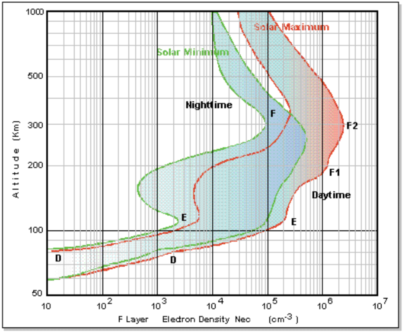
The Wang-Sheeley Interplanetary Magnetic Field (IMF) Model is used to predict Sun's IMF polarity. When the polarity of the IMF is negative a visible mid latitude Aurora display is likely as a Coronal Mass Ejection (CME) strikes the Earth's magnetic field.

Radio Wave Propagation

Because the different levels in the ionosphere are electrically conducting, they interact with electromagnetic radio waves bending them in much the same manner that glass or water bends light. The refractive index of a layer in the ionosphere depends on its electron density and has an effect on waves according to their wavelength. Levels with higher electron densities (higher altitudes where recombination is slower) have lower refractive indices. As a wave passes up from below into such layers they get refracted, or bent back down towards the lower electron density layers. The amount of bending depends on the incident angle and the frequency of the wave. Higher frequencies are less affected. Finally, in passing through conducting layers, energy in the wave vibrates the electrons thus transferring some energy into the layer and being partially absorbed in the process.

For much of the radio spectrum the frequencies are simply too high to be refracted back to the earth given the range electron densities which exist and propagation angles required. This is not true in the HF band of frequencies between a few hundred hertz and about 30 megahertz. There a delicate balance exists where, depending on the natural variations in density of the ionosphere, radio waves may be either refracted back to the earth or passed out into space. For the case of vertical incidence and a given ionospheric density there is a critical frequency above which no reflection will be received. Inversely, you can say that for a given frequency there is a

The early study of the ionosphere involved measuring its density variations and electrical properties. Most work was done in conjunction with radio studies and radio waves remain the primary way to probe its structure. Studies focus on its variability and the nature and causes of disturbances. In the process much has been learned about the solar-terrestrial connection. With a communications receiver and an inquiring mind, anyone can reach above the sky and touch the near-space environment.



Daytime to nighttime electron concentrations which constitute the midlatitude Ionosphere. Graph with variation between solar minimum and solar maximum curves. (from Tascione, 1988)

12.) Geological/Meteorological Effects On Medium Frequency Propagation-

Geological effects such as earthquakes and volcanic eruptions, as well as meteorological effects such as Troposphere originating Internal Buoyancy/Gravity Waves (IBGW's), Stratosphere level Quasi Biennial Oscillations (QBO) and warming (STRATWARM) have a negative effect on medium frequency RF signals in the form of small to medium increased absorption variations of medium frequency RF signals via the D layer, due to traveling ionosphere disturbances (TID's).

Also temperature and moisture discontinuities involved with cold frontal inversions and air mass triple points involved with extra-tropical low pressure systems can refract, diffract or scatter medium frequency radio signals in unpredictable ways, most notably on high transmitted RF power levels. This is another concept that a fellow Physicist and expert in optics took me to task over.

As far as medium frequency refraction it's more significant at say 3000 kc, then 1850 kc or 1500 kc. But it's also more noticeable with higher transmitted RF powers, i.e. WSAI 1530 50 KW and even more so with BSKA 1521 KC 1000 KW and now defunct 2000 kc region 100 KW marine stations.

We know that the medium frequency spectrum is defined as 300-3000 kc but the differences in refractive properties between 300 and 3000 is very significant At 3000 kc refraction is a good description, on 160 scattering, at 300 kc diffraction.

Using the strictest definition of RF refraction, its effect on 160 meters is small but it has been measured by government researchers as significant enough to impact 160 but near the air mass triple point. In my opinion scattering is actually the more consistent propagation medium for 160 meters along a cold front, away from the extra-tropical cyclone center.

However the temperature and moisture discontinuities in the vicinity of a triple point air mass structure such as seen with a mature extra-tropical cyclone is very complex and fluid. The NW quadrant of the extra-tropical cyclone is the location that the original government researchers identified as the region of existence for the complex temperature/moisture discontinuity structure that allows for refraction of RF signals as low as 1500 kc. I have not been successful at garnering data from the federal government that can be released to the general public. NOAA has been similarly stymied and therefore is now conducting similar research.

The QBO is a wind shift in the equatorial stratosphere, an oscillation from easterly to westerly and back on the time scale of approximately two years (26 months) and is a source of Internal Buoyancy/Gravity Waves (IBGW) which create absorptive perturbations in the D and E layers and even possibly the F 1/2 layer. A note, the E-valley/Flayer ducting propagation mechanism does not exist only during gray line periods. Internal Buoyancy/Gravity Waves (IBGW's) are a source of the ducting mechanism and allow for occurrences of ducting along any propagation path in total darkness. Measurement of the timing of arrival of propagated medium frequency RF signals demonstrates the existence of the ducting mechanism, versus conventional numerous E layer land/ocean surface hops.

The HAARP ionosphere program, earthquakes, volcanic eruptions, thunderstorms, lightning (especially positive cloud to ground strokes), elves, tornadoes and hurricanes and even

Earth's Ionosphere

The density and composition of the earth's atmosphere changes with height above the surface. From the sun, solar ultraviolet radiation impacts the upper atmosphere, ionizing the atoms there in the process of being absorbed. As the density of the atmosphere falls to very low levels the time it takes for ionized electrons and their atomic nuclei to recombine becomes sufficiently long to form a persistent ionized zone. This zone of ionized particles is called the earth's ionosphere. Due to the chemistry of the atmosphere, density variations, and varying energy levels in the ionizing ultraviolet radiation, the ionosphere forms distinct zones or layers which have been given the rather unimaginative names of D, E, F1 and F2 with increasing height above the earth.

With the complex interplay of the different factors involved, the ionosphere varies considerable with time. Regular variations form from the diurnal rotation of the earth bringing different parts of the atmosphere under the radiation effects of the sun, and from seasonal changes, and from the regular change in solar energy associated with the sunspot cycle. Other more random variations result from interactions of the earth's magnetic field with the charged particles in the ionosphere, and from disturbances to the magnetic field by solar activity. Its behavior also varies by latitude, with polar, mid-latitude, and low-latitude regions all behaving in characteristic ways.

visible and radio wavelengths. Visible-light observers generally monitor the sun in Hydrogen-alpha light where the flares shine brightest. Radio observation has traditionally utilized the very low frequency band. According to Mr. Hudak, (Sky and Telescope, 1984) this method requires a radio-quiet observing site, something simply not available to most amateurs today. This report describes observations using his method of shortwave fadeout to detect flares. In addition, the data gathered reveal several other interesting phenomena which I describe as well.

man made activities such as rocket launches including the space shuttle, are all sources of (IBGW's).

Many times I've heard ham's lament that propagation was going to go to crap due to another NASA Space Shuttle launch, in a sense they are correct.

13.) Polar Cap Absorption (PCA)-

An anomalous condition of the polar Ionosphere whereby medium frequency (300-3000 kc) radio waves are absorbed, and LF and VLF (3-300 kHz) radio waves are wave guided at lower altitudes than normal. In practice, the absorption is inferred from the proton flux at energies greater than 10 MeV (10+0), so that PCA's, Polar Radio Blackouts and Proton Events are interrelated and often simultaneous.

((((NOTE!!! high latitude radio propagation paths may still be disturbed for days, up to weeks, following the end of an official proton event.)))) This fact is still stubbornly opposed by some otherwise very knowledgeable space weather physicists, hung up on threshold Riometer readings.

-----

14. Sunspot Group-

Sunspot groups are bipolar magnetic concentration regions on the photosphere of the Sun where magnetic field strengths many thousands of times stronger than the Earth's magnetic field reside. Sunspots appear as dark spots on the surface of the Sun because temperatures in the dark centers of sunspots drop to approximately 3700 K compared to 5700 K for the surrounding photosphere. The difference in temperature makes the spots appear darker than elsewhere. Sunspots typically last for several days to several weeks. They are seen to rotate around the sun, since they are on the surface, and the sun rotates fully every 27.5 days.

Sunspot groups have a magnetic classification as follows:

Solar Flares

August 7th, 1972

The study of solar flares is driven by both practical as well as scientific reasons. Flares are explosive eruptions of energy on the surface of the sun. These releases are the most powerful form of solar activity and occasionally have severe impact on terrestrial communications and power distribution. Tight magnetic fields associated with active regions on the sun form sunspots. These magnetic fields become twisted and kinked, storing tremendous amounts of energy. The process that causes the flare energy release is not well understood, and no predictive model exists which allows scientists to know in advance when or where a flare will erupt.

The energy released in a flare occurs over the full spectrum of wavelengths from the radio to visible, to ultraviolet and x-ray. By far the major release of energy is in the shorter wavelength ultraviolet and x-ray regions. Ultraviolet energy radiates away from the sun at the speed of light and, upon impacting the earth's ionosphere 8 minutes later, rapidly ionizes all levels disrupting communication. Charged particles released in the outburst take longer, arriving about 1 to 4 days after a major flare. They interact with the earth's magnetic field causing further communications disruptions and auroral displays.

Fortunately, flares last only a short time, up to several hours in their extended, or "main" phase after the initial burst. Given their terrestrial effects and short duration, flares have long been a welcome challenge to amateurs observing at both

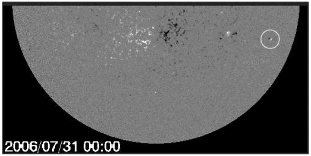
A - Alpha (a single polarity spot)
B - Beta (a bipolar spot configuration)
G - Gamma (an atypical mixture of polarities)
B-G - Beta-Gamma (a mixture of polarities in a dominantly bipolar configuration)
D - Delta (an opposite polarity umbrae within single penumbra)
B-D - Beta with a Delta configuration
B-G-D - Beta-Gamma with a Delta configuration

Sunspots usually come in groups with two opposing sets of spots. Whether two or twenty sunspots exist in a particular group they are counted as one sunspot group and numbered, such as 10500. That number would signify sunspot group number 10500, with the number counting system beginning in 1972 if my memory serves me correctly.

One set of sunspots will have a positive or north magnetic field while the other set will have a negative or south magnetic field. See image below.

The magnetic field is strongest in the darker parts of the sunspots called the umbra and weaker and more horizontal in the lighter part called the penumbra. The twisted magnetic fields associated with sunspot groups are one source of the solar flares, coronal mass ejections and geomagnetic storms that wreak havoc with the ionosphere here on Earth.



Magnetogram Image

The current system of counting sun spots hails from a previous era when direct observation of sun spots was inherently inaccurate. The sunspot number is derived by counting 10 points for each sunspot group and then adding one point for each spot. So if a sunspot group contains 1 individual sunspot the official count becomes 11. 4 individual sunspots in a sunspot group equals 44 sunspots. (See definition #24. Plage).

15.) Short Wave Fadeout (SWF)-

During a Sudden Ionosphere Disturbance (SID), which is tied to a Solar Flare and Coronal Mass Ejection, abrupt increased ionization of the D layer results in reduced to total absorption of medium frequency circuits which are refracted by the Ionosphere on the sun lit hemisphere of the earth. This is known as a Shortwave Fadeout (SWF).

Solar flares produce copious amounts of electromagnetic radiation including energetic protons which increase the ionization of the daytime D layer. Medium frequency communication depends on the refraction of signals from the

A indices (a, A, ap, and Ap)
Indices derived from the K index but converted to a linear scale as follows:

K	0	1	2	3	4	5	6	7	8	9
a	0	3	7	15	27	48	80	140	240	400

The Ap, or planetary A index is an average daily report which I have commonly used to indicate geomagnetic conditions. The equivalent values are defined thus:

Ap	Condition
0-7	Quiet
8-15	Unsettled
16-29	Active
30-49	Minor Geomagnetic Storm
50-100	Major Geomagnetic Storm
>100	Severe Geomagnetic Storm

Some Definitions

Sunspot Number
This is a measure of the number and area of both individual sunspots and sunspot groups. Naturally this is based on visual observations from a number of observatories, the data reduced and averaged. Sunspot numbers were introduced in 1848 by the Swiss astronomer J.R. Wolf and have been calculated, with caution, back to around 1610 making this the longest continuous record of solar activity available. Sunspot numbers range from lows near 0 to highs over 200 during maximums of solar activity.

Solar Flux
In many ways similar to the sunspot number, and well correlated, the solar flux index is a measure of solar radio flux at a frequency of 2800MHz, or 10.7 cm as it is commonly called. This measure was introduced in 1947 at Ottawa, Canada and has obvious advantages over the sunspot number in that it does not rely on visual, often subjective observations.

K indices (K, Kp)
Quasi-logarithmic index of geomagnetic activity relative to quiet levels for a local recording station. These measurements are taken over a 3-hour period and reported on a scale of 0 to 9. Planetary (Kp) values are determined from data from 12 to 13 stations worldwide. This indice was begun in 1949 at the Institut für Geophysic, Göttingen University, Germany.

higher E and F2 layers and these signals must travel through the D layer at least twice.

Lower frequencies are affected first and higher frequencies last. The stronger the event, the stronger the ionization of the D layer, the higher the frequency effected via absorption.

Daytime E layer propagation of the medium frequency AM broadcast band and 160 meters (See definition #1. Overview) usually only occurs during the winter season and especially at higher latitudes with a lower sun angle, also at the bottom of a sunspot cycle, therefore Swift's rarely are rarely noticed. The 80/75 meter and 40 meter bands are most noticeably affected, with the higher bands least affected.

An SWF can last from several hours on the lower frequencies to minutes on the higher frequencies. (See definition #16. Solar Flare).

16.) Solar Flare-

A day side Earth bound solar filament and/or approximate C5 class or higher solar flare can move the proton flux >10 MeV (10+0) and initiate large scale high latitude propagation path absorption but even smaller C4 class flares and weaker are the culprit behind hour-to-hour and night-to-night variations in signal strength on the MF AM broadcast band and 160 meters, both stateside and DX. This transfer of increased density and RF signal absorption from the day-side D layer to night-side of the ionosphere occurs through high level neutral winds.

X-Ray Class Solar Flare. The rank of a solar flare based on its X-ray energy output. Flares are classified by the order of magnitude of the peak burst intensity (I) measured at the earth in the 1 to 10 angstrom band as follows:
Class (in Watt/sq. Meter)
B- I less than (l.t.) 10.0E-06
C- 10.0E-06 l.e.= I l.t.= 10.0E-05
M- 10.0E-05 l.e.= I l.t.= 10.0E-04
X- I g.e.= 10.0E-04

Background radiation in the 1 to 10 Angstrom range (Hard X-Ray's), as well as Solar and Galactic Cosmic Rays and ionization of Nitric Oxide (NO) in our atmosphere is the source of ionization of the D layer.

Basically a C-class solar flare possesses energy 1/10 the level of an M- class solar flare and an M-class solar flare possesses energy 1/10 the level on an X-class solar flare. (See definition #15. Shortwave Fadeout).).

Solar flares are not random meaningless explosions but instead a process inter-related with Coronal Mass Ejections (CME's), by which the Sun expels complex magnetic signatures enroute to changing its magnetic polarity or said a different way the swapping of the Sun's magnetic poles. Basically the Sun swapped it magnetic polarity at the peak of present Solar Cycle 23 somewhere between July 2000 and December 2001. The next polarity swap will occur during Solar Cycle 24 somewhere around 2010-2011.

A true confession, while I can ponder for hours the possible physical reasons behind a discontinuity in the data, I personally get little pleasure from soldering two wires together. With modern Pentium PC computers its probably best just to purchase a manufactured A/D circuit and concentrate on the science. My own C64 retired soon after the end of this study in 1991.

described a scanner controller project for use with a Commodore 64. Two circuits were presented of which, one was an interface between the radio automatic gain control (AGC) and a C64 computer "paddle" port. I suspected that the unit would work as well with my Yaesu 7700 shortwave receiver and there followed correspondence with Dr. Maloney. He was a great help and in fact he had the same radio. The circuit had one major drawback from my perspective, it was battery operated and I was proposing to make regular observations of 15 plus hours duration. Finally the solution came in the form of a modification by my clever brother in Seattle allowing the interface to run off the 11vDC power supply or the radio itself.

With the hardware in place after my years of waiting, I was ready to go to work. September 1987 was only a year past the minimum between sunspot cycles 21 and 22 and the solar activity was still fairly low, but picking up rapidly. My goals included both detecting flares and a more general one of observing radio propagation variation from minimum to maximum in the sunspot cycle, a project therefore lasting several years. In actual fact I gathered data weekly from September 1987 until July of 1991. Each Friday early I would switch on the computer and radio and, with a homebrew Basic program, monitored WWV's signal at 15MHz.

A technical note on the interface. The device works by taking the variable voltage output of the receiver's AGC circuit, accessible easily from the rear of the unit, and converting it to a variable resistance. The Commodore 64 computer game port could read both joysticks and the even-then obsolete game "paddles" which worked on resistance. The computer read the resistance and converted it to digital values, a built-in analog to digital interface.

17.) Sporadic-D (Ds) Absorption & Wave Guiding-

Sporadic-D (Ds) occurrences have an inter-relationship with brief but intense Sun based and Galactic X-rays and Galactic Cosmic Rays, huge positive cloud to ground lightning strokes and interrelated Elves and Sprites. Very large bursts of Gamma Rays have also been observed to occur in conjunction with Sprites.

Sporadic-D (Ds) absorption occurs both at day and night. Much of the night time occurrence of Sporadic-D (Ds) absorption is often masked by lightning QRN, as well as a lack of radio operation during thunderstorm events, due to the lightning strike hazard and also due to the operator not being able to recognize the mode due to unfamiliarity with it. It's doubtful that you will read about the Sporadic-D (Ds) phenomena anywhere else other then on this website.

While on the topic of lightning and propagation, an ionized lightning channel which normally has a maximum diameter of approximately a silver dollar, can reflect RF much like meteor trails do. I've personally noticed it on the 70 cm band, as a single propagation burst lasting 1/4 to 1/2 second. (See definition #20. D Layer Mid Winter Absorption Anomaly).

18.) Sporadic-E (Es) Absorption, Blocking & Refraction-

Just as the E layer is the main refraction medium for medium frequency (300-3000 kc) signal propagation within approximately 5000 km/3100 mi, so is a Sporadic-E (Es) cloud. Sporadic-E (Es) clouds occur at approximately 100 km/60 miles in altitude and generally move from ESE to WNW.

Like Stratosphere level warming and Troposphere level temperature and moisture discontinuities, Sporadic-E (Es) clouds can depending on the circumstances absorb, block or refract medium, high and very high frequency RF signals in an unpredictable manner.

The main source for "high latitude" Sporadic E (Es) clouds is geomagnetic storming induced radio aurora activity.

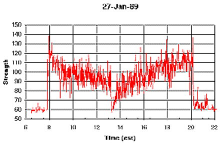
The main source for "mid latitude" Sporadic-E (Es) clouds is wind shear produced by internal buoyancy/gravity waves

Solar Flare detection by Shortwave Radio

Kevin Smith

http://www.lessmiths.com/~kjsmith/radio/r0ctnts.shtml

Introduction:
Fun with radio, a hobbyists' dash into the ionosphere..



This is the tale of a project long in the making, nurtured over three years of thinking and patience, of persistent attention, and finally of research and discovery. I hope it will fascinate and inspire the reader as much as it did myself.

The object of this study was to observe solar flares via shortwave radio. The technique, described in an article by Mr. John Hudak, (Sky and Telescope, Nov. 1984), involves monitoring the shortwave signal of a distant beacon and looking for a characteristic fadeout signature indicative of a solar flare. The equipment utilized in the article included a shortwave receiver and a chart recorder. I was interested in this project and had the necessary receiver, but no chart recorder so things merely stewed in my mind. It would not be easy or practical to purchase a chart recorder for a single purpose. Instead I considered ways of utilizing a Commodore 64 computer for the purpose of recording the data.

Things stood that way for three years until one day while shopping with my family I picked up a Radio Electronics magazine quite on a lark. Reading it later at home I was quite stunned to find an article by Dr. Frank Maloney which

(IBGW's), that create traveling ionosphere disturbances (TID's), most of which are produced by severe thunderstorm cell complexes with overshooting tops that penetrate into the Stratosphere. Another tie in between Sporadic-E (Es) and a severe thunderstorm is the Elve.

The main sources for "low latitude" Sporadic-E (Es) clouds is wind shear produced by internal buoyancy/gravity waves (IBGW's), that create traveling ionosphere disturbances, most of which are produced by severe thunderstorm cell complexes tied to tropical cyclones. High electron content in the Equatorial Ring Current also plays a role.

The forecasting of Sporadic-E (Es) clouds has long been considered to be impossible. However it is possible to identify certain troposphere level meteorological conditions that can lead to the formation of Sporadic E (Es) clouds. One is as mentioned above the severe thunderstorm cell complex.

Sporadic-E (Es) clouds have been observed to initially occur within approximately 150 km/90 mi to the right of a severe thunderstorm cell complex in the northern hemisphere, with the opposite being observed in the southern hemisphere. To complicate matters is the fact that Sporadic-E (Es) clouds that initially form to the right of a severe thunderstorm complex in the northern hemisphere, then move from ESE-WNW and end up to the left of the severe thunderstorm complex in the northern hemisphere. So one has to look for Sporadic-E (Es) clouds on either side of a severe thunderstorm cell complex. Things get even more complicated when two severe thunderstorm cell complexes exist approximately 1000- 2000 miles apart.

Not all thunderstorm cell complexes reach severe levels and not all severe thunderstorm cell complexes produce Sporadic-E (Es). This is where knowledge in troposphere physics and weather analyses/forecasting is necessary. Coincidentally I have a B.S. in Meteorology and an M.S. in Space Plasma Physics and am qualified to identify which severe thunderstorm cell complexes are most likely to produce Sporadic-E (Es) clouds.

Some of the key elements in identifying which severe thunderstorm cell complexes have the potential to produce Sporadic-E (Es) via wind shear, from internal buoyancy/gravity waves, that produce traveling ionosphere disturbances include:

1.) Negative tilted mid and upper level long wave troughs.

2.) Approximate 150 knot/170 mph jet stream jet maxes that produce divergence and therefore create a sucking vacuum effect above thunderstorm cells, that assist thunderstorm cells in reaching and penetrating the Tropopause into the Stratosphere.

3.) 500 mb temperatures of -20 deg. C or colder, which produce numerous positive and negative lightning bolts and inter-related Sprites and Elves.

DISCUSSION

Leonard F. Fuller (by letter): Operators using continuous waves have frequently observed that altho the received night signals may be stronger on the shorter waves, fading is so much more frequent on these that they are often commercially inferior to longer waves even for night work.

This may be explained by the following:

If the mean of the observations on curve Figure 13 of the American Institute of Electrical Engineers' paper mentioned by Professor Marchant are plotted, a curve of received watts is obtained following approximately the curve of energy radiated from the transmitting antenna.

This is as it should be and is the reason for the first of the practical observations of operators. The second may be explained by the following consideration of the theory of Fgure 3 of Professor Marchant's paper.

As he points out, interference bands, in the sense in which they are usually understood in light phenomena, do not exist if we consider the path of transmission parallel to the earth surface as a whole or even locally at *A* and *B*. Inasmuch as the possible number of Heaviside cloud arrangements are infinite, there are possibilities of an infinite number of points similar to *A* and *B*. Thus regions of weak or strong signals may be entirely irregular as to dimensions and spacing.

These regions are produced by the superposition of two waves of the same frequency, *out of phase*, rather than by the combination of two waves of different frequency. The relative amount of signal fading or amplification at a given point is therefore dependent upon the angular phase displacement of the two interfering waves. This displacement is dependent upon the actual mechanical dimensions of the convolutions on the under side of the Heaviside layer. Assuming the contours of this layer constantly changing, it is obvious that the longer the wave length the less the phase displacement of the interfering waves for a given change in the Heaviside layer. Thus fading may be less troublesome on the longer waves and their commercial value enhanced thereby.

Fuller's results now confirm this explanation, tho it is necessary in addition, in the San Francisco-Honolulu tests, to assume refraction. It is to be hoped that experiments may be continued, since, besides giving a great deal of information on radio telegraphic technology, such tests may enable us to gain further knowledge of the nature of the upper atmosphere, at altitudes higher than those at which balloon observations are possible. The author wishes to express his indebtedness to Professor Wilberforce for his co-operation.

SUMMARY: Variations in received signal strength are ascribed partly to the existence of a "Heaviside cloud" layer consisting of masses of ionized gas at considerable heights. A partial bibliography of the subject is given.

The theory of interference caused by a spherical reflector is given, and results of receiving experiments due to Mr. Leonard Fuller, are studied in the light of the derived theory. It is shown that the Heaviside layer is probably quite irregular, and that refraction of the traveling waves is probably existent

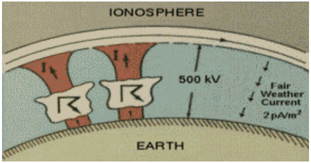
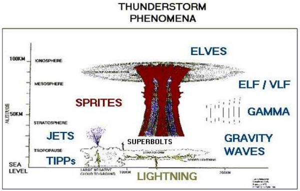
4.) Approximate 150-175 knot/172-200 mph updrafts within thunderstorm cells complexes that create overshooting tops (see photograph above) that penetrate the Tropopause into the Stratosphere (See definition #20 on Stratospheric Warming), launching upwardly propagating internal buoyancy/gravity waves, which create traveling ionosphere disturbances and then wind shear.





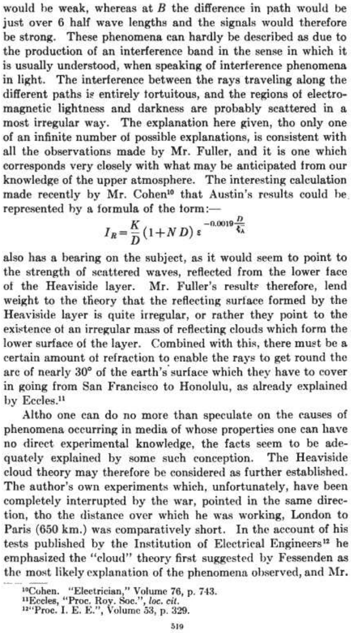
Lightning And Thunderstorms And Their Interaction With The Ionosphere

-----

19.) Long Delayed Echo (LDE)-

A fairly common propagation mechanism by which an RF transmitted signal returns to the sender within 1.25-5 seconds and in rare cases of up to 30 seconds. Research in the 1980's with HF OTHR discovered one propagation mechanism which involves ducting of the transmitted signal in the E-valley-F layer duct region of the ionosphere. A signal traveling along a magnetic field line much like a lightning induced whistler is another possibility.

The best time to observe an LDE is during the Fall/Spring equinox period when conditions are more balanced in the ionosphere. LDE's are very noticeable on amateur and SW broadcast signals between 17-28 mc with a peak near the maximum usable frequency (MUF). As recently as fall 2003 I did my own brief experiments using Morse code (CW) on the 15 meters band. I personally observed LDE's of my own



would be weak, whereas at B the difference in path would be just over 6 half wave lengths and the signals would therefore be strong. These phenomena can hardly be described as due to the production of an interference band in the sense in which it is usually understood, when speaking of interference phenomena in light. The interference between the rays traveling along the different paths is entirely tortuitous, and the regions of electromagnetic lightness and darkness are probably scattered in a most irregular way. The explanation here given, tho only one of an infinite number of possible explanations, is consistent with all the observations made by Mr. Fuller, and it is one which corresponds very closely with what may be anticipated from our knowledge of the upper atmosphere. The interesting calculation made recently by Mr. Cohen[10] that Austin's results could be represented by a formula of the form:—

$$I_R = \frac{K}{D}(1+N\,D)\,\varepsilon^{-0.0019\frac{D}{\sqrt{\lambda}}}$$

also has a bearing on the subject, as it would seem to point to the strength of scattered waves, reflected from the lower face of the Heaviside layer. Mr. Fuller's results therefore, lend weight to the theory that the reflecting surface formed by the Heaviside layer is quite irregular, or rather they point to the existence of an irregular mass of reflecting clouds which form the lower surface of the layer. Combined with this, there must be a certain amount of refraction to enable the rays to get round the arc of nearly 30° of the earth's surface which they have to cover in going from San Francisco to Honolulu, as already explained by Eccles.[11]

Altho one can do no more than speculate on the causes of phenomena occurring in media of whose properties one can have no direct experimental knowledge, the facts seem to be adequately explained by some such conception. The Heaviside cloud theory may therefore be considered as further established. The author's own experiments which, unfortunately, have been completely interrupted by the war, pointed in the same direction, tho the distance over which he was working, London to Paris (650 km.) was comparatively short. In the account of his tests published by the Institution of Electrical Engineers[12] he emphasized the "cloud" theory first suggested by Fessenden as the most likely explanation of the phenomena observed, and Mr.

[10] Cohen. "Electrician," Volume 76, p. 743.
[11] Eccles, "Proc. Roy. Soc.", *loc. cit.*
[12] "Proc. I. E. E.", Volume 53, p. 329.

in Figure 3, interference might take place between the waves reflected from two regions *C E* and *D F*. If one assumes a reflecting surface of such a nature[8] that the angle of incidence of a ray on it changes considerably for slightly differing altitudes as indicated in the figure, i. e., if the reflecting surface is irregular, a series of rays may be reflected at different angles by such a cloud at such points as *C E* (closely adjacent) in directions *C A* and *E B*, and it is easy to see that the difference in length of the path from *C* to *A* direct, and by the path *C D A* may be an odd number of half wave lengths, while the difference in length of path from *E* to *B* direct, and by the path *E F B* may be an even number of half wave lengths.[9] If this is the case, the distance between the two positions *A* and *B* at which the two waves would reinforce and neutralize each other respectively, may vary within wide limits. The diagram has been drawn to correspond, as nearly as possible, with the conditions given in Mr. Fuller's paper in which he has two stations 9 miles apart. The difference in length of the two paths to *A* is about 30 kilometers and to *B* about 26 kilometers. For a wave length of 7,500 meters, the signals at *A* would be strong, since the difference in path is 8 half wave lengths, at *B* the signals would be weak, since the difference in path is nearly 7 half wave lengths. For a wave length of about 8,500 meters the difference in path to *A* would be just under 7 half wave lengths so that signals

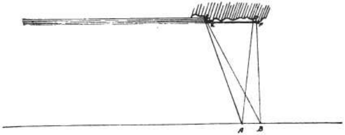

FIGURE 3

---

[8] It is perhaps misleading to speak of angle of incidence when the dimensions of the reflecting surface are of the same order of magnitude as the wave length, the incident radiation is really scattered.

[9] Altho the diagram has been drawn with the two interfering rays in one plane, it is clear that the rays may be reflected from other directions not coplanar.

transmitted signal of approximately 1.5-3 seconds and I could hear a mushy kind of Doppler shift on my returned signal frequency.

Claims of very long delayed echo's (VLDE) on the order of hours a4nd even days have been reported since the beginning of radio. Time periods of this magnitude would point to the "seeming possibility" of a refracting ionosphere type medium outside of Earth's own ionosphere, possibly somewhere past Pluto in the Oort Cloud. However no evidence so far has been found of such a medium and 99% of reported VLDE's are "probably" hoaxes.

http://heim.ifi.uio.no:80/~sverre/LDE
http://www.qslnet.de/member/la3za/prop

20.) Sudden Stratospheric Warming (STRATWARM ALERT)-

Sudden Stratosphere Warming is a major temperature change of the Winter time Polar and middle atmosphere from the Tropopause, where the Troposphere transitions into the Stratosphere to the base D layer of the ionosphere, which is at Mesosphere level. The warming lasts for many days at a time and is characterized by a warming of the Stratosphere temperature by some tens of degrees (temperature inversion), in unison with adjacent Troposphere cooling.

Another way to explain Stratosphere Warming is a major disturbance of the Winter time Polar middle atmosphere from the lower Stratosphere to the Mesosphere, resulting from a breakdown of the single Arctic Circumpolar Vortex into two circulation cells. Air trapped in the vortexes is mixed by the new meridional flow and is exposed to sunlight. Solar Lyman Alpha ionizes the Nitric Oxide (NO) gasses, resulting in an increase in electron density and producing strong medium frequency signal absorption at D layer height.

A little related Troposphere level Meteorology:

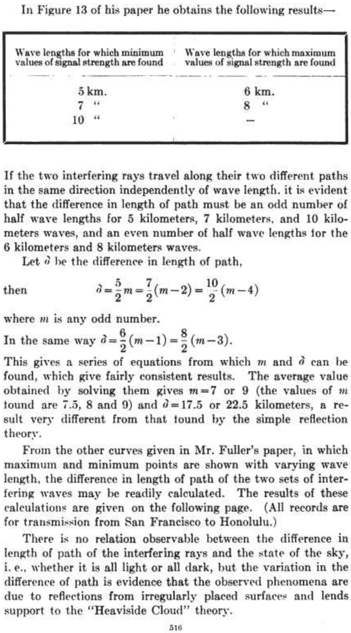
Interrelated with the splitting and shifting of the Arctic Circumpolar Vortex, is a Troposphere level negative North Atlantic Oscillation (NAO) and Pacific-North America Anomaly (PNA), mid and upper air height anomaly pattern. This equates to a large high pressure ridge in Western North America extending northward all the way into the Yukon region of Canada and a deep trough in the Eastern North America, from the eastern U.S. extending down into the Yucatan region of Mexico, with a second ridge in the western North Atlantic Ocean. This pattern is also called a dual blocking ridge and taps Siberian Arctic air, sending it across the North Pole into the eastern 2/3's of Canada and the U.S. providing for very cold surface temperatures.

As the Stratosphere lies below the Ionosphere, which is at Mesosphere and Thermosphere height, you would not expect to see Stratosphere Warming effect medium frequency propagation in any way BUT medium frequency signals do propagate off of Troposphere temperature inversions and moisture discontinuities and a temperature inversion is involved with Stratosphere Warming. So it's probable that a medium frequency signal could do any number of things when scattering off of a temperature inversion at any height. Unfortunately though some otherwise very knowledgeable Physicists stubbornly resist this concept.

Curve, Figure, Number	Date, 1914	San Francisco Time	Difference in length of path of interfering waves.	Condition of intervening space
5	Mar. 8	3 p.m.— 3.54 p.m.	28 km.	all light
6	" 15	10.30 a.m.— 12 p.m.	21 "	" "
7	" 15	3 p.m.— 4 p.m.	35 "	" "
8	Apr. 1	3 a.m.— 4 a.m.	28 "	all dark
10	May 17	11.30 a.m.— 12 a.m.	15 "	all light
11	" 24	10.25 a.m.—11.25 a.m.	36 "	" "
12	" 24	11.25 a.m.— 12 a.m.	14 "	" "
13	June 13	2.45 a.m.— 3.30 a.m.	20 "	all dark
14	" 22	10.30 a.m.—11.15 a.m.	average 15 km.	all light
15	" 28	10.45 a.m.—11.30 a.m.	36 "	" "

There is, of course, a difference between the day and night records in that the variations at night, due to altering wave length, are usually greater than they are in the day time, thus showing that the interfering waves are more nearly equal in intensity at night than they are by day. This is clearly shown in Figure 13 of Mr. Fuller's paper. The morning records give large variations also, and it would appear that altho the intervening space is fully lit, night conditions of semi-transparency still supervene. One of the most interesting results mentioned at the end of Mr. Fuller's paper is that he finds that the character of the land or water between the stations appears to make very little difference in long distance transmission, i. e., that the signals over land are as strong as they are over water. This seems almost conclusive proof that the observed signals are due to rays which are almost entirely refracted and reflected. The result, of course, is at variance with observations with shorter wave lengths over smaller distances. In dealing with interference phenomena it may be assumed therefore that the two rays travel round the earth thru the narrow passage formed by the earth and the Heaviside layer, being refracted as they pass, as was explained by Dr. Eccles, and being also reflected from the lower surface of the Heaviside layer.

If one assumes a ray refracted so as to follow nearly the curvature of the earth, which strikes a reflecting surface as shown



In Figure 13 of his paper he obtains the following results—

Wave lengths for which minimum values of signal strength are found	Wave lengths for which maximum values of signal strength are found
5 km.	6 km.
7 "	8 "
10 "	–

If the two interfering rays travel along their two different paths in the same direction independently of wave length, it is evident that the difference in length of path must be an odd number of half wave lengths for 5 kilometers, 7 kilometers, and 10 kilometers waves, and an even number of half wave lengths for the 6 kilometers and 8 kilometers waves.

Let δ be the difference in length of path,

then $$\delta = \frac{5}{2} m = \frac{7}{2}(m-2) = \frac{10}{2}(m-4)$$

where m is any odd number.

In the same way $\delta = \frac{6}{2}(m-1) = \frac{8}{2}(m-3)$.

This gives a series of equations from which m and δ can be found, which give fairly consistent results. The average value obtained by solving them gives $m=7$ or 9 (the values of m found are 7.5, 8 and 9) and $\delta = 17.5$ or 22.5 kilometers, a result very different from that found by the simple reflection theory.

From the other curves given in Mr. Fuller's paper, in which maximum and minimum points are shown with varying wave length, the difference in length of path of the two sets of interfering waves may be readily calculated. The results of these calculations are given on the following page. (All records are for transmission from San Francisco to Honolulu.)

There is no relation observable between the difference in length of path of the interfering rays and the state of the sky, i. e., whether it is all light or all dark, but the variation in the difference of path is evidence that the observed phenomena are due to reflections from irregularly placed surfaces and lends support to the "Heaviside Cloud" theory.

516

You can almost always correlate the coldest weather occurrences with poor medium frequency signal propagation conditions.

Also Stratospheric Warming (STRATWARM) has a negative effect on medium frequency propagation, due to increasing medium frequency radio wave absorption by the D layer, via upward propagating Internal Buoyancy/Gravity Waves (IBGW's).

This phenomenon also occurs in Southern Hemisphere Winter but is less pronounced.

U. Of Berlin Germany Stratospheric Research Group Layer
http://www.geo.fu-berlin.de/en/met/ag/strat/index.html

21.) D Layer Mid Winter Absorption Anomaly-

A period of increased medium frequency radio wave absorption at high and mid latitudes occurring in mid winter and is associated with sudden stratospheric warming and the Quasi Biennial Oscillation (QBO). If you look in your radio logs for 160 meters you will notice that most of your good DX contacts are in the fall and spring. This is due to the D Layer Mid Winter Absorption Anomaly. (See definition #17. Sporadic-D (Ds) Absorption & Wave Guiding). (See definition #20. Sudden Stratospheric Warming (STRATWARM ALERT).

Weather In The Upper Atmosphere
http://www.albany.edu/faculty/rgk/atm101/weather.htm

22.) F3 Ionosphere Layer-

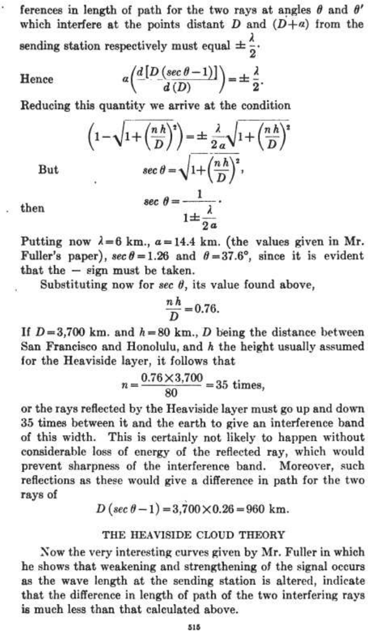
A PDF Article Via IPS Australia About The Long Suspected But Only Recently Verified F3 Ionosphere Layer
http://www.wcflunatall.com/F3layer.pdf

The F3 layer primarily exists only in the vicinity of the Earth's magnetic equator. This may represent part of an explanation for (TEP) Trans Equatorial Propagation.

23.) The Gray line/Gray line Propagation-

A general east-west transition between daytime and nighttime (twilight) where enhanced propagation conditions "may" occur. Near local sunrise the absorptive D layer has yet to become illuminated by the Sun, though the higher in altitude F/F2 layer has. Inversely near local sunset the absorptive D layer is losing illumination by the Sun, though the higher in altitude F/F2 layer still is. There is also a strengthening and weakening process in the E layer, as well as angle tilts and altitude changes in the D, E and F layers.

This process can allow for enhanced propagation conditions within the general north-south gray line corridor. It is most pronounced on 30, 40 and 60 meters and less so on 80 and 160 meters. Actually most gray line propagation on 160 meters and to a lesser extent on 80 meters is perpendicular (right angles) to the corridor. In my professional observation the gray line propagation enhancement process is still not totally understood and it's benefit exaggerated to almost mythical proportion.



ferences in length of path for the two rays at angles θ and θ' which interfere at the points distant D and $(D+a)$ from the sending station respectively must equal $\pm\frac{\lambda}{2}$.

Hence $$a\left(\frac{d\left[D\,(sec\,\theta-1)\right]}{d\,(D)}\right)=\pm\frac{\lambda}{2}.$$

Reducing this quantity we arrive at the condition

$$\left(1-\sqrt{1+\left(\frac{n\,h}{D}\right)^2}\right)=\pm\frac{\lambda}{2\,a}\sqrt{1+\left(\frac{n\,h}{D}\right)^2}$$

But $$sec\,\theta=\sqrt{1+\left(\frac{n\,h}{D}\right)^2},$$

then $$sec\,\theta=\frac{1}{1\pm\frac{\lambda}{2\,a}}.$$

Putting now $\lambda=6$ km., $a=14.4$ km. (the values given in Mr. Fuller's paper), $sec\,\theta=1.26$ and $\theta=37.6°$, since it is evident that the $-$ sign must be taken.

Substituting now for $sec\,\theta$, its value found above,

$$\frac{n\,h}{D}=0.76.$$

If $D=3{,}700$ km. and $h=80$ km., D being the distance between San Francisco and Honolulu, and h the height usually assumed for the Heaviside layer, it follows that

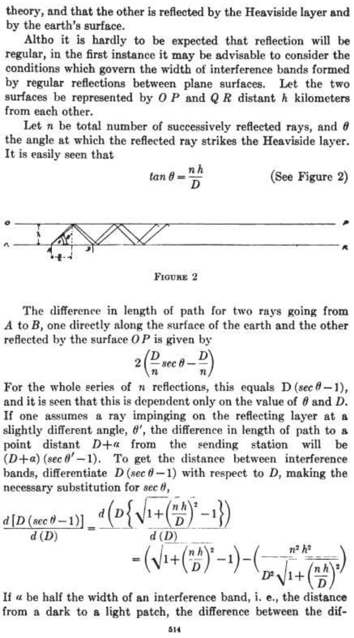
$$n=\frac{0.76\times3{,}700}{80}=35 \text{ times},$$

or the rays reflected by the Heaviside layer must go up and down 35 times between it and the earth to give an interference band of this width. This is certainly not likely to happen without considerable loss of energy of the reflected ray, which would prevent sharpness of the interference band. Moreover, such reflections as these would give a difference in path for the two rays of

$$D\,(sec\,\theta-1)=3{,}700\times0.26=960 \text{ km.}$$

THE HEAVISIDE CLOUD THEORY

Now the very interesting curves given by Mr. Fuller in which he shows that weakening and strengthening of the signal occurs as the wave length at the sending station is altered, indicate that the difference in length of path of the two interfering rays is much less than that calculated above.



theory, and that the other is reflected by the Heaviside layer and by the earth's surface.

Altho it is hardly to be expected that reflection will be regular, in the first instance it may be advisable to consider the conditions which govern the width of interference bands formed by regular reflections between plane surfaces. Let the two surfaces be represented by $O\,P$ and $Q\,R$ distant h kilometers from each other.

Let n be total number of successively reflected rays, and θ the angle at which the reflected ray strikes the Heaviside layer. It is easily seen that

$$tan\,\theta = \frac{n\,h}{D} \qquad \text{(See Figure 2)}$$

FIGURE 2

The difference in length of path for two rays going from A to B, one directly along the surface of the earth and the other reflected by the surface $O\,P$ is given by

$$2\left(\frac{D}{n}\,sec\,\theta - \frac{D}{n}\right)$$

For the whole series of n reflections, this equals $D\,(sec\,\theta - 1)$, and it is seen that this is dependent only on the value of θ and D. If one assumes a ray impinging on the reflecting layer at a slightly different angle, θ', the difference in length of path to a point distant $D+a$ from the sending station will be $(D+a)\,(sec\,\theta' - 1)$. To get the distance between interference bands, differentiate $D\,(sec\,\theta - 1)$ with respect to D, making the necessary substitution for $sec\,\theta$,

$$\frac{d\,[D\,(sec\,\theta - 1)]}{d\,(D)} = \frac{d\left(D\left\{\sqrt{1+\left(\frac{n\,h}{D}\right)^2} - 1\right\}\right)}{d\,(D)}$$
$$= \left(\sqrt{1+\left(\frac{n\,h}{D}\right)^2} - 1\right) - \left(\frac{n^2\,h^2}{D^2\sqrt{1+\left(\frac{n\,h}{D}\right)^2}}\right)$$

If a be half the width of an interference band, i. e., the distance from a dark to a light patch, the difference between the dif-

of the atmosphere which act as reflectors and refractors for the waves that are used for the transmission of radio signals.

Other facts bearing on the presence of this layer have been dealt with by Dr. Eccles in a paper published by the Royal Society.[7] It will not be necessary to reproduce the argument he uses to prove its existence, that may be assumed. It is the object of this paper to discuss to what extent the Heaviside layer can explain the phenomena described by Mr. Fuller.

THEORY OF INTERFERENCE BANDS ON A SPHERICAL REFLECTOR

In the first place, the conditions governing the production of interference bands on a spherical surface with a surrounding envelope, also of spherical form, whose internal surface acts as a reflector, may be discussed. It is usually assumed that the height at which the Heaviside layer becomes sufficiently conducting to act as a reflector is about 50 miles (80 km.). This is shown to scale in Figure 1, the points *A* and *B* corresponding respectively with San Francisco and Honolulu. It is clear that the passage between this layer and the earth is very much in the nature of a narrow crevasse between two parallel surfaces or reflecting mirrors.

FIGURE 1

It is sufficient, as a first approximation, to consider, therefore the formation of interference bands by reflection from a pair of flat parallel surfaces. The distance between the bands of electromagnetic lightness and darkness is determined by the fact that the difference between the paths of the rays reaching these points by two alternative routes is half a wave length. If the difference in distance along the two paths is a multiple of a wave length the point is one of brightness; if it is an odd number of half wave lengths the point is dark.

It may be assumed in the first instance that one ray travels along the surface of the earth, as supposed in Sommerfeld's to that already available for the discussion of this subject, and it may be useful, therefore, to consider them in their bearing on the existence and probable nature of what, in this country, is generally called the "Heaviside layer."

Tho it is usually called by this name, Professor Fleming[4] observed recently that it was Sir James Dewar, who was one of the first to draw attention to its existence. In a lecture to the Royal Institution in 1902[5], when discussing the constitution of the atmosphere Dewar pointed out that there were really two parts to it: the lower part in which atmospheric currents circulated, and in which the constituents were similar to those of the atmosphere at lower levels, and the upper part in which the distribution of gases was governed by their density. In two lectures delivered recently to the Royal Institution[6], Professor Fleming has discussed the formation of this upper ionized layer and the causes which produce it. He points out that, in order to produce ionization in such a gas as oxygen, by light radiation, it is necessary to have a wave length of the order of 1,500 to 1,800 ångstrom units (10^{-7} mm.), that is, light which is far beyond the ultra violet end of the spectrum. If such light really produces any ionization, then it is to be expected that the ionization would be reduced at night; and, therefore, that signals might be expected to vary in strength at night, if these ionized gases are the cause of signal variation. Professor Fleming suggests, however, that at heights of the order of 60 miles (100 km.), where the ordinary constituents of the atmosphere disappear and are replaced by hydrogen and helium and possibly other lighter gases, the most likely agency in producing ionization is the solar dust projected from the sun and transmitted to the earth thru the agency of light pressure. This explanation of the production of an upper ionized layer of gas is verified by the fact that the time interval elapsing between the passage of a sun spot across the solar meridian and the corresponding magnetic storm, as shown by Arrhenius, is about 45 hours, a figure which agrees fairly closely with the time Professor Fleming calculates that a particle of 1,200 ångstrom units diameter would take to pass from the sun to the earth. Whatever the cause which produces this layer, there is little doubt that such a layer exists, not necessarily in the form of a shell concentric with the earth, with fairly flat surfaces, but more likely in the form of large masses of gases in the upper regions

CHEN-PANG YEANG[*]

The study of long-distance radio-wave propagation, 1900-1919

GUGLIELMO MARCONI'S TESTS of the trans-Atlantic wireless telegraphy made sensational news at the turn of the 20th century. Since the early 1890s, the Italian-born inventor-entrepreneur had established radio communication links spanning as far as the English Channel but what he did in 1901 was unprecedented. He attempted to exchange telegraphic signals between Britain and North America without submarine cables or other mediation. Marconi's moment came on December 12. Sitting in a station on a hill in Newfoundland, Canada, Marconi and his assistant George Kemp heard regular sharp clicks from earphones connected to the receiving apparatus. They had heard a wireless message transmitted from the high antenna tower energized by a spark-gap circuit located at Poldhu, England. The New York Times quickly featured Marconi's story.[1]

The trans-Atlantic wireless test not only caught the attention of the general public, corporate capitalism, and the electrical industry for its technological implications, but also raised a curious scientific question. To establish a link across a distance as long as one sixth of the earth's perimeter, the wireless waves had to travel along a path conforming to the curved surface of the earth. Why do wireless waves, which behave much like optical and acoustic waves, not follow rectilinear trajectories? Why does the curvature of the earth not block them?

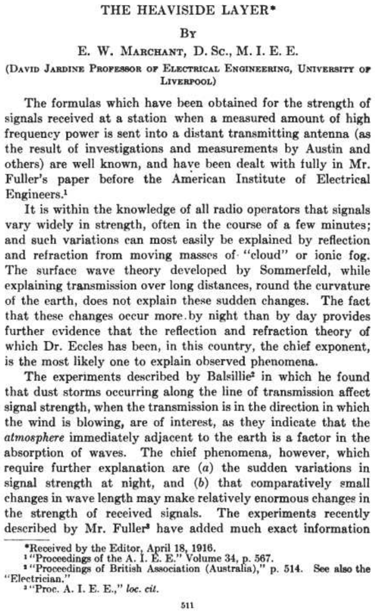
This paper shows how these problems were turned into mathematical representations, and how the empirical observations made by industrial practitioners evolved toward quantitative experimental data. It explores how engineering technologies affected experimental investigations, how traditions of applied mathematicians shaped numerical problems and approaches, and how theoretical tendencies of late-19th-century microphysics directed the formation of physical models. It also discusses how the problem of long-distance transmission emerged as a conjunction of distinct collective cultures, and how these cultures meshed with broader social contexts.

Two alternative theories of the peculiarly long transmission were proposed: the wave propagating along the surface results from diffraction by the body of the earth; and the wave bounces back and forth between the earth's surface and a conducting layer in the upper atmosphere. While theorists discussed these alternatives, experimenters worked on constructing empirical quantitative relations among the physical variables involved in long-distance transmission.

Three communities of researchers may be identified. European mathematical physicists and mathematicians worked on diffraction theories and developed mathematics to convert the diffracted fields into numerically tractable forms. Anglo-American electrical engineers and experimental physicists focused on atmospheric reflection and explored the conducting properties of the air. American wireless telegraphers established the empirical formula governing the relation between received wave intensity and distance for given wavelengths. It proved difficult to decide between the two theoretical models. The quantitative predictions of the diffraction theorists disagreed with the empirical formula. The reflection theorists could explain the bending of the waves and static noise qualitatively, but could not make quantitative predictions. The indeterminacy ended in 1919 when the English mathematician George Neville Watson developed a new mathematical technique for the diffraction theories and used it to demonstrate the superiority of the reflection approach.

The three different practices were significantly shaped by distinct intellectual traditions, purposes, and research styles. The long-distance radio experiments related to pragmatic instrumentality in wireless engineering: to test the validity of high-power transmitters and sensitive radio detectors for the first long-range radio station of the U.S. Navy. The mathematics of series or integral approximations used in the diffraction theories incorporated then recently developed complex-variable analysis in mathematics. The reflection model, which began as a speculation among electrical researchers, became part of the Maxwellian-microphysics agenda.

Proceedings of the Institute of Radio Engineers: 1916



THE HEAVISIDE LAYER*

By

E. W. MARCHANT, D. Sc., M. I. E. E.

(DAVID JARDINE PROFESSOR OF ELECTRICAL ENGINEERING, UNIVERSITY OF LIVERPOOL)

The formulas which have been obtained for the strength of signals received at a station when a measured amount of high frequency power is sent into a distant transmitting antenna (as the result of investigations and measurements by Austin and others) are well known, and have been dealt with fully in Mr. Fuller's paper before the American Institute of Electrical Engineers.[1]

It is within the knowledge of all radio operators that signals vary widely in strength, often in the course of a few minutes; and such variations can most easily be explained by reflection and refraction from moving masses of "cloud" or ionic fog. The surface wave theory developed by Sommerfeld, while explaining transmission over long distances, round the curvature of the earth, does not explain these sudden changes. The fact that these changes occur more by night than by day provides further evidence that the reflection and refraction theory of which Dr. Eccles has been, in this country, the chief exponent, is the most likely one to explain observed phenomena.

The experiments described by Balsillie[2] in which he found that dust storms occurring along the line of transmission affect signal strength, when the transmission is in the direction in which the wind is blowing, are of interest, as they indicate that the *atmosphere* immediately adjacent to the earth is a factor in the absorption of waves. The chief phenomena, however, which require further explanation are (*a*) the sudden variations in signal strength at night, and (*b*) that comparatively small changes in wave length may make relatively enormous changes in the strength of received signals. The experiments recently described by Mr. Fuller[3] have added much exact information

• = SIGNAL FROM NORFOLK

These communities worked toward different goals, legitimized different methodologies, and gave priority to different technical and social concerns.

Diffraction theorists and the reflection modelers did not compete directly; their practices, and those of the experimenters, exhibited more complementary than competitive elements. Although the three communities were tied together by the same question (the possibility of long-distance radio-wave transmission), the most important aspect of their intertwined history was not the mutually exclusive and competitive answers they reached, but their contributions of different pieces of knowledge eventually subsumed in the solution.

The three communities' essential differences and the intellectual content of their interactions may be understood by analyzing their epistemic status—their judgments about what was known, what was important to know, and possible to know. Here reference to the teachings of Pierre Duhem and Sylvain Bromberg are in order. Duhem distinguished two aims of a physical theory: [to explain] a group of laws experimentally established, and "to *summarize* and *classify logically* a group of experimental laws without claiming to explain these laws."[2] Duhem's mathematical calculus for organizing scientific knowledge included quantitative and logical reasoning, numerical predictions, and recursive revision. Similarly, Bromberger distinguished theory as an intellectual device that could systematically generate answers to questions from theory as an answer to a why question.[3] Following Duhem's and Bromberger's theories of epistemic status, analyzing what is known, important to know, and possible to know amounts to deciding whether, for the historical actors, a piece of knowledge is explanatory or representational, an answer to a question or a part of a question-answering device.

The essential distinction between the diffraction theorists and the reflection theorists concerned the kinds of questions asked and the kinds of knowledge required, not the mutual exclusiveness of their physical models. The diffraction theorists developed rigorous mathematical theories to represent a physical model that aimed to account for only one wireless phenomenon—long-distance propagation. For this single phenomenon, they could mobilize quantitative reasoning and consolidate numerical predictions from mathematical theories. The reflection theorists constructed elaborate physical models to account for several significant wireless phenomena—not only long-distance transmission but also the diurnal and seasonal variations of signals and atmospheric noise. But their mathematical tools lagged much behind the diffraction theorists'. The diffraction theorists asked questions about mathematical tractability. The reflection theorists asked questions about the causes of various puzzling observations. Their theories were mainly explanations. But until a late stage they did not contain a systematic means for giving qualitative or quantitative predictions.

The epistemic approach helps to understand the activities of the experimenters as well. The questions they asked were practical—they wanted to know the performances of transmitters and receivers under operating conditions in order that the U.S. Navy's first long-distance wireless would function properly. They were not motivated by theory-driven questions to conduct experiments. Likewise, their measured results served as reference for engineering specifications rather than as tests of theories. Because, however, the physics-trained experimenters believed that representing the measured results in terms of a mathematical formula, which was much more convenient than raw numbers for the theorists to work with, served engineering, they did provide material for checking theoretical predictions.

1. EMPIRICAL OBSERVATIONS

Guglielmo Marconi invented a transmitter and receiver for wireless telegraphy in the 1890s. Oliver Lodge in Britain, Alexander Popoff in Russia, Edouard Ducretet in France, and Ferdinand Braun in Germany made similar inventions about the same time.[4] The European and American governments, commercial and industrial enterprises, and inventors, engineers, and scientists quickly recognized the potential of these devices. Numerous sophisticated novel technologies of wireless telegraphy were developed between 1895 and 1920.

To the engineering communities, the primary concern with wireless telegraphy was the improvement of transmitters, receivers, and techniques of measurements.[5] They were not as successful in modeling the process of wave transmission as in engineering transmitters and receivers. They had too little information about wave propagation in the real world for which they intended the devices. To proceed, they needed to establish the empirical phenomena of wireless wave transmission. That task began only in the first few years of the 20th century.

The empirical problem may be stated as follows: under what environmental or instrumental conditions does the propagated electromagnetic energy experience a certain amount of change. The relevant major phenomena discovered before 1910 consisted of:

- Marconi's achievement of wireless communications over one sixth of the earth.
- The effect of the terrain. The maximum effective transmission distance of a wireless wave is the longer the greater the ground conductivity; thus a wave over sea usually propagates farther than one over land. The British naval officer Henry Bradwardine Jackson deduced the effect from experiments conducted on his own while serving on British warships between 1899 and 1902.[6]

SUMMARY: The strength of received signals from two stations was measured at the Bureau of Standards over a period of about two years. The transmitting wave length was 1,000 meters, spark frequency, 1,000, and sending antenna current about 10 amperes for each of the transmitters. Their distances were respectively 185 and 235 kilometers. The curves giving variation in intensity of received signals are shown and discussed.

DISCUSSION

Robert H. Marriott: It will be found interesting and instructive to compare what Dr. Austin has found with the results I described in my paper on "Radio Range Variation" before the Institute, (PROCEEDINGS OF THE INSTITUTE OF RADIO ENGINEERS, Volume 2, Number 1, page 37) and especially with chart 3, Figures 1 and 12 of that paper.

Alfred N. Goldsmith: It is evident from Dr. Austin's results that for the particular stations under consideration, the day of best transmission is close to January 1st, and the day of most difficult transmission to July 15th. The average ratio of received energy in winter to received energy in summer (for the extreme cases) is found to be 6.3. However, this last result is not very accurate, since the individual values of the ratio lie between 3.9 and 10.

was 69 ohms. The figure shows a well marked difference between the summer and winter intensities, but the great variation among the individual values makes it difficult to draw quantitative conclusions; observations on succeeding days in several instances differing from each other in a ratio of more than two to one, while the errors of observation are certainly less than 10 per cent. Rough curves have been drawn among the individual points of observation, indicating the general course of the changes. The Philadelphia values in general lie higher than the Norfolk values, with the exception of those taken in the Autumn of 1912 before certain changes were made in the Philadelphia antenna which appear to have increased its efficiency. No observations were taken in Norfolk after November, 1913, as changes in that station made it impossible properly to make comparison between the observations before and after that time. Notwithstanding the irregularities among the observations, a few facts appear fairly certain: The seasonal variations seem to be different in different years, the minimum of 1912 being higher than that of 1913. The rise in the curves in the Autumn of 1912 appears to be steeper than that of 1913, the practical maximum being attained by November 1st in 1912 and not until the middle of December in 1913. It has not been found possible definitely to connect the strength of signal with the changes in foliage conditions, altho it is possible that this is an important factor in the variations. Contrary to the ideas previously held, there seems to be no very marked connection between rainfall and the transmission of the signals. This was especially noticeable in the Autumn of 1912, when after a dry period, rain set in and fell heavily for four days. This, however, caused no certain increase in the strength of the received signals.

This preliminary series of observations shows that for a thoro study of the subject it will be necessary to observe at least twice a week, and preferably every day, for a long period of time. From these observations it will then be possible to derive average values from which the general course of the phenomena can be deduced with some degree of accuracy. It may then be possible by comparison with the curves of meteorological and magnetic phenomena to find relations which will help to explain the seasonal changes, and also the irregularities among the single observations.

Most of the observations have been taken by my assistant: H. J. Meneratti, Chief Electrician, U. S. N

- A wave goes further in dry than in humid air (Jackson).
- The maximum effective distance at night exceeds that in daytime (Marconi).[7]
- Noise, "static," or "stray wave" is more serious at night than in daytime (Jackson), during the summer than during the winter (Jackson), and at low than at high latitudes (Popoff, Feriyi, and Turpain).[8]
- The received energy generally increases with the length of the wave and the arrangement of the antenna.
- The radiation pattern of an antenna system can be different at different directions. A vertical aerial receives maximum energy when tilted along the transmission direction; several aerials with identical phase delay can give a strongly directional transmission (Marconi, Zenneck, Sigsfeld, Braun).[9]

Until 1905, the antenna consisted of a long vertical conducting wire connected at its lower end to a spark gap. The amplitude of received current is independent of the direction of the receiver's location with respect to the antenna, provided the receiver is on the ground. In 1906, Marconi suggested that a directional effect antenna could be obtained with a horizontal antenna.[10] The received current attains the maximum when the transmitter-receiver direction lies along the direction of the transmitter or the receiver antenna. Typically, reception is a minimum at angles of 110° or 250°. The minimum loci and the shape of the radiation pattern vary with antenna parameters. Figure 1 illustrates two of the radiation patterns Marconi measured.

Many of the empirical observations were qualitative descriptions that made either ontological assertions identifying physical factors relevant to the propagation of electromagnetic waves or quasi-quantitative comparative statements linking propagation with increase or decrease of a physical quantity. Quantitative descriptions of the empirical observations existed as tabulated data, not mathematical formulas. However far this phenomenological knowledge was from ideal scientific evidence, theorists had no choice but to use them as empirical evidence for their theories. Rigorous and controlled quantitative experiments on long-distance wave transmission remained to be done.

2. SURFACE DIFFRACTION THEORIES

The British initiative

To the community of physicists in the late 19th century, the phenomenon of long-distance wireless wave transmission was not altogether unfamiliar. The physical picture associated with this phenomenon could be found in the physical optics of diffraction and in acoustic scattering theory. Lord Rayleigh had developed a set of analytic techniques to deal with the acoustic problem.[11]

Between 1901 and 1919, two groups of mathematical physicists and mathematicians developed Rayleigh's approach for application to radio-wave transmission. One was a British group at Cambridge University plus the French mathematician Henri Poincaré. The other group was led by the mathematical physicist Arnold Sommerfeld at the University of Munich and the German electrical engineer Jonathan Zenneck.

Hector Munro Macdonald received a bachelor's degree at the University of Aberdeen before moving to Cambridge University, where he became fourth Wrangler in the Mathematical Tripos of 1889. His research agenda was set by the Adams Prize problem of 1901: to describe the propagation of electromagnetic waves under a number of boundary conditions with simple geometry. Published in 1902 as *Electric waves*, Macdonald's prize-winning essay applied an electromagnetic theory based on an energy expression to study the effect of an antenna on its electrical oscillating frequencies, and to solve the diffraction field at the edge of a perfectly

SEASONAL VARIATION IN THE STRENGTH OF RADIOTELEGRAPHIC SIGNALS*

By

Louis W. Austin, Ph.D.

(*Director of the United States Naval Radiotelegraphic Laboratory*)

In 1912, experiments were begun at the Bureau of Standard on the measurement of the strength of the receiving antenna current produced by signals sent from the radio stations in the Philadelphia and Norfolk Navy Yards. The object of the experiments was the determination of the variation in the strength of the signals at different times of the year.

It had been known qualitatively that the winter signals in general were stronger than those of summer, especially when the transmission took place overland. The reason ordinarily given for this was the absorption of the waves during the summer, due to the vegetation.

The conditions of the experiments were as follows: The sending wave length was 1,000 meters, and the spark frequency was approximately 1,000 per second, the sending antenna current being kept not far from 10 amperes, and care being taken that waves of only one frequency were emitted. The height to the center of capacity of the Philadelphia antenna was 39 meters, and of the Norfolk antenna 52 meters. The antenna at the Bureau of Standards is a harp 55 meters high, having an effective height to the center of capacity of 30 meters. The capacity is 0.0014 microfarad. The distance from the Bureau of Standards to the Philadelphia station is 185 kilometers, and to the Norfolk station 235 kilometers. The method of measuring the received antenna current has been described in another place.†

The observations are shown in the accompanying figure. The ordinates represent microamperes of received current reduced to a constant sending antenna current of 10 amperes. The total receiving antenna resistance, including that of coupling, conductingprism.[12] When the news of Marconi's trans-Atlantic transmission spread in 1901, Macdonald was ready to work out a theoretical account of the phenomenon based on diffraction model.

---

* Delivered before The Institute of Radio Engineers, New York, December 2, 1914.

† Bulletin, Bureau of Standards 7, p. 295, 1910. Reprint No. 157.

Macdonald's paper of 1903 begins with a simple model that included all the supposedly relevant physical characteristics of wireless wave transmission.[13] The transmission antenna appears as a vertically polarized point current source, the so-called "Hertzian dipole," above the ground. Macdonald treated the atmosphere as free space with uniform dielectric constant and permeability and zero conductivity, and the earth as a perfect conductor (figure 2). The model captured some reality; but also erred seriously in giving the atmosphere no role (different from free space) in wave transmission. All diffraction theorists after Macdonald began their theoretical work by imposing the assumption.[14]

To calculate the intensity of the electric and magnetic fields at any point on the earth, Macdonald solved Maxwell's equations for the electromagnetic fields. He wrote down the wave equation for the azimuthal component of the magnetic field intensity in spherical coordinates (the axis of the azimuth is the radius connecting the earth's center and the dipole's location). Following Rayleigh's *Theory of sound*, Macdonald expressed the solution as a series of Bessel-Hankel functions and Legendre polynomials.[15] He determined the coefficients of the terms in this series from the conditions that the field intensity be infinite at the location of the Hertzian dipole and the tangential component of the electric field at the surface of the perfect conducting earth should vanish.[16]

The diffraction theorists in the first twenty years of the 20th century agreed with all Macdonald's arguments up to this point. They disagreed about how to approximate the analytical solution in a numerically tractable form. Macdonald noticed that the problem had exactly the same form as one dealt with in Rayleigh's *Theory of sound*. Following Rayleigh, Macdonald exploited the asymptotic properties of Hankel functions to establish that when the wavelength λ is much smaller than the radius of the earth a, the field intensity obeys a simple relation. The ratio of the electric field at the sphere's surface at the separation angle θ (the angle between the oscillator P and the point of observation C as seen from the earth's center) to the electric field at $\theta=0°$ is $1-\cos\chi$, χ being the angle between the observer and the earth's center as seen from the dipole.[17]

This overly succinct result implies that the electric field produced by a Hertzian dipole does not vanish at any point on the earth, including the diametrically opposite point, $\chi = 0°$. It means that the earth never casts any shadow on the propa-

gation of the electromagnetic field. The field can travel anywhere on the earth. Thus the magic of trans-Atlantic wireless transmission: the field diffracts across the surface of the earth. Macdonald considered this conclusion to be a complement to Rayleigh's discovery in acoustics.[18]

Unfortunately, Macdonald's approximation scheme had a serious problem, which Rayleigh pointed out. Rayleigh claimed that a shadowless wireless wave could not move around the earth since it would lack analogy to the optical case. The wavelength of the wireless wave (less than 50 kilometers) had about the same ratio to the radius of the earth as the wavelength of visible light had to one inch; but the light shining on a conducting ball one inch in radius does not creep around the ball to illuminate its rear surface. Furthermore, Rayleigh points out that Macdonald's asymptotic approximation did not in fact hold when the wavelength is much smaller than the radius of the sphere owing to a property of the Bessel functions that need not be detailed here.[19] Henri Poincaré also pointed out the difficulty with Macdonald's asymptotic approximation.[20]

In the following decade, the mathematical problem of how to approximate the exact solution of the diffracted field given by Macdonald was widely discussed among mathematicians and mathematical physicists, who proposed new approaches to the notorious Bessel functions. None of these efforts survived criticism. Discus-

H. E. HALLBORG: We should try more transmission experiments between stations lying north and south, so as to be able to compare ranges with those lying east and west. It has already been noted by ship stations that the transmission of signals in a north and south line is superior to that in an east and west line.

GUY HILL: Referring to the surface waves, Marconi has used wires on the ground for long distance reception, and some time ago Fessenden received messages over 600 miles on ground antennae.

A. E. KENNELLY: We may assume, in the present state of the theory of radio-telegraphic received signals, that the voltage of a signal received from a given steady wave-train is directly proportional to the maximum height of the receiving antenna above the plane of the equivalent perfect ground surface. The electric energy of the signal, however, is of course proportional to the received voltage and the received quantity. The quantity probably depends on the extent of wave surface area on the wave-front intercepted by the antenna. If this way of considering the matter is correct, a very low antenna of great length might give as strong a receiving signal as a high antenna of small width or surface area.

ALFRED N. GOLDSMITH: There seems to be a non-reciprocity of sending and receiving properties, on which Lord Rayleigh has already commented. A high antenna is necessary for transmission, but since reception of messages is largely accomplished on surface waves (at least for long distances) a low receiving antenna suffices.

CHARLES A. LE QUESNE, JR.: In a recent number of the Telephone and Telegraph Age I find a reference to some experiments by Austin Curtis on an effect of moonlight on reception of signals. The effects presented were similar to those for sunlight.

ALFRED N. GOLDSMITH: These experiments were originally disclosed in The London Electrician for March 21, 1913, (page 1104) and May 2, 1913, (page 143), and they have been considered by Dr. Eccles in the same periodical for March 28, 1913, (page 1144).

antennae, λ the wave length, and s, the distance between the stations.

$$I_2 = \frac{4.25\ I_1\ h_1\ h_2}{s}\ \varepsilon^{-\frac{\alpha s}{\sqrt{\lambda}}}$$

where α is a constant, equal approximately to 0.0015.

These experiments covered several types of antennae, and distances up to 1,000 miles (1,600 km.) with various antenna currents. The current for audibility (thru an equivalent resistance of 25 ohms) was taken as 10 microamperes. It appears that we need only 5 microamperes, or with the heterodyne receiver less than 2.5 microamperes. Making this change in the equation above, the results had in the recent Arlington-Salem tests offer good substantiation of the relation. With a sending antenna effectively 450 feet (138 meters) high, and a receiving antenna of 130 feet (40 meters), groups of thirty-word messages have been consistently received by daylight up to a distance of 2,383 miles (3,830 km.). From this it can be shown by a graphical solution of Austin-Cohen equation that the daylight range of an Arlington-type station to a similar station is 2,920 miles (4,700 km.) at a wave length of 4,000 meters; and rises to 3,400 miles (5,500 km.) at a wave length of 10,000 meters. (Further details of these heterodyne experiments, and the Arlington-Salem tests are given in the latter portion of the next paper in this issue of the Proceedings. Editor.)

I wish to endorse Professor Kennelly's suggestions. I trust that the observations will cover all parts of the twenty-four hour day, and that transmitting station records, as recommended by Mr. Weagant, may be secured.

LLOYD ESPENSCHIED: Such experiments as just proposed can be best carried on by the Navy. They would materially add to the efficiency of the Weather Bureau's work, if properly planned.

CAPT. F. J. BEHR (Coast Artillery Corps, U. S. A.): This subject is one of great interest to us; particularly the relative advantages of "damped" and "undamped" waves. These meetings of THE INSTITUTE OF RADIO ENGINEERS are doing yeoman service in calling attention to these points and the proper method of investigating them.

sion of the problem was dominated by Cambridge-trained people—and by Henri Poincaré.

Poincaré tried to work out an adequate and rigorous approximate solution for the mathematical problem formulated by Macdonald. He worked at it from 1909 until his death in 1912, publishing nine papers in all, including a 100-page monograph published in 1910.[21] Poincaré's strategy was to convert the infinite series obtained by analytically solving the wave equation into a definite integral and to employ Cauchy's residue theorem to evaluate it. Like Macdonald, Poincaré expressed the analytical solution of the wave equation in terms of a series of spherical harmonics constituted of Bessel functions and Legendre polynomials. In the case of a dipole on the ground, the infinite series can be converted into a sum of integrals associated with the poles of the spherical harmonics. When the size of the conductor is much larger than the wavelength, the term corresponding to the pole with the smallest imaginary part dominates the other terms. Poincaré proved that the dominant-pole contribution to the field intensity on the spherical surface is proportional to $\exp[-\rho(ka)^{1/3}\theta]$, where θ is the angle defined in figure 2, $k=2\pi/\lambda$ is the earth's radius and ρ is an unspecified constant. The field intensity produced by a Hertzian dipole on a spherical conductor has the form of exponential decay with respect to the separation angle.[22]

Poincaré's work involved esoteric theories of Bessel functions and complicated mathematical manipulations. But its conclusion had a clear and straightforward physical meaning: the diffraction field on a conducting sphere decays exponentially: the larger the wavelength, the longer the transmission distance. Four years after Poincaré published his important formula, a debate broke out over whether the field's decay rate varied with $\lambda^{1/3}$, as required by his theory, or with $\lambda^{1/2}$, as revealed from experiment. But Poincaré's result also was incomplete. It did not specify the numerical values of the decay rate γ and the amplitude constant. Without these values, the mathematical theory of diffraction could not produce quantitative results strictly comparable to the experimental data. The task of obtaining the missing numerical value of the decay rate fell to John William Nicholson.

Nicholson, Cambridge Wrangler began to publish on the diffraction problem in 1910. He opened with a criticism of Poincaré's method.[23] Poincaré had not carried out the asymptotic approximation of the Bessel functions correctly, and his procedure for converting the infinite series to an integral was not adequately rigorous. Nonetheless, like Poincaré Nicholson converted the series into an integral and obtained its approximate value by the contribution from the dominant pole. He examined the pole structures of the functions and concluded that for *ka*>>1, the magnetic field intensity is dominated by the contribution from the zero of the de-

rivative of the Hankel function with the smallest imaginary part. The imaginary part of this zero has the form of $\rho(ka)^{1/3}$. Thus the approximate field is proportional to $\exp[-\rho(ka)^{1/3}\theta]$.

This conclusion is the same as Poincaré's. In addition, Nicholson solved for the numerical value of the attenuation coefficient ρ and obtained the value 0.696. Having this numerical information, Nicholson constructed tables providing quantitative predictions of the diffracted electromagnetic waves around the earth.

No quantitative experimental data on wireless wave transmission were available when Nicholson finished his calculation. Still he could make a definitive and surprising statement: "diffraction must be a relatively insignificant agency in the success of experiments such as those of Marconi."[24] Nicholson's confidence came from a dramatic discrepancy between the numerical scale of the diffraction theory and that of Marconi's experiment. The exponential decay at $0.696(ka)^{1/3}$ made the diffracted field diminish much faster than it should have done if diffraction was responsible for long-distance wave transmission. Although Nicholson continued to work on the diffraction theory for a few years, he no longer believed that it could explain long-distance transmission. He thought that reflections from the upper atmosphere offered a more plausible theory.

Nicholson's conclusion did not destroy the diffraction theory. His mathematical solution to Macdonald's predicament was not the final one. Other mathematicians developed different methods that generated numerical results different from his. Also, while the British-French diffraction theorists all stuck to the assumption that the earth can be modeled as a perfect conductor, which guides the diffracted field around the earth, the German diffraction theorists did not focus only on this case.

German follow-up

In Germany, a group of diffraction theorists worked on the problem of wireless-wave transmission over ground. They believed that finite ground conductivity played a role in several wireless phenomena. They assumed that a "surface wave" would rise above the ground and creep along the ground surface. The finite ground conductivity could modify the polarization of the wave. The German diffraction theorists during the 1900s and the 1910s included an electrical engineer, Jonathan Zenneck, at Braunschweig, the theoretical physicist Arnold Sommerfeld, and his protégés at the University of Munich.

In 1889, while pursuing his doctoral degree at the University of Tübingen, Zenneck became assistant of Ferdinand Braun, a pioneer of radio research in Germany. During their work together (1892 to 1906) Braun's research group competed fiercely with Marconi's team. In 1899, Braun launched experiments on long-distance wireless telegraphy in the Cuxhaven region near Hamburg. Zenneck was

---

their use for a stated amount of energy. But it is as yet an obscure point.

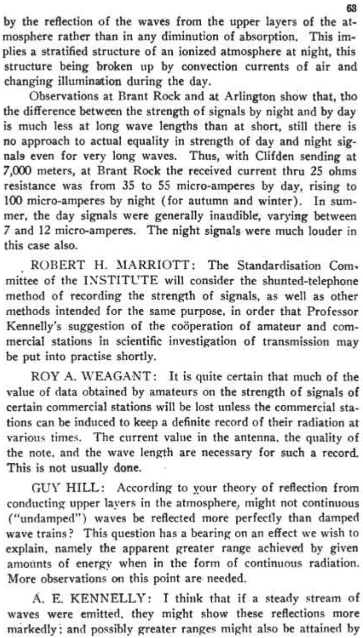
JOHN L. HOGAN, JR.: The point that Mr. Hill suggests regarding the prominence of reflection (and interference) effects with sustained waves is well substantiated by some observations presented by Dr. de Forest before this INSTITUTE. (Proceeding of the Institute of Radio Engineers, Vol. 1, Number 1, page 37.) He shows that if continuous waves pass from a transmitting station to a receiving station by two different routes, one of which is direct and the other of which is caused by reflection of waves which strike elevated cloud layers, very marked interference effects will be produced at certain frequencies. That is, at definite wave lengths the signals will be either markedly weakened or strengthened. Change of wave length may bring the signals to normal strength.

It is possible that these selective absorption effects are phenomena based on slow resonance, and that therefore they should be more marked with sustained than with damped waves. Instances of marked reflective amplification may be responsible for the transmission of long-distance signals which have brought forward the contention that the range to be attained by the use of sustained waves is greater for equal output than with damped waves. I have discussed this claim with Dr. Austin while in Washington, and he appeared very sceptical concerning it. We felt that we had not enough data to warrant acceptance of it and that there should be no great difference in the transmission of sustained waves as compared with those of low decrement.

It seems to be a wonderful confirmation of Professor Kennelly's hypothesis that even such observations as those taken between Clifden and Glace Bay (where signals were graded in strength by simple aural classification as "very strong," "strong," "moderate," "weak," and "very weak"), are in such good accord with the theoretical conclusions.

In connection with abnormal daylight absorption treated by Dr. Kennelly, it is interesting to note that the value and relation for normal daylight absorption have been partially confirmed.

In 1911, Drs. Austin and Cohen, on the basis of experimental work performed from Brant Rock, gave the following law for the received antenna current I_2 in terms of I_1, the transmitting antenna current, h_1 and h_2, the heights of transmitting and receiving



by the reflection of the waves from the upper layers of the atmosphere rather than in any diminution of absorption. This implies a stratified structure of an ionized atmosphere at night, this structure being broken up by convection currents of air and changing illumination during the day.

Observations at Brant Rock and at Arlington show that, tho the difference between the strength of signals by night and by day is much less at long wave lengths than at short, still there is no approach to actual equality in strength of day and night signals even for very long waves. Thus, with Clifden sending at 7,000 meters, at Brant Rock the received current thru 25 ohms resistance was from 35 to 55 micro-amperes by day, rising to 100 micro-amperes by night (for autumn and winter). In summer, the day signals were generally inaudible, varying between 7 and 12 micro-amperes. The night signals were much louder in this case also.

ROBERT H. MARRIOTT: The Standardisation Committee of the INSTITUTE will consider the shunted-telephone method of recording the strength of signals, as well as other methods intended for the same purpose, in order that Professor Kennelly's suggestion of the coöperation of amateur and commercial stations in scientific investigation of transmission may be put into practise shortly.

ROY A. WEAGANT: It is quite certain that much of the value of data obtained by amateurs on the strength of signals of certain commercial stations will be lost unless the commercial stations can be induced to keep a definite record of their radiation at various times. The current value in the antenna, the quality of the note, and the wave length are necessary for such a record. This is not usually done.

GUY HILL: According to your theory of reflection from conducting upper layers in the atmosphere, might not continuous ("undamped") waves be reflected more perfectly than damped wave trains? This question has a bearing on an effect we wish to explain, namely the apparent greater range achieved by given amounts of energy when in the form of continuous radiation. More observations on this point are needed.

A. E. KENNELLY: I think that if a steady stream of waves were emitted, they might show these reflections more markedly; and possibly greater ranges might also be attained by

deeply involved in the Cuxhaven project. By 1905, Zenneck had become an authoritative figure in the community of telegraphy engineer. In 1906, he became a professor at the Braunschweig Technical University.[25]

Zenneck's first work of interest here concerned wave propagation along an infinite planar interface between the air and a conductor (figure 3).[26] The novelty of Zenneck's approach in comparison with the British theorists did not lie only in the geometry. In contrast to previous work, he did not use any information about the dipole oscillator to solve the overall field generated by the source and shaped by the boundary condition. He supposed a particular form for the electric and magnetic fields and confirmed that it satisfied Maxwell's equations and the boundary condition. This form was a plane wave with field components containing a factor $\exp[i\,(\omega t+sx)]$, where ω is the angular frequency and s is the wave number in the horizontal direction. Plugging these expressions into Maxwell's equations and the boundary condition, he found that the field quantities above the surface are proportional to $\exp[i(\nu t+sx-r_0z)]$, and those below the surface to $\exp[i(\nu t+sx+r_1z)]$, where $r_0= (k_0{}^2-s^2)^{1/2}$ and $r_1= (k_1{}^2-s^2)^{1/2}$, and k_0 ands k_1 are the wave numbers in the air and on the ground, respectively. The values of s, r_1, and r_0, all obtained by solving simple algebraic equations, are determined by the dielectric constants and conductivities of the air and the ground. They were complex numbers.

The physical implications of Zenneck's field solution are extraordinary. First, unlike the optical plane waves in free space, Zenneck's wave not only propagates but also attenuates along both the *x* and *z* directions. In addition, the polarization of Zenneck's wave is determined by the ground conductivity and dielectric constant. In contrast to free-space plane waves, the polarization of Zenneck's waves cannot be chosen freely.

When the ground conductivity is finite (in the scale of earth, stone, or sand conductivity), the polarization direction of Zenneck's wave inclines along the direction from which the wave comes. Zenneck pointed out that Marconi's experimental results on the directive antenna agreed with this finding. Marconi discovered that the receiving antenna receives maximum power when the aerial inclines along the line of sight between the transmitter and the receiver. According to Zenneck's theory, the finite ground conductivity causes the direction of polarization of the propagating wireless wave to incline toward the direction of propagation; the antenna has maximum efficiency to convert the field into an oscillating current when it aligns with the polarization direction of the field (figure 4).

The attenuation of Zenneck's wave along the propagation direction reaches its maximum at a finite ground conductivity. When the conductivity is either zero or infinite, the attenuation is zero. A ground with high resistance (a dielectric material) could support long-distance propagation. Zenneck also showed that the at-

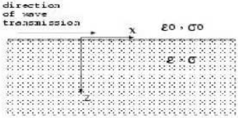

FIG. 3 Zenneck's boundary condition.

tenuation decreases with wavelength and is much more serious along the vertical than along the propagation direction. The field intensity decreases to $1/e$ of the original intensity at $z=0$ in some centimeters along the vertical and in some kilometers along the horizontal. Most of the energy is concentrated near the air-ground boundary; Zenneck's wave is a "surface wave."

Zenneck's work provided a novel insight. Unlike the British and French diffraction theorists, who held that the shape of the earth enabled long-distance wave propagation, Zenneck suggested that the ground resistance also played a critical role. Nonetheless, his paper of 1907 could not be considered as a complete work. "Zenneck's wave" is only one possible solution of the Maxwell's equations and the boundary conditions, not necessarily the solution describing physical reality. In contrast to the British diffraction theory, Zenneck's approach did not specify the source that generated his wave; we not only have no idea how to generate it, we do not know whether it can be generated at all! Enter Arnold Sommerfeld.

Sommerfeld had worked on optical diffraction before he took up radio waves. His novel approach of converting the solution of a differential equation with a proper boundary condition into a closed-form complex integral suitable for numerical evaluation would become a hallmark of his work.[27] He published his first paper on the Hertzian waves in 1899.[28] It studied the propagation of electromagnetic waves along a conducting wire. Sommerfeld demonstrated that as current flows in the wire, the Hertzian wave it produces also propagates along the wire. Once electrical phenomena were conceived in terms of waves in the aether, there was no essential difference between the wired and the wireless. Since the energy transfer associated with the flow of an electric current in a wire could be understood as the propagation of an aetherial wave along the wire, it was reasonable to understand a wave propagating above ground in terms of a flow of energy guided by the ground.

Dr. L. W. AUSTIN (by letter): An idea, held some time ago, that the difference between the strength of signals by day and those by night was due to the ionization of the air around the sending antenna, caused by the ultra-violet light from the sun, has been entirely abandoned.

An alternative explanation, that the increased strength of signals at night was due to diminished conductivity in the upper conducting layers of the atmosphere at night, seems improbable in view of data in the possession of the U. S. Navy Department.

This data shows that: (1) In certain regions and at certain wave lengths the ground absorption is greater than over equal stretches of salt water in the ratio of as much as twenty to one. Yet signals are sometimes received in such regions at night with the same strength as if there were no absorption at all. The sunlight can hardly affect ground absorption. (2) When working with sustained waves from arc radio-telegraph sets, the strength of signals may be great on certain wave lengths and very weak at other slightly different wave lengths. Thus a change of two or three per cent. in wave length produces enormous changes in intensity of signals. The probable explanation of this effect is, in accordance with Dr. de Forest's suggestion, (Proc. Inst. Radio Engineers, Vol. I, No. 1, page 37, 1913) that interference between a set of waves travelling along the earth and another set which have been reflected from conducting layers of the upper atmosphere takes place. There is no doubt as to the existence of this effect. The probable reasons for the failure to observe it with spark sets is partly because of the greater changes of wave lengths employed with such apparatus, and partly because the shortness of the wave trains does not permit the direct and reflected waves to overlap and interfere for any considerable number of wave lengths.

The most probable explanation of the increased strength of night signals is to be found in an increase of energy received

Sommerfeld recognized that he could resolve the questions how or whether Zenneck's surface wave could be produced by the mathematical techniques he had developed in the mid-1890s to tackle diffraction problems and wired waves. In 1909 Sommerfeld showed that Zenneck's "surface wave" could be generated by a vertically polarized Hertzian dipole oscillator located above the flat conducting surface.[29]

---

[29] Arnold Sommerfeld, "Über die Ausbreitung der Wellen in der drahtlosen Telegraphie," *AP*, *28* (1909), 665-736.

Sommerfeld's problem has the same geometry condition as Zenneck's: an infinite flat interface separating the conducting material below and the air above. But different from Zenneck, he put a vertical Hertzian dipole on the ground as the source of waves. To solve the problem with his Hertzian radiator, Sommerfeld expanded the Hertzian potential in terms of a set of basis functions more convenient for mathematical manipulations than Macdonald's. However, Sommerfeld's expansion is not a discrete sum of spherical harmonics with various half-integer orders. As was typical of his mathematical approach in the 1890s, it was an integral expansion involving only the Bessel function of order 0. The different choices of expansion led to an essential difference between the British-French and the German theories of diffraction. Sommerfeld noticed that any cylindrical wave in the form of $CJ_0(q\,r)\exp[(q^2-k^2)^{1/2}z]$, is a solution of the wave equation where q is a free parameter and J_0, is the 0th order Bessel function. Sommerfeld's solution of the Hertzian potential has the form of an integral expansion of cylindrical waves over q.

To evaluate this integral, Sommerfeld used Cauchy's residue theorem to convert the integral over the entire real axis into a contour integral over the entire complex plane. The integral came out as the sum of three terms; one of which had the same form as Zenneck's surface wave. Furthermore, the other terms became insignificant at long distance. In short, Sommerfeld proved that Zenneck's surface wave is the asymptotic solution of the diffracted field produced by a vertically polarized Hertzian dipole sitting just above the flat boundary surface.

The German diffraction theory differed from the British-French rival by indirectly showing that not only the geometric shape of the boundary surface but also the resistance of the ground affect the transmission distance. Moreover, Sommerfeld's approach to the diffraction problems created a unique tradition of practices. Expanding the field with respect to an integral of cylindrical waves differed significantly from the common technique that expanded the field over a sum of discrete-order spherical harmonics. Sommerfeld knew that his approach engendered many problems, which he gave to his students at the University of Munich. Herman William March wrote a thesis in 1911 extending Sommerfeld's integral approach to the diffracted wave along a spherical conductor. Witold von Rybczynski wrote on a similar topic in 1913.

3. ATMOSPHERIC REFLECTION HYPOTHESES

A few very important phenomena could not be explained by a surface wave that depends solely upon the characteristics of the ground. The moisture effect, the daylight effect, and "stray rays" all strongly suggested that the propagation of an electromagnetic wave has to do with air as well as ground. This consideration lay behind the theory that extended wave transmission arises from reflection of electromagnetic waves by an electrically conducting layer in the upper atmosphere. Around 1902, Oliver Heaviside, Arthur Edwin Kennelly, André Blondel, Henri

(a) Long waves, because their concentration factor is larger, that is, they follow the earth more closely. In fact, in

(b) Any conditions where surface waves predominate, e. g., over water.

The increased dielectric constant of moisture laden air may account in part for certain well-defined interference effects, as explained by Dr. Lee de Forest (19).

Dr. W. H. Eccles (20) gives a theory of wave propagation in ionised air which, under certain conditions, leads to conclusions directly conflicting with those of Fleming. Thus, according to Eccles, as a result of ionisation of the upper layers of the atmosphere, the wave front may be tilted forward so as to follow the earth's surface more closely; in fact, ionisation might thus assist long distance transmission. There are, then, two opposing effects, the relative preponderance of which determines whether the wave front is tilted forward or backward.

(a) It is tilted backward if, because of ionisation there is a deposition of water on the ionic nuclei, with a consequent increase in the dielectric constant.

(b) It is tilted forward if the presence of ions of molecular dimensions increases the velocity of the waves.

Further experiment on these points is highly desirable.

It will, however, be noted, that regardless of whether effect (a) or (b) predominates, Professor Kennelly's explanation of the sunrise and sunset effects as due to reflection at the boundary surface between ionised and un-ionised air still holds. Effect (a) would provide a more nearly complete reflection.

It has been further suggested that the antenna may be actually discharged by ultra-violet light in sunlight falling on it (Hallwachs effect). This, and other interesting points relative to the influence of atmospheric conditions on transmission and reception are fully treated in a recent publication by M. Dieckmann (21). The attention of the experimenter in this field is directed particularly to Professor Fleming's valuable paper before the British Association (22) and to the chapter on electric wave transmission in Professor Zenneck's "Leitfaden der Drahtlosen Telegraphie" (23) to both of which sources I desire to acknowledge my indebtedness for suggesting some of the material given in this discussion.

A complete theory of propagation of electromagnetic waves on a sphere of material of *finite* conductivity has not yet been developed.

There is another source of loss of energy in transmission which is generally not considered, namely, the loss thru ground currents in the immediate neighbourhood of the antenna. Inasmuch as considerable absorption of energy undoubtedly takes place in this vicinity, some interest is attached to conclusions drawn by Brylinski (16) relative to the resistance to alternating current of a homogeneous plane conductor of indefinite extent, the current flow being parallel to the plane. (It has been shown experimentally that this is very nearly the case for actual transmitting stations). Brylinski shows that the resistance increases with the specific resistance of the material, with the frequency of the current, and with the damping of the current. Remembering that the nearest approach to an ideal Hertzian doublet, radiating without loss in the surrounding medium would be attained by having a perfect conducting mass extending thru the equatorial plane of the doublet, and that this implies that the ground resistance to an infinite distance is zero, we find that long distance transmission is best attained by the use of sea water grounds, long waves, and continuous radiation of energy. The first two of these conclusions are in accord with the facts, the third point is one requiring further investigation.

Returning to the effect of atmospheric ionisation on transmission, an ingenious explanation of daylight absorption has been suggested by J. A. Fleming (17), (18). If the upper layers of the atmosphere are strongly ionised by sunlight, the ions produced may act as nuclei for the condensation of water vapor. As a result of the presence of the water drops, and the high dielectric constant of water (namely, 80) the upper layers of air have a higher dielectric constant after exposure to sunlight. Fleming experimentally found that the dielectric constant of steam-laden air varied between 1.004 and 1.026. Therefore the electric waves will travel more slowly in the upper layers of air than in the lower, and the wave front will be tilted backward relative to the direction of transmission. In consequence of this tilting back of the wave surface, the entire wave may pass directly over the receiving station. The effect is quite similar to diminishing the concentration factor. On Fleming's hypothesis, daylight absorption should be least for

Poincaré, and Charles-Edouard Guillaume all considered the possibility of atmospheric reflection.[30] But only Heaviside and Kennelly published their ideas.

Oliver Heaviside, a self-educated theorist unaffiliated with any academic institute, developed a mathematical model for telegraph-signal transmission, a new formulation of Maxwell's theory, and the technique of operational calculus for solving linear ordinary differential equations.[31] He never studied wireless telegraphy seriously. But his work on wired signal transmission played a significant heuristic role in his thought on the transmission of wireless waves.

In 1901, Heaviside was studying the electromagnetic field patterns produced by an electrical signal transmitted through a coaxial cable. He obtained the electromagnetic field by solving Maxwell's equations for the boundary condition specified. Additionally, he made various geometric metamorphoses of the coaxial cable to other mathematically tractable structures, for example, transformation of the cylindrical condition to a point source sitting on top of a large hemisphere surrounded by another hemisphere.[32] He found that this structure can support the transmission of waves along the curved surfaces and conjectured that the same mechanism accounted for Marconi's wireless signals across the Atlantic Ocean.

He published this idea in 1902, in a short paragraph in an introductory article on telegraphy in the *Encyclopedia Britannica*.[33] In it Heaviside observed that, because both the sea and the land have non-vanishing conductivities, wireless waves could travel along the earth's surface in the same manner as electromagnetic waves

travel along a conducting telegraph wire. He added the possibility that traveling waves are bounded not only by the earth's surface but also by a conducting layer in the upper atmosphere. That was all. He did not discuss the source of the conducting layer, empirical evidence for it, or the behavior of waves propagating between the concentric spherical conductors.

The other man holding the hypothesis of an atmospheric reflection layer was Arthur Edwin Kennelly. Born in India, he left the University of London, where he was a student, to become a full-time telegrapher. After working in the Eastern Telegraph Company for years, he joined Thomas Edison's West Orange laboratory in 1887. The experience transformed him from an operation engineer to a researcher on new electrical technologies. He became a professor of electrical engineering at Harvard University in 1902, and stayed there until 1913.[34] His principal interests were electric circuits and power systems and his contribution to wireless telegraphy was comparatively minor. His primary contribution was popularizing the theories and technologies of wireless telegraphy to the public by providing simple physical explanations of the phenomena encountered in wireless practices. He emphasized physical intuition rather than complicated mathematical theory.

In 1902 Kennelly published a paper with a model similar to Heaviside's.[35] Unlike Heaviside, however, Kennelly explained the existence of the atmospheric conducting layer. The explanation rested on J.J. Thomson's discovery that the air has an electric conductivity when thinned. The more dilute the air, the higher the conductivity. Kennelly evoked the standard dependence of atmospheric pressure on height and Thomson's extrapolated experimental formula to deduce that at the height of 80 kilometers the air conductivity is 20 times that of sea water! After securing the causal explanation of the atmospheric conducting layer, Kennelly argued that if the propagation space is confined by the atmospheric conducting layer and the earth surface, then the wave's energy density diverges as fast as a cylindrical wave's. In the absence of an atmospheric conducting layer, the energy density diverges as fast as a spherical wave's. The argument concerning energy divergence plus the atmospheric reflection model account for a higher field intensity over a given distance.

Kennelly's paper in 1902 gave a causal explanation of the existence of the conducting layer and a more exact estimate of its height. But he did not connect the hypothesis with observed phenomena. Nor did he devise a quantitative theory of wave transmission from Maxwell's equations and the given boundary condition, as the diffraction theorists had done.

papers relate to the superiority of long wave transmission, and transmission over water. A further aspect of the problem is considered in them, namely the effect of the curvature of the conducting sheet or ground.

It will be remembered that Sommerfeld regarded this conducting sheet as plane, and it would certainly seem that the transmission of electromagnetic waves over an earth quadrant despite the curvature requires explanation. The papers just cited supply this explanation. They show that

(a) For a spherical, perfectly conducting ground, the energy of the wave decreases not as $\frac{1}{S}$ but as $\frac{1}{S}\sqrt{\frac{\theta}{\sin\theta}}$ (6)

where θ is the angular separation of the points considered measured along a great circle of the earth (neglecting "scattering").

It follows, therefore, that the amplitude at any distance from the antenna will be greater than for a plane ground, and may even rise to considerable values at the antipodes. There is, however, a second consideration, namely, the failure of the energy to fully follow the earth's surface and its consequent re-radiation or "scattering." It results in the introduction of what I shall call the "concentration factor."*

The theory shows that for a spherical, perfectly conducting ground

(b) The energy of the wave, taking account of scattering or re-radiation of energy from the surface wave, is obtained by multiplying the value obtained under statement (a) above by the concentration factor:

$$\varepsilon^{-0.0019\frac{s}{\sqrt[3]{\lambda}}} \qquad (7)$$

where λ is the wave length (wave length and distance expressed in kilometers).

The calculated values of the concentration factor for a distance of 5,000 km. is 0.0025 for a wave length of 4,000 meters and 0.0086 for a wave length of 8,000 meters. The advantage of using long waves is again apparent.

The expression for the energy of the wave obtained according to statement (b) above is in reasonable agreement with the results obtained experimentally by Dr. Louis W. Austin (15).

---

*Usually called "Zerstreuungs Faktor," or "scattering factor."

media (that is, in space, and in the partially conducting sheet).

The relative importance of the space and surface waves is found to be determined by the value of ρ. The value of ρ for sea water is 0.03, for pure water 30, for wet earth 6.5, and for dry soil 300 (for a wave length of 2,000 meters at a distance of 2,500 km.) It is seen that the numerical distance increases with the real distance, diminishes with increased wave length, and is less for equal distances over sea water than over land. Furthermore, Sommerfeld's analysis shows that the assumption of perfect conductivity of the ground is allowable only for short distances over sea water. The distance from the antenna at which the surface or space waves predominate is determined as follows:

(a) For small values of the numerical distance, the space waves predominate.
(b) For larger values of the numerical distance, surface waves predominate.
(c) For very large values of the numerical distance, the space waves may again predominate, but this last effect may be neutralized by the effect of the curvature of the earth, and is probably not important in practise.

The surface wave is the more desirable one for long distance reception because it decreases far more slowly with distance than the space wave. The numerical distance should therefore be kept small so that the surface waves soon predominate. This may be secured by the following means:

(a) Increasing the wave length.
(b) Increasing the conductivity of the ground.
(c). Increasing the dielectric constant of the ground.

These conclusions are well borne out in practise. Sommerfeld has also suggested that daylight absorption is due to higher conductivity of the air causing an increase in U_1, and thereby increasing the numerical distance. In support of this, he mentions that Ebert found that the conductivity of air at a height of 2,500 meters was 23 times greater than at the earth's surface. It is, however, the opinion of other investigators, notably Messrs. Zenneck and Pierce, that the ionisation of the air due to sunlight is entirely insufficient to account for the magnitude of the observed effects.

Sommerfeld's work has been carried further by H. March (10), H. Poincaré (11), (12), J. W. Nicholson (13), and W. V. Rybczynski (14). The practical conclusions to be drawn from all these

---

The experiments done by Louis Austin's team at the U.S. Naval Wireless Telegraphic Laboratory in 1910 were thought to be the only high-quality evidence for long-distance wireless-wave transmission. The mathematical formula synthesized from the experimental results, known as the "Austin-Cohen formula," turned out to be the empirical law governing the relationship between the field intensity and the large transmission distance. Nevertheless, the broad acceptance of the empirical formula made people overlook the fact that the Navy's "experiments" were actually organized not for scientifically investigating long-distance wave transmission phenomena, but for testing the equipment of the Navy's recently installed high-power wireless-telegraphy station.

In 1899 the Bureau of Equipment of the U.S. Navy established a Radio Division to look into replacing flag-and-light signaling with wireless. The plan failed owing to cultural gaps and the associated organizational inertia. Experienced seamen rejected the new gadgets without performance records. Engineering officers living in a conservative military culture clashed with the wireless inventors who preferred flexibility and novelty. The Bureau of Equipment did not have enough power to overcome the opposition. The Navy ended up on-board radio sets rarely used by the combat units and without a system of standardized training in operational and maintenance procedures.[36]

The opposition had much to say for its position. The wireless technology of the early 20th century was unreliable. The mainstream transmitter (spark-gap discharger) suffered from its highly damped oscillation. The mainstream receiver (coherer) could not follow faithfully the continuous variation of a signal and performed unstably. To incorporate the radio into operation, the Navy required reliable data and reliable instruments for which they could develop standard operational-maintenance procedures and systematic procurement schemes. It needed a research establishment for equipment tests, accurate measurements, and technical evaluation of wireless technologies.

The head of the Radio Division, Cleland Davis, and the director of the U.S. National Bureau of Standards Samuel Wesley Stratton, agreed to station the laboratory be stationed within the existing organizational structure of the Bureau. The Naval Wireless Telegraphic Laboratory thus was born.[37] Its first head, Louis Winslow Austin, a physicist then working at the Bureau, had obtained a doctoral degree at the University of Strassburg. After graduation, he worked at the Reichsanstalt, the German model for the Bureau of Standards, which he joined on his return to the U.S. in 1904. He was transferred to the Navy Department in 1908 in order to head the Wireless Telegraphic Laboratory. He started with an assistant, George H. Clark, and a few part-time technicians.

Howeth, *History of communications-electronics in the United States Navy* (Washington, D.C., 1963), chapts. 12, 13.

[37] Louis W. Austin, "The work of the U.S. Naval Radio-Telegraphic Laboratory," American Society of Naval Engineers *Journal, 24* (1912), 122-141.

In 1908, the Navy issued a tender for its first high-power wireless station in Arlington, Virginia. It specified that the transmitter should be capable of sending messages at all times and at all seasons to a radius of 3000 miles in any navigable direction. The National Electric Signaling Company (NESCO) obtained the contract in 1909. The transmitter would be similar to the 100 kilowatt Fessenden synchronous rotary spark discharger then installed at NESCO's experimental wireless station at Brant Rock, Massachusetts. Both the Navy and NESCO knew that this machine could not meet the long-distance specification in the contract. Nonetheless, the Navy awarded the contract with NESCO in the belief that the Fessenden discharger was the best available. To legitimate the compromise, the Navy required further technical tests and measurements of the existing system at Brant Rock while the construction for the Arlington station proceeded.[38] The task of testing and measuring the 100-kw rotary spark discharger at the Brant Rock station was assigned to the Naval Wireless Telegraphic Laboratory. During the summer and autumn of 1909, the electricians of the Laboratory conducted preliminary measurements on the wireless sets at Brant Rock and on communications from there to the scout cruisers *Birmingham* and *Salem*.[39]

From subsequent field tests done in July, 1910 Austin synthesized the first empirical formula governing the relation between distance and radiation intensity for long-range wave transmission. That realized the major aim of the tests: to evaluate the communication qualities of particular wireless sets, namely the Fessenden rotary-spark transmitters, not to produce an empirical law for the science of wave propagation. Austin paid attention to particular instrumentality rather than general regularity.

The experiments of 1910 were not the first attempts to obtain quantitative relations between received antenna current and distance. William Duddell and J.E. Taylor in Britain and Camille Tissot in France did similar experiments in 1904 and 1906. Within a range of 50 miles, they discovered that the current is inversely proportional to distance.[40] Austin's tests ran to 1000 miles. *Birmingham* sailed about 1200 miles south from Brant Rock, *Salem* about 450 miles southeast; through the voyages the wireless sets at Brant Rock and on the cruisers regularly transmitted and received signals from one another, both day and night. The whole experimen-

part in radio telegraphy are A. Blondel (5), E. Lecher (6), and K. Uller (7), (8). However, it remained for A. Sommerfeld in 1909 (9) to give a broad theoretical treatment of the spread of electromagnetic waves over a partially conducting sheet placed, as before, in the equatorial plane of the oscillator; the sheet being plane. Because of their importance, Sommerfeld's explanations and his conclusions will be considered in some detail.

He first discusses the fundamental energy distinction between space and surface waves. Space waves, such as electromagnetic (Hertzian) waves and sound waves, spread three-dimensionally. Their energy (per unit area of wave front) is therefore proportional to the inverse square of the distance from the source. Surface waves, such as ripples on water, electric waves on wires, and elastic waves of surface distortion in solids, decay according to a different law of energy diminution. Thus, for waves spreading circularly over water, and neglecting dissipative absorption in the medium, the energy varies inversely with the distance; not as the inverse square.

Sommerfeld defines a quantity U in his paper as follows:*

$$U^2 = \frac{K \mu n^2 + j \mu \sigma n}{c^2} \tag{3}$$

where K is the dielectric constant, μ is the permeability,
σ is the conductivity, j is $\sqrt{-1}$,
n is the frequency, c is the velocity of light.

From U_1 and U_2, the values of U for air and the conducting sheet respectively, he builds up a new quantity ρ, which he calls the "numerical distance." If S is the actual distance, ρ is defined by the following equation:

$$\rho = \frac{U_1^4}{U_2^4} \cdot \frac{U_1^2 - U_2^2}{U_1^2} \cdot \frac{U_1 s}{2} \tag{4}$$

Sommerfeld sets up the partial differential equation for his problem, introduces the necessary boundary conditions, and, after a series of elaborate analytical transformations, arrives at the following value for Π, the vector potential at any point:

$$\Pi = P + Q_1 + Q_2 \tag{5}$$

Herein P represents that portion of Π. which is due to a true surface wave, and Q_1 and Q_2 represent space waves in the two

---

*The quantity U is Sommerfeld's "k". The notation here employed is, where possible, that recommended by the Standardisation Committee of THE INSTITUTE OF RADIO ENGINEERS.

(b) The electric and magnetic field intensities are in phase.

It will be noted that these conditions apply only when the equatorial plane is a *perfect* conductor. This is nearly the case for sea water, but not at all for dry land. J. Zenneck considered this problem in detail for the case of an imperfect conducting plane. (2) For the case of the partial conductor he found

(a) The lines of magnetic force are parallel to the plane, the lines of electric force are inclined in the direction of motion of the wave.

(b) The electric force has a horizontal component which is nearly in phase with the magnetic force.

(c) The vertical component of the electric force and the horizontal component of the electric force are out of phase with each other.

There is a resultant rotary electric field at the surface of the plane.

Zenneck gives the following values for the field forces at a distance from an antenna of height h, of form factor α, in which flows a current I_m, and from which are radiated waves of length λ:

$$\text{Electric Force} = 4\pi \frac{\alpha h}{\lambda} I_m \frac{\varepsilon^{-\beta s}}{s} 3.(10)^{10} \quad \text{C. G. S. Units} \quad (1)$$

$$\text{Magnetic Force} = 4\pi \frac{\alpha h}{\lambda} I_m \frac{\varepsilon^{-\beta s}}{s} \quad (2)$$

where β is a constant. It will be seen that the values of these forces are dependant on the wave length.

The effects of the conductivity of the ground plane and of underground water or rock have been exhaustively studied by F. Hack (3) and P. Epstein (4) has given figures for the electric lines of force of actual waves (of length of 2,000 meters) passing over soil of high conductivity, and at considerable distances from the antenna.

Of particular interest in these latter papers is the proof of the existence of a varying horizontal component of the electric force on the wave front. Such electric forces exist on wires along which guided or surface electric waves are passing, and the question naturally arises whether we are not dealing with surface waves if the case of terrestrial radio transmission. Among the earlier investigators of such guided waves and of their probable

tal process, including instrument calibration and maintenance, on-site measurements, and data analysis, was executed by electricians hired by the Naval Wireless Telegraphic Laboratory and engineers of NESCO.[41]

Austin carefully documented the instrument specifications in the report he wrote for the Bureau's *Bulletin*. The transmitters were Fessenden synchronous rotary-spark dischargers, powered at 100 kw at the Brant Rock station and 2 kw on the cruisers. The broadcasts occurred at 1000 meters and 3750 meters. When the separation between the transmitter and the receiver exceeded 100 miles, operators used charcopyrite zinkite rectifiers with galvanometers, and shunted telephone circuits, to detect the antenna current. Both kinds of sensors had high sensitivity for weak current.

During the voyage the electricians noticed several unusual phenomena. After the departure of the ships, the signals became too weak for detection by the crystal-rectifier detector. Except for a few signals taken in the first two days, all the data were taken by the shunted telephone. In addition, the electricians observed that the signals received at night were significantly more erratic than those received during the day. The signal level at night was usually stronger, but it had more fluctuation and experienced more disturbance. The nine-day experimental campaign produced five tables of measured data (for example, see figure 6).

The Austin-Cohen formula

Austin at first tried to fit the daytime data with Duddell's formula that made received antenna current inversely proportional to distance. The inverse law gave much higher values than the measured data beyond 200 miles. Then he tried the ad hoc assumption that the received current experiences an additional exponential factor owing to atmospheric absorption. The NESCO engineer Louis Cohen discovered that a fixed damping coefficient A could reproduce all the data for the same wavelength; to capture the data better for both wavelengths, he set $A = \alpha\lambda^{-1/2}$. Thus the exponential factor is $\exp[\alpha\lambda^{-1/2}d]/d$. They specified that $\alpha = 0.0015$, when the distance d and wavelength λ are expressed in kilometers.[42]

The Laboratory also sought an empirical law governing the transmitted antenna current and the heights of the transmitting and receiving antennas. Experiments conducted between Brant Rock and Washington, D.C. after the sea voyage in mid-July 1910 showed that the receiving antenna's current was proportional to the transmitting antenna current and to the heights of both antennas, and inversely proportional to the wavelength (regardless of the exponential decay factor). Combining these relations, Austin obtained the famous empirical "Austin-Cohen formula:"

[41] Austin (ref. 39), 320-330.

[42] Ibid, 326-327.

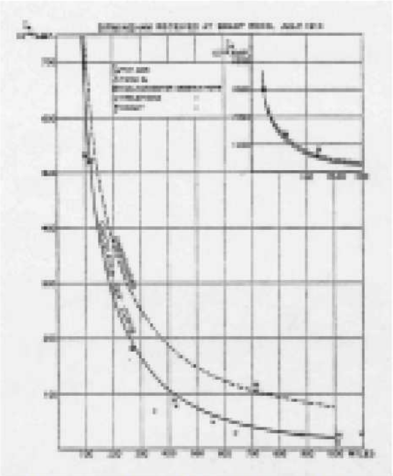

FIG. 6 Birmingham's signal as and received at Brant Rock (July 1910); 3750 meters. The vertical axis represents the received antenna current, the horizontal axis the distance. The solid curve is calculated from the Austin-Cohen formula, the dashed curve from the inverse law "N" denotes data from night-time measurements. Austin (ref. 39), fig. 4.

where I_r is the current received through an antenna with an equivalent resistance of 25 ohm; I_s, the transmitting antenna current; h_1, the height of the transmitting antenna; h_2, the height of the receiving antenna; λ the wavelength; d the distance; and $\alpha=0.0015$; all the lengths being in kilometers and the current in amperes. According to Austin, the formula is "an equation which will cover the normal day received current over salt water through 25 ohm for two stations with flat-top

up this question experimentally, and should endeavour to lay a firm foundation for a theory of long-distance radio-telegraphy by accumulating information on the important question of the electric conductivity and ionisation of our atmosphere at various heights above the earth's surface. Something might be done by the use of a Gerdieu's ionimeter in dirigible balloons or in aeroplanes.

University College, London; June 24th, 1913.

ALFRED N. GOLDSMITH: There are a number of effects in the transmission and reception of signals by radio communication which are as yet only partly explained. Those most closely related to the present paper may be classified as follows:

(1) The superiority of transmission over water as compared with transmission over land.

(2) The superiority (under certain conditions) of transmission on high wave lengths as compared with transmission on short wave lengths.

(3) The clinging of electromagnetic waves to the earth's surface, in spite of the considerable curvature of the globe.

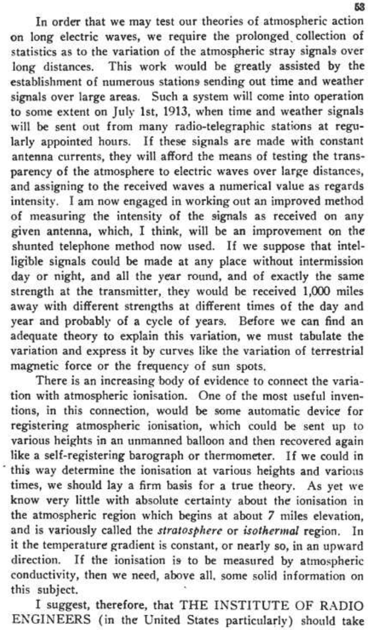
(4) The superiority of transmission by night as compared with transmission by day.

(5) The "daylight effect," or change in intensity of received signals at or near sunrise and sunset.

Before classifying the proposed explanations of these effects, we shall consider briefly the bibliography of the propagation of electro-magnetic waves thru space and over the surfaces of more or less perfect conductors. The classical papers of Hertz and his immediate followers have rendered wave transmission thru space alone thoroly clear. The next problem in order of complexity is the radiation from a Hertzian doublet (dumb-bell oscillator) thru the equatorial plane of which a perfect conductor of indefinite extent stretches. Such a plane conductor may be regarded as a first approximation to the "ground" of a radio-telegraphic station.

M. Abraham, in 1901, gave the mathematical solution of this case (1) and its physical interpretation. Considering the wave at a distance from the oscillator, he found that

(a) The lines of electric force were perpendicular to the conducting plane, the lines of magnetic force parallel to it.



In order that we may test our theories of atmospheric action on long electric waves, we require the prolonged collection of statistics as to the variation of the atmospheric stray signals over long distances. This work would be greatly assisted by the establishment of numerous stations sending out time and weather signals over large areas. Such a system will come into operation to some extent on July 1st, 1913, when time and weather signals will be sent out from many radio-telegraphic stations at regularly appointed hours. If these signals are made with constant antenna currents, they will afford the means of testing the transparency of the atmosphere to electric waves over large distances, and assigning to the received waves a numerical value as regards intensity. I am now engaged in working out an improved method of measuring the intensity of the signals as received on any given antenna, which, I think, will be an improvement on the shunted telephone method now used. If we suppose that intelligible signals could be made at any place without intermission day or night, and all the year round, and of exactly the same strength at the transmitter, they would be received 1,000 miles away with different strengths at different times of the day and year and probably of a cycle of years. Before we can find an adequate theory to explain this variation, we must tabulate the variation and express it by curves like the variation of terrestrial magnetic force or the frequency of sun spots.

There is an increasing body of evidence to connect the variation with atmospheric ionisation. One of the most useful inventions, in this connection, would be some automatic device for registering atmospheric ionisation, which could be sent up to various heights in an unmanned balloon and then recovered again like a self-registering barograph or thermometer. If we could in this way determine the ionisation at various heights and various times, we should lay a firm basis for a true theory. As yet we know very little with absolute certainty about the ionisation in the atmospheric region which begins at about 7 miles elevation, and is variously called the *stratosphere* or *isothermal* region. In it the temperature gradient is constant, or nearly so, in an upward direction. If the ionisation is to be measured by atmospheric conductivity, then we need, above all, some solid information on this subject.

I suggest, therefore, that THE INSTITUTE OF RADIO ENGINEERS (in the United States particularly) should take

---

antennas of any height, with any value of sending current and any wave length, provided the sending station is so coupled as to give but one wave length." It had the further limitation that it had been tested on only the Fessenden rotary spark charger. The coefficient 4.25 in equation (1) is particularly dependent on the instrument. Austin pointed out it applied strictly only to the antennas used in the experiments of 1910.[43]

The Austin-Cohen formula became the most important, and perhaps the only quantitative, empirical basis for all theories of long-distance wireless wave transmission. Before its publication in 1911, scientists worried whether their theories were consistent with physical intuition or wireless know-how, after 1911, they worried whether their numerical results fit Austin's quantitative data or the Austin-Cohen formula. That altered the epistemic situation significantly.

5. DIFFRACTION THEORIES AGAIN

The fit between diffraction theories and the Austin-Cohen formula was far from satisfactory. The theorists adopted several strategies to save the day. The German physicist Witold von Rybczynski showed that his calculations agreed with selected data from Austin's report better than the Austin-Cohen formula did. The English physicist Augustus Edward Hugh Love questioned whether the detector in Austin's experiments had functioned properly. Meanwhile, the experimenters strengthened their position by confirming the Austin-Cohen formula. The test campaign made by the U.S. Naval Radio Telegraphic Laboratory in 1913, which was planned to choose between the rotary-spark discharger and the arc oscillator as the future standard transmission technology, gave an opportunity to produce more measured data. The Austin-Cohen formula survived the tests.

$$I_r = 4.25 \frac{{}_s h_1 h_2}{d\lambda} \exp\left[\frac{-\alpha d}{\tilde{A}\lambda}\right] \tag{1}$$

The Germans

Sommerfeld assigned the problem of wireless-wave diffraction along the earth surface to an American doctoral student, Hermann William March, who completed the project in 1911.[44] March expressed the fields as the spatial derivatives of a Hertzian potential and the general solution of the wave equation as an expansion in spherical harmonics. The British theorists took such an expansion as a sum over a discrete index. In contrast, March expanded the solution as an integral over a continuous index. He matched the integral with the spherical boundary condition to determine the functional form of the integrand, which turned out to be inversely proportional to the derivative of the Hankel function with argument *ka*. To evaluate the integral, March developed the Hankel function for large *ka* asymptotically in the same way as Macdonald had done. Then the integral could be calculated analytically. In March's final result, the Hertzian potential is proportional to $\exp[-ika\theta]/(\theta\sin\theta)^{1/2}$ for large *ka* (θ is the usual angle of separation between the transmitter and the receiver). March's solution did not have any exponential decay with respect to θ like $\exp[-\rho(ka)^{1/3}\theta]$; the exponent $\exp[-ika\theta]$ is a sinusoidal function of θ.

---

[43] Ibid, 340-341.

[44] Hermann William March, "Über die Ausbreitung der Wellen der drahtlosen Telegraphie auf der Erdkugel," *AP, 37* (1912), 29-50.

March's result, though fresh, had the defect of decaying much more slowly with distance than British theorists predicted and wireless practitioners observed. March's mathematical problem was identical to Macdonald's: in integrating the derivative of a Hankel function for large *ka*, the asymptotic expansion cannot be performed in the usual way. The publication of a new version of this error energized Poincaré, who pointed out the illegitimate approximation in a letter to Sommerfeld.[45] In a short published note on the matter, Poincaré observed that March's predictions disagreed with Austin's experimental data.[46]

Sommerfeld put Rybczinski in the problem. Following Poincaré, Rybczinski took the dominant contribution of the integral from the pole with the smallest imaginary part.[47] He replaced March's integral with another similar in functional form; but the value of Rybczinski's integrand at the projected point of the dominant pole on the real axis equalled that of Poincaré's integrand at the same point. He thus retained the virtues of both March's and Poincaré's approximations: the new integrand was more precise than March's in the region that gives the dominant contribution, and much easier to integrate analytically than Poincaré's. Rybczinski obtained a radiation intensity proportional to $\exp[-0.33(ka)^{1/3}\theta]/(\theta\sin\theta)^{1/2}$.

Rybczinski showed more persuasively than March that the diffraction theory could produce an exponentially damped wave along a large spherical conductor. Rybczinski's factor $\exp[-0.33(ka)^{1/3}\theta]$ differed from Nicholson's factor $\exp[-0.7(ka)^{1/3}\theta]$, and both formulas disagreed with Austin-Cohen's formula in their dependence on wavelength. The diffraction theories stuck with decay rates inversely proportional to $\lambda^{1/3}$, whereas the empirical regularity required $\lambda^{1/2}$. Nicholson's formula decays significantly faster than Rybczinski's, the Austin-Cohen formula significantly slower. As we know, Rybczinski justified his form by appealing to a selected set of data from Austin's paper of 1911 (seven daytime and four nighttime data points for $\lambda = 3750$ meters between 400 and 1000 miles). For these cases, Nicholson's predictions were too low, the Austin-Cohen's too high.

Rybczinski's theory met with approval by some wireless telegraphers, especially the German school. They did not think that he had given a complete physical

probably be willing to assist by furnishing a continuous record of the current and voltage in their sending antenna.

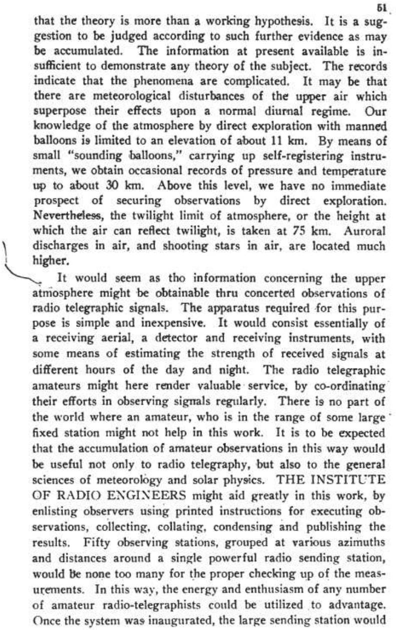
SUMMARY: The influence of solar radiation on radio transmission is discussed. The changes of intensity of signals near sunrise and sunset are explained by reflecting effects which may be expected at the boundary surface or "shadow wall" between darkness (air of small conductivity) and illumination (ionised air of marked conductivity). The theory and recorded observations are found to be in reasonable agreement.

It is proposed that amateur radio telegraphists shall cooperate with THE INSTITUTE OF RADIO ENGINEERS in gathering data on the strength of received signals under various conditions.

DISCUSSION.

DR. J. A. FLEMING (by letter): The subject of Dr. Kennelly's Paper is one which continues to attract great attention from radio-telegraphists on account of its practical importance. Unfortunately, it is a large scale effect, and one not very amenable to laboratory experiments. Much, however, may be done by systematic observations of stray atmospheric waves and on the signals sent out from large stations.

At the British Association Meeting last year, at Dundee, I had the honor of opening a discussion on "Some of the Unsolved Problems of Radiotelegraphy," and at the conclusion of that paper made the suggestion that the British Association should appoint a Radio Telegraphic Committee to bring conjoint investigation to bear on some of these questions. That suggestion was adopted, and the Committee appointed with Sir Oliver Lodge as Chairman. The Committee has already held one meeting. I hope that, as one result, an attempt will be made to organize systematic observations on the number and intensity of atmospheric stray waves during the hours of day and night, and over large areas. This is a work in which we may enlist the assistance of amateurs, and it has the advantage that it is entirely receptive work, and involves no production of waves or disturbance of the ether. Much of the amateur work hitherto done has been merely playing at radio-telegraphy, and has had no other result except to disturb commercial work.



that the theory is more than a working hypothesis. It is a suggestion to be judged according to such further evidence as may be accumulated. The information at present available is insufficient to demonstrate any theory of the subject. The records indicate that the phenomena are complicated. It may be that there are meteorological disturbances of the upper air which superpose their effects upon a normal diurnal regime. Our knowledge of the atmosphere by direct exploration with manned balloons is limited to an elevation of about 11 km. By means of small "sounding balloons," carrying up self-registering instruments, we obtain occasional records of pressure and temperature up to about 30 km. Above this level, we have no immediate prospect of securing observations by direct exploration. Nevertheless, the twilight limit of atmosphere, or the height at which the air can reflect twilight, is taken at 75 km. Auroral discharges in air, and shooting stars in air, are located much higher.

It would seem as tho information concerning the upper atmosphere might be obtainable thru concerted observations of radio telegraphic signals. The apparatus required for this purpose is simple and inexpensive. It would consist essentially of a receiving aerial, a detector and receiving instruments, with some means of estimating the strength of received signals at different hours of the day and night. The radio telegraphic amateurs might here render valuable service, by co-ordinating their efforts in observing signals regularly. There is no part of the world where an amateur, who is in the range of some large fixed station might not help in this work. It is to be expected that the accumulation of amateur observations in this way would be useful not only to radio telegraphy, but also to the general sciences of meteorology and solar physics. THE INSTITUTE OF RADIO ENGINEERS might aid greatly in this work, by enlisting observers using printed instructions for executing observations, collecting, collating, condensing and publishing the results. Fifty observing stations, grouped at various azimuths and distances around a single powerful radio sending station, would be none too many for the proper checking up of the measurements. In this way, the energy and enthusiasm of any number of amateur radio-telegraphists could be utilized to advantage. Once the system was inaugurated, the large sending station would

picture of long-distance wireless-wave transmission. Trans-Atlantic radio communications was still not fully explained. But at a minimum Rybczinski's theory gave an approximately correct picture of wave propagation along the earth without atmospheric reflection. Sommerfeld wrote to Wilhelm Wien in November, 1913. that Rybczinski's theory was analytically right and gave a rate of attenuation that matched experiment to some extent. But (Sommerfeld continued) reflection from conducting layers in the upper atmosphere probably played the major role for very long-distance transmission.[48]

Rybczinski's work did not fare as well outside as inside the Sommerfeld school. His ad hoc procedure of approximation lacked mathematical rigor. He did not select the most reliable data. His seven points, taken from the voyage of 1909, were obtained with instruments still under adjustment and under severe weather conditions. And four of his data points came from measurements at night time, when wireless signals are notoriously unstable. In a paper written in 1914, Austin criticized Rybczinski's data points for these reasons.[49]

A new experiment

The results from the test voyages of 1910 did not significantly hinder the promise of the Fessenden rotary-spark discharger. The Arlington station went on line in February, 1913. The Laboratory tested the transmission equipment. The U.S.S. *Salem* proceeded to Gibraltar, 6400 km Washington, D.C.[50] A critical task of the voyage was to compare the signal from the Fessenden rotary-spark transmitter with that from a new technology—the arc transmitter.

The arc transmitter used the negative resistance created by an electric arc in a low-density gas. Because the value of the negative resistance was precise, the electric arc could be used to design an oscillating circuit with a sharp resonance spectrum. The acceptance test for the Arlington station offered a good opportunity to carry out systematic measurements of the arc transmitter's operational conditions. *Salem* simultaneously received signals from the 100 kw Fessenden transmitter. The round trip to Gibraltar took about six weeks. The arc out-performed the spark.[51] Austin: "At distance over 1000 miles the arc waves appear to begin to show advantages over the spark waves."[52]

The Gibraltar voyage also offered an opportunity to test the Austin-Cohen formula under a set of physical conditions different from those of the 1910 tests: a new (arc) transmitter, a different set of wavelengths (3800 and 2000 meters), and a much longer maximum distance (3500 miles).

Austin and John L. Hogan, an engineer at NESCO, found that the day-time data in 1913 agreed well with the empirical formula. Hogan called the agreement "exceptionally close."[53] Austin went further. He compared Rybczinski's formula, the Austin-Cohen formula, and the new experimental data. Most data points fell closer to the Austin-Cohen formula than to Rybczinski's. Austin again: "There can be no doubt from these results that the theoretical equation [Rybczinski's] gives values too low to be reconciled with the observations, but that they are in very fair agreement with the semi-empirical equation."[54]

Still, something might be retained from the diffraction approach. Austin wrote Zenneck:[55]

> I am becoming quite convinced that the theoretical transmission formula, given in your book, represents approximately the weakest signals observed; while our Navy formula gives a fairly good average. Although I have taken a great many observations, I am still somewhat doubtful regarding the power to which the wave length should be raised in the exponential term. The observations are exceedingly discordant, apparently due to selective reflection.

The British

In January, 1914, Macdonald proposed a new method to approximate the infinite series of his diffraction theory.[56] He introduced a new series, much easier to sum up, that approximated the original series quite well where the spherical harmonic of $n+1/2$ equals ka. Macdonald argued that the new sum well approximated the old one because the dominant contribution of the sum came from this neighborhood. There he replaced the Hankel functions of order $n+1/2$ and its derivatives by Hankel functions of order 1/3 and 2/3. He evaluated the integral via Cauchy's residue theorem. When ka is large, the pole of the Hankel function of order 2/3 with minimum imaginary part dominates. Macdonald found that the resultant field intensity had an exponential decay in the form of $\exp[-\beta(ka)^{1/3}\sin(\theta/2)]$. The functional form of Macdonald's exponential decay differed from both Nicholson's and Rybczinski's factors, $\exp[-\rho(ka)^{1/3}\theta]$.

Enter Augustus Edward Hough Love, still another Cambridge-trained mathematician (second Wrangler, 1885). At the time he contributed to the theory of wireless telegraphy he was a professor of Natural Philosophy at Oxford.[57] In a paper published in 1915, Love gave a comprehensive overview of the research

black dots. There is a reinforcement after the dip, and perhaps also before it. On the other hand, at sunset, no dip is indicated, such as the foregoing theory would indicate.

Figure 7 is taken from observations by Messrs. Dolbear and Proctor (8) in March, 1911. Here Glace Bay is again the sending station; while there were two independent receiving stations, one at Somerville, and the other at Revere; both suburbs of Boston. The diagram, taken from the published article, purports to give the general average of all the observations made at both receiving stations, at a period of the year near the vernal equinox. It will be seen that there is a dip both at mid-sunrise and at mid-sunset, with reinforcements both before and after each dip. There is a nocturnal maximum and a daylight reduction. The results set forth in this particular diagram are in closer accordance with the hypothesis here put forward than almost any others, but no explanation was offered or theory advanced in the article, by its writers.

Figure 8 gives some observations reported from Madrid, and Barcelona in Spain, and also Ceuta, in Africa, nearly opposite to Gibraltar. Here the nocturnal maximum is very short. There is a sunrise and sunset dip, with reinforcement before and after.

Figure 9 gives a published series of observations reported from Clifden, Ireland, as to the diurnal strength of signals from Glace Bay, N. S. One column gives the diurnal chart for each day in April, 1911. Here the agreement with the theory is not so good. There is usually, but not always, a dip at mid-sunrise and mid-sunset. Sometimes the sunrise dip is missing, and sometimes the sunset dip. There is often a reinforcement in the signals before and after a dip; but in many instances such a reinforcement is not indicated.

The records appear to have been made in all cases by shunting the receiving telephone with non-inductive resistance down to the point of inaudibility. The strength of signals is then estimated from the conductance of the limiting shunt.

It appears, therefore, that there is sufficient warrant from the observations at hand in giving the theory here suggested for the sunset and sunrise dips further consideration. It is not claimed

status of long-distance wireless-wave transmission; computed the numerical values of the diffraction series with an approach different from all previous ones; compared his calculations with the values obtained from Macodnald's new formula, found them in agreement, and declared Macdonald's theory the best of the lot; and reinterpreted the long-distance experimental data by correcting the asserted relation between the audibility factor, the results from the shunt-telephone measurements, and the antennacurrent.[58] That improved the fit with his (and hence Macdonald's) predictions.

Love's method of approximation was numerical. Like Nicholson and Macdonald, Love approximated the terms in the neighborhood of $n+1/2 = ka$. Then he computes the numerical values of a sufficient number of terms, added them up, and compared the numerical results with those he obtained from Macdonald's method at several separation angles.[59]

The Austin-Cohen formula made the field intensity proportional to $[1/\theta]\exp[-9.6\lambda^{-1/2}\theta]$, which was quite different from all the diffraction formulae, including Macdonald's.[60] Love saved the phenomena by reinterpreting the measured data. Love noticed that Hogan used a "law of device" to convert the data from the measured audibility factor to the antenna current (he made the audibility factor proportional to the square of the antenna current). However, from Austin's 1911 report, this device law did not always hold. Austin's measurements for calibration for weak signals suggested that the audibility factor was proportional to the antenna current. Considering that most data were taken when signals were weak, Love argued that the proper device law was the direct proportion. He modified Hogan's data accordingly and thus gave empirical support to the diffraction theory.

Were Love's conclusions justified? No! His numerical method was based on assumptions about infinite series identical to Macdonald's; it was not a surprise that the two methods gave similar predictions. The real issue, whether the underlying assumptions employed for the purpose of approximation were legitimate, remained unsettled. Moreover, Love's reinterpretation of the data was prblematic. He relied on regularities measured in 1911. Austin reported the same experimental results as Hogan did in 1913, but he did not discover any significant deviation of the measured data from the Austin-Cohen formula.

6. ATMOSPHERIC REFLECTION AGAIN

Atmospheric reflection produced much less literature after 1911 than surface diffraction theories. The wireless communities found it convenient to interpret radio phenomena in terms of atmospheric effects, but much more difficult to elaborate a reflection model via experimental or theoretical means. Still, atmospheric reflection theorists managed to go one step further than Heaviside and Kennelly. They wished to understand why static noise is greater at night, and why the transmission efficiency of the wireless signals experiences a diurnal change. Having different research agendas and satisfied with qualitative explanations they did not compete directly with the mathematical physicists working on diffraction theories. Rather, they drew on the intellectual tradition of microphysics, which studied electromagnetic wave propagations in various media in order to reveal the internal molecular structures of materials.[61]

William Henry Eccles, who earned a bachelor's degree in physics from the University of London in physics in 1898, joined Marconi's research team on wireless telegraphy in 1899. It was as a professor at the University of London, where he moved in 1910, that he taught the general wireless communities the empirical ground of the atmospheric-reflection hypothesis.[62]

Eccles discovered that if static was detected at one station, then it was very likely to be detected simultaneously at others some distance away. He deduced that the effect involved a long-distance mechanism, perhaps the discharge of atmospheric electricity at hundreds or thousands of miles away from the receiver stations.[63] In a paper published in 1912, he attempted to explain the cause of diurnal variations of the static intensity. Since trans-Atlantic telegraphic signals and static can be transmitted over long distances, they might propagate in a similar manner.[64] A correct physical model for long-distance wave propagation might explain the data on trans-Atlantic wireless telegraphy and on static.

In Eccles's model, the earth is surrounded by a permanent conducting (Heaviside) layer in the upper atmosphere, and another, concentric layer between the Heaviside and the earth. This new layer corresponds to a region of air with gradually changing physical properties. The ultraviolet component of sunlight ionizes the air in this region.[65] Since sunlight alternates with penetration into this region, the number of charged particles per unit volume in it increases with height.

Eccles evoked a simple microphysical model to describe wave propagation in this medium. When an electric field is applied, the ions move; Eccles deduced the average induced ionized current from Newton's second law of motion. Incorporating the induced current into Maxwell's equations, he expressed the refractive index of the medium in terms of the ions' number density, mass, and charge. From this simple Maxwellian theory, Eccles demonstrated that the phase velocity of an electromagnetic wave increases with the number density of ions.

(5) When both stations are in full sunlight, their signals are subjected to daylight attenuation, by diffused conduction in the upper air.

(6) When the sunset wall gets behind the eastern station, as at 17, 17′, the wall will temporarily serve as a reflector behind the latter, and strengthen the signals.

(7) When the sunset wall intervenes between the stations, the wall will act as an intercepting barrier, reflecting waves back, and markedly, weakening the signals.

(8) When the sunset wall gets behind the western station, there will again be a temporary increase of signals by reflection. After this the conditions should approach those of permanent shadow, or night time.

In one revolution of the earth, therefore, we should expect to find maximum strength on full night shadow, a lowered strength in full daylight, and a marked weakening of the signals, with the wall between the stations, either at mid-sunrise, or at mid-sunset. (6) Each of these dips in the strength of signals should be both preceded and followed by a brief interval of stronger signals, due to partial reflection, in the same way as a rough or imperfect sheet reflector behind a lamp intensifies its rays.

On the other hand stations on the same parallel of longitude should have no dip on signals on the equinoxes; but should have a dip at sunrise and sunset with the sun near the solstice. (December and June.)

Stations north and south might expect a longer signaling range than those east and west owing to the aid of partial reflections along the shadow wall.

We may now compare the foregoing deductions with recorded observations. Figure 6 is taken from observations by Mr. G. W. Pickard in 1909, (7) as published in Figure 97 of Prof. G. W. Pierce's book on Wireless Telegraphy. It will be observed that there is a marked dip in the intensity of signals received at Amesbury, near Boston, Massachusetts, when sunrise was about midway between Amesbury and the sending station at Glace Bay, Nova Scotia. Both of these stations are indicated in Figure 4 by

Eccles explained three distinct wireless phenomena on his model: the possibility of wave transmission along the surface of the earth, the radiation directivity of Marconi's tilted aerial, and the diurnal variation of static. The theory of ionic refraction suggested that the larger the density of ions, the higher the phase velocity. From Eccles's physical model, the ion density increases with height, as, therefore, does the wave's phase velocity. According to Snell's law, an upgoing radio wave would be gradually drawn downward by the refraction in the gradually varying medium. The wave path would curve. If its curvature equalled that of the earth, the wave could run naturally along the surface without any action of the ground material. Unfortunately the quantitative prediction from ionic refraction disagreed with the Austin-Cohen formula.[66]

Eccles' theory suggested that the amount of refraction decreases with frequency. When the frequency falls low enough, the curvature of the refracted wave path becomes larger than the earth's curvature. In this case, the wave path is obliquely incident to the ground and the direction of wave polarization no longer remains vertical. To match the polarization to the maximum extent, the receiving antenna must be tilted toward the direction of transmitter. Thus Eccles reached the same conclusion as Zenneck's without using the "surface wave."

The ionized layer results from sunlight and thus does not exist at night. In England, the major source of long-distance static comes from Africa, where thunderstorms and other electrically disturbing weather processes are more severe. In the daytime, long-distance static is controlled by refraction in the ionized layer in the middle and lower atmosphere. During the night, long-distance static is directed by reflection from the conducting Heaviside layer in the upper atmosphere. The waves refracted through the absorptive ionized atmosphere suffer more energy dissipation than the waves reflected by a conducting surface. Hence static during the daytime is weaker than that at night.

Eccles's atmospheric refraction theory contained an essential difference from Heaviside's. In Heaviside's model, radio waves are guided by the concentric spheres of the earth and the permanent conducting layer in the upper atmosphere in accordance with the conductivities of the air and the ground. In Eccles's model, radio waves are directed by the refractive condition of the ionized atmosphere and do not respond to the condition of the ground. For Eccles, ionic refraction alone explains the bending of the wave propagating direction.[67]

Eccle's work of 1912 brought the atmospheric reflection theory from a tentative hypothesis to a sophisticated model. Heaviside and Kennelly attended to only one fact. In contrast, Eccles covered several apparently unrelated phenomena—long-distance wave transmission, tilted polarization, and diurnal variation of static. Eccles's model was essentially a theory of the qualitative behavior of wireless phenomena. Only partial and preliminary results were achieved by efforts to describe the wave-propagation characteristics mathematically, and these were not consistent with the empirical regularity (the Austin-Cohen formula).

[67] Eccles to Heaviside, 27 Nov 1912, Heaviside Papers, UK0108 SC MSS 005/I/6/10, Institute of Electrical Engineers Archives, London.

The English physicist John Ambrose Fleming followed up Eccles's work by trying to account for the diurnal variations of wireless signals. But the static patterns seemed too complex for a consistent explanation. In the annual meeting of the British Association for the Advancement of Science (BA) in 1912, Fleming had organized a discussion on "The scientific theory and outstanding problems of wireless telegraphy" and suggested that the BA form a committee to guide and formulate research on them. The committee was formed and planned systematic observations on atmospheric stray rays. It did not achieve significant results.[68]

Kennelly attended Fleming's radio-telegraphic session at the BA meeting in 1912. Kennelly agreed that the boundary between the sunshine and the shadow regions formed a reflecting surface critical to the diurnal variation observed in wireless telegraphy. He proposed a model for the variation of wireless signals around twilight. Two wireless stations sit in an east-west direction and the transitional band moves gradually toward the east station. Before the band crosses when both stations are on the same side of the blocking curtain formed at the transitional band, it does not affect signal transmission between them. When the band moves behind the east station (shortly before the east station's sunrise), the blocking curtain functions as a reflecting surface to bounce the overshoot waves from the west station back to the east station. Hence the received signal strength there is intensified. After sunrise at the east station, the band moves between the stations, wave transmission is blocked, and the received signal strength diminishes significantly. When the sunrise just passes the west station, the band functions again as a reflecting surface behind the west station to enhance the received signal strength there. As the band moves farther away, the reflective enhancement also wanes. The same pattern happens around sunset. Kennelly's mechanism predicts that a wireless signal transmitted along an east-west direction has a maximum just before the twilight of the east station and right after the twilight of the west station, and a minimum in between. The pattern of the signal variation predicted from Kennelly's model agreed with observations made at wireless stations at Nova Scotia and Amesbury, Massachusetts.[69]

These investigations typified the work of the atmospheric-reflection theorists. They paid much more attention to the diurnal variation of wireless energy than to mathematical relation between the signal intensity and the distance, and they emphasized qualitative characteristics rather than quantitative information in the experimental data. Their theoretical work involved sophisticated model-building and simple mathematical theories of wave propagation based on microphysics.

Toward 1920, several young experimental physicists well trained in applied mathematics began to appreciate the physical importance of the ionic-atmosphere

toward G in the diagram. All that can be asserted definitely is that there is a greater probability of a transition layer, or partially reflecting layer, being formed between sunshine and shadow at sunrise and sunset, than at any place in the sunlit region of daylight. The ionised layer boundary cannot coincide with the shadow boundary AB, but will lag behind it, and will rise more nearly vertically, owing to the effects of atmospheric absorption, and of building up with time. We may call this hypothetical transition layer, or boundary between daylight and darkness, the "shadow wall" accompanying sunrise or sunset.

In Figure 4 we have a stereographic projection of part of the northern hemisphere. The lines of longitude at hourly intervals may be considered as representing the positions occupied by either the sunrise or sunset shadow walls, at successive hourly intervals at the equinox, when the sun appears on the equator. The shadow, considered as an imperfect electromagnetic mirror, may only extend upwards say from the 30 km. level to the 130 km. level; or may only occupy a height of say 100 km. in all; but, if it exists, it extends northwards and southwards for thousands of kilometers. In summer, the wall would slant from S. E. to N. W., and in winter from S. W. to N. E., across the globe.

If the boundary surface between day and night; or the shadow wall, possesses roughly reflecting or scattering influence on electromagnetic waves, we should expect to find the following series of phenomena in relation to two stations east and west, on or near the same parallel of latitude, as indicated in Figure 5; where the observer is supposed to be at the earth's south pole looking at the rotating pole beneath him.

(1) When both stations are in full shadow, as at 20, 20′; 21, 21′; 22, 22′; 23, 23′; 0, 0′; 1, 1′; 2, 2′; 3, 3′; 4, 4′; the signals exchanged should be normal, in the absence of thunderstorms or meteorological disturbances.

(2) When, shortly before dawn, at the eastern station, the shadow wall gets behind that station, it should act as a partial reflector to that station, and intensify the signals.

(3) When the shadow wall advances to a point between the stations, as at 6, 6′, the wall should act as a partial barrier between them and weaken the signals.

(4) When the wall reaches a point a little beyond the western station, as at 7, 7′, it should act as a temporary reflector to the latter, and temporarily strengthen the signals.

vation bb′, 50 km. above the sea level GG′, the air pressure and density are 0.05 per cent of those on the sea, while 99.95% of the air lies below this level. Again, at an elevation of approximately 60 km., the density has fallen to 0.01%, and 99.99% of the total atmosphere lies beneath. In each 10 km., the air pressure is falling to one-fifth. A vertical sunbeam, reaching the level BB′, has passed thru 0.01% of the total atmosphere. The successive levels AA′, BB′, are lines of equal penetration, and there should be equal intensities of ionisation over each such level; but there should not be any layer of sudden transition.

Figure 2 represents the same atmosphere conditions as in Figure 1; except that the sun's rays are supposed to be entering the atmosphere at an inclination of 60° with the zenith, as indicated by the arrows on either side. Along these inclined paths, the sunbeam will encounter approximately twice as much air between any two given elevations as in Figure 1. Consequently, at the 50 km. elevation, the sunbeams have traversed 0.1% of a vertical atmosphere, instead of only 0.05%. The levels AA′, BB′, CC′ of 0.001%, 0.01% and 0.1% respectively are all raised about 5 km. with respect to those on Figure 1. Otherwise, there is very little change between the conditions of penetration by rays from an overhead sun at the equator, and those from the sun at either 8 A. M. or 4 P. M. There should be no sudden transition layer or surface of discontinuity in ionisation, in either case.

When, however, the sun's rays are striking tangentially over a place on the globe as in Figure 3, there tends to be a transition along the line AB, between air in the shadow and air in the sunshine. If the condition represented is that of sunrise, then the air still in shadow is presumably air that has become neutralized during night, with a relatively low conductivity. The illuminated air on the other hand is rapidly becoming ionised and more conductive. While, therefore, we cannot expect the moving shadow plane to be a sharply defined surface separating ionised from neutral air, we might reasonably expect a roughly defined bounding surface, such as might produce some diffuse reflection of electromagnetic waves. No attempt is made to indicate the lines of equal penetration or ionisation, owing to the complexity of the actions. It is known that there is a very appreciable refraction of the beams of light. We should also expect absorption to take place at different elevations, and inoisation to increase to some extent with time. The shadow boundary AB steadily advances

---

model. They tried to bring together the work of all three communities. One of them was Balthasar van der Pol, who worked at the Cavendish Laboratory between 1917 and 1919. In 1918, he tackled the discrepancies among different diffraction formulas (Nicholson, Rybczinski, Macdonald). He reasoned that if he could show that one of them was mathematically rigorous, he could demonstrate that diffraction could not account for the Austin-Cohen formula. The mathematics required was too difficult to him. He turned to a Cambridge-trained mathematician, George Neville Watson, for help.

7. WATSON'S WORK

Like Macdonald, Nicholson, and Love, Watson excelled at the Cambridge training in mathematics, becoming Senior Wrangler, Smith's Prize man, and a Fellow of Trinity College. In 1918, he took up the professorship of mathematics at the University of Birmingham. Unlike the diffraction theorists, Watson was almost detached from physics at Cambridge. He specialized in complex-variable theory applied to Bessel functions. He was also interested in theories of approximation, numbers and computability.[70] He was just the man to solve van der Pol's problem.

Papers of 1918 and 1919

In 1918, Watson gave a rigorous mathematical proof that the field intensity diffracted along the curvature of a large conducting sphere has an exponential factor whose decay rate is proportional to $\lambda^{-1/3}$ rather than $\lambda^{-1/2}$ (as required by the Austin-Cohen formula). In 1919, he showed that the field intensity diffracted in a space bounded by a large conducting sphere and a conducting surface exterior and concentric to the sphere has the $\lambda^{-1/2}$ dependence.[71] The atmospheric reflection theory can explain the empirical regularity.

Watson found the rigorous solution of the diffraction problem without the mathematical problems of previous diffraction theories by working on the Hertzian potential instead of the magnetic field intensity. True to the Cambridge approach, he expanded the Hertzian potential in terms of a discrete sum of spherical harmonics instead of an integral. The result was an infinite series different from Macdonald's, but with a similar angular dependence and pole structure.

Watson's great innovation was to convert the series expansion of the Hertzian potential into an integral expansion without infinities. He interpreted all terms in the diffraction series as residues of a complex function associated with poles on the real axis and so expressed the diffraction series as a contour integral in the complex plane. This procedure, later known as "Watson's transformation," converted the Hertzian potential from a series to a complex integral. This integral as evaluated by Cauchy's residue theorem contained an exponential decay $\exp[-23.94\lambda^{-1/3}\theta]$, quite close to Nicholson's $\exp[-23.8\lambda^{-1/3}\theta]$.[72] Watson confirmed that the intensity of the field diffracted along the earth's surface was significantly weaker than the Austin-Cohen formula required. The exponential decay of the one contains $\lambda^{-1/3}$, of the other to $\lambda^{1/2}$. The diffraction theory was mathematically consistent, but empirically inadequate.

Watson located the problem in the physical model. All the diffraction theorists assumed that the earth's surface alone diffracts the field radiated by the dipole oscillator. Since the surface diffraction alone cannot account for the empirical observations, the upper reflective regions of the atmosphere might play the dominant role at long distances. Could diffraction theory incorporate the physical assumption of an atmospheric reflective layer? Watson took up the question in his paper of 1919. He took the earth to be a conducting sphere on which the Hertzian dipole sits, and the atmospheric reflective layer to be concentric with the earth.[73]

To evaluate the Hertzian potential in this new boundary condition, Watson expanded the Hertzian potential in a series of spherical harmonics, applied "Watson's transformation" to convert the series into a complex integral, analyzed the pole structure of the integrand, and evaluated the integral in terms of these poles. He discovered that when both the inner and outer conductors are perfect, the field intensity is a superposition of oscillatory modes periodic with the distance, that is, that the field does not decay at all! When both the inner and outer conductors are good but imperfect, the field has an exponential decay proportional to $\lambda^{-1/2}$. By adjusting the conductivity of the ionized layer, Watson could match the numerical value of the decay rate of his theory and the Austin-Cohen formula.

Reception

Watson established a conjunction of mathematical representations, explanatory models, and experiments in the study of long-distance wave transmission. He applied the complex-variable techniques of the diffraction theories to the physical model entertained by the atmospheric-reflection theorists to derive quantitative results consistent with the empirical formula obtained from long-distance experiments. By connecting the mathematical representation with the formulated experimental data, Watson gave the atmospheric-reflection theory the promise of becoming a question-answering device operated and using standard mathematical techniques. When it left his hands, Watson's theory lacked verisimilitude. The physical model of a homogeneous and sharp conducting boundary was an over idealization. Watson did not incorporate a vertical atmospheric profile with gradually varying refractive indices. His theory could not incorporate Eccles's ion-refraction theory in a profound way. Nor was Watson's theory able to marshal em-

low, we should expect that surface to behave electrically like an inverted sea. Electro-magnetic waves, reaching this surface from below, would not penetrate it appreciably, but would be reflectively guided over it, as they are guided over the salt-water ocean below, and the waves would then spread over the surface of the globe in two dimensions only, like the growth of a stone-throw ripple in a pond, instead of in three dimensions, like the growth of a soap bubble. This would much reduce the natural three-dimensional attenuation, and increase the intensity of signals received at long distances. It has been suggested that some of the abnormally long signalling ranges occassionally reached at night may be due to the presence of such a reflecting layer (2). If, on the other hand, the conducting layer exists, but is not sharply defined, the conductivity gradually increasing to a maximum as we approach from above or below, we might expect marked conductive dissipation with little or no reflection; so that long-distance signals might be weakened instead of strengthened, owing to the presence of the conducting layer.

Whatever the facts may be concerning the action of the air near the 70 km. level, it seems likely that, during full daylight, the solar ionisation cannot develop any sharp transition layers or reflecting boundaries in the atmosphere. That is, the daylight effect should tend to increase the attenuation of electromagnetic waves.

In order to form a definite conception of the relations between air-pressure and elevation above the sea, Figure 1 has been prepared on certain assumptions; namely, that the temperature of the air is uniformly -35° C. for the sea-level up to a height of 12 miles or 19.3 km. where the observed air-pressure is (3) 1⅞ inches (4.76 cm., or 0.0625 of normal sea level pressure). Up to this level, the "height of the homogeneous atmosphere" (4) is taken as 7 km. Above this level, the temperature has been assumed constant at -60° C. and the height of the homogeneous atmosphere uniform at 6.23 km. No correction has been made for changing chemical composition of the atmosphere at different elevations. (5) Thus premised, Figure 1 indicates that at the ele-

pirical evidence beyond the Austin-Cohen formula, for example, the diurnal variation of static.

Appreciation of Watson's contributions came slowly. The first few published papers to mention his work all emphasized the mathematical rather than the empirical implication. Van der Pol stressed Watson's mathematical contribution to clarifying the controversy involving different approximation methods for wave diffraction above a spherical conductor, rather than Watson's theoretical prediction of the Austin-Cohen formula.[74] Macdonald commented on Watson's work without addressing empirical adequacy at all. He concentrated on extending Watson's approach to the general case where single-frequency time-dependence does not hold.[75] Sommerfeld's student Otto Laporte used Watson's results to reconcile the British representation of the diffracted field in terms of a series with the German representation in terms of an integral, not for their own sake.[76]

Most scientists who elaborated the atmospheric-reflection model in the 1920s, studied wave propagation through ionic media. They downplayed Watson's old-fashioned model (the sharply defined "Kennelly-Heaviside layer") and counter-intuitive approach (the complex-variable theory of diffraction). In a classic paper on the subject written in 1924, Joseph Larmor mentioned Watson only at the end of a list of diffraction theorists beginning with Macdonald, and then as the man who demonstrated that surface diffraction cannot account for long-distance wave transmission around the earth.[77] Among these initial responses to Watson's papers, one thing stands out: after Watson had proved the mathematical rigor of Nicholson's predictions, no one attempted to reconcile the experimental data with the surface diffraction theory. Watson's paper in 1918 tilled the diffraction theory as a physical model for long-distance wave transmission.

Watson's fortunes improved in the late 1920s. In 1928, G.W. Kenrick of the University of Pennsylvania reinvestigated the mathematical and empirical significance of Watson's theory. Kenrick pointed out that much work had recently been done to explain short wave transmission by reflection and refraction of electric waves, but "less attention has been given to modifications produced in the classical Hertzian solution for the field at a distant point due to an oscillating doublet."[78] He called for a reexamination of Watson's work in the interest of short-wave analysis. Kenrick calculated the electromagnetic field radiated by a Hertzian dipole using the same boundary condition that Watson had. Instead of working on the residue waves, he computed the multiple reflected rays bouncing through the space between the earth and the atmospheric layer, and summed all the reflective terms. He thus reproduced Watson's mathematical formula and hence the Austin-Cohen formula. Watson's work became significant not only for disproving the diffraction model but also for its quantitative predictions of observed phenomena.

The radio scientists and engineers of the 1930s worked intensely on wave propagation under various scenarios specified by atmospheric and terrestrial conditions. A theory of pure refraction without taking into account the effect of the earth was no longer adequate. Their theoretical exercise dealt with wave diffraction above a ground with different possible geometric and material specifications in a heterogeneous atmosphere. "Watson's transformation" proved a very useful technique for analyzing these problems. In 1937, a Harvard professor of physics, Harry R. Mimno reviewed the literature on the physics of the ionosphere.[79] He highlighted the significance of the discrepancy between the $\lambda^{-1/3}$ dependence predicted by all the diffraction theorists before Watson and the $\lambda^{-1/2}$ dependence given by the Austin-Cohen formula, and he stressed Watson's contribution in providing a theoretical account of the empirical $\lambda^{-1/2}$ dependence. Van der Pol's student H. Bremmer wrote that "the pioneering work clearing the way for further investigations was done by Watson in 1918. By a transformation with the aid of an integral in the complex plane, this author succeeded in transforming the rigorous series of zonal harmonics into a new series converging rapidly enough to be of use in the radio problem. As a matter of fact, almost all of the later literature is based upon this transformation of Watson."[80]

Often in the history of science two mutually exclusive theories compete for the answers to the same set of questions. In the case considered here, two mutually exclusive theories address different types of questions. The essential difference between the surface diffraction theories and the atmospheric reflection theories was their distinct epistemic status rather than their different physical models. The surface diffraction theorists began by investigating the possibility of long-distance radio-wave transmission. To answer this question, they constructed a straightforward physical model and attempted to develop a rigorous mathematical solution of the problem described by the physical model. But they soon discovered a mathematical difficulty in obtaining an accurate approximate solution. They switched to a mathematical question—what is an accurate approximation of the diffracted field intensity above a large conducting sphere? Almost all their effort involved proper approximations of the analytic form of the diffracted field.

The atmospheric-reflection theorists asked for causal explanations for a broader realm of wireless phenomena, including long-distance transmission, diurnal variation of signal strength, static, the effect of weather fluctuation, and the directive

Commencing, say, at zero, with sufficient height; it might increase to a maximum at a moderate height, and then dwindle down to a minimum near the earth's surface. If the sunlight ionisation, instead of varying gradually in this way terminated suddenly, so that, at some particular elevation a bounding surface formed with non-conducting air on one side, and conducting air on the other; then this boundary surface might be expected to develop strong reflecting properties, on the principle that wave disturbances are subject to reflection at surfaces of discontinuity. Thus clouds, or diffused masses of water vapor, reflect both sound and light. A travelling compression wave, or sound wave in air, reflects light. Any change in a medium for wave transmission, occurring at a surface, is known to set up a reflection. If the change is sudden and well-marked, so that the bounding surface is sharp, the reflection will be definite and powerful. If the change is gradual, and by easy transition; so that the bounding surface is not clearly defined, the reflection will be diffusely scattered and weak.

Consequently, if the ionisation of the air developed a sharp transition layer, or succession of layers, we might expect reflection to occur at and from such layers, with a lessening of attenuation; whereas, if the ionisation were gradually varying from layer to layer, with no clearly marked transition, there would be mere dissipation of energy by conduction or scattering without any gain by reflection, thereby increasing the attenuation.

It was pointed out by Dr. J. J. Thomson (1) that rarefied air at a pressure of 0.01 mm. of mercury in a glass chamber devoid of metallic electrodes, conducts electricity in the laboratory as well as an aqueous solution of sulfuric acid. At an elevation of about 70 km. (43.5 miles) above the sea level, and a uniform temperature of -60° C., such an air density may be expected to exist. If this free rarefied air conducts electricity in response to the feeble electric intensities of radio telegraphy, as well as it does in vacuum tubes to the more powerful intensities used in the laboratory; then, whether the sun is shining on this or not, we should expect a conductivity in it of the same order of magnitude as in ocean water. If such a conducting layer developed suddenly at a certain elevation, so that a definite bounding surface separated the conducting air above from non-conducting air be-

beyond, the violet, when the sun's rays fall perpendicularly as at the tropical noon-day. At morning or evening, when the sun's rays pass aslant thru much greater distances of air before reaching the ground, the violet, and even the blue rays largely disappear, leaving a predominance of red in the light that remains, and thus producing the ruddy hues of dawn or evening landscapes.

If the upper regions of the atmosphere are appreciably ionised by full and sustained solar radiation during daylight hours we may consider that these regions are thereby rendered partially conducting. That is to say, instead of being a perfect insulator, like free space or un-ionised air, ionised air has a certain small conductivity. This would involve a loss of energy in any electromagnetic waves traversing it, which, in turn, would involve additional attenuation of such waves. Moreover, if the ionisation-conductivity were not uniform but developed in clouds or patches, there would be scattering as well as absorption of energy.

It seems therefore possible to explain the weakening effect of broad sunlight upon radio-transmission signals by attributing conductivity, distributed either uniformly or non-uniformly thru the sunlit upper atmosphere, where the ultra-violet waves are likely to be more intense than in the region near the ground. We have no direct evidence, however, as to whether such ionisation-conductivity is quantitatively sufficient to account for the observed effects. It has been pointed out by Zenneck that the observed conductivity of air near the earth's surface for continuous current is far too small to account for the effects in question; but we have no experimental evidence as to what the conductivity may be at high atmospheric levels to alternating electric intensities.

If we assume, for simplicity, a tropical sun sending its rays perpendicularly down thru normally distributed air towards the earth, the degree of ionisation should be uniform over any surface situated at a uniform level. That is, the ultra-violet radiation would be most intense at a great height, and gradually weaken by absorption as it penetrated downwards. On the other hand, the number of air molecules per c.c.; i. e., the air density, would be relatively very small at a great height, and would increase exponentially with the downward penetration. In any one horizontal layer of air, the number of free ions might be assumed uniform.

antenna pattern. To answer these questions, they constructed elaborate physical models. They were partially successful in offering reasonable causal explanations to observed wireless phenomena. But they failed to develop a mathematical theory for systematic quantitative predictions before 1910, succeeded to a very limited extent after Eccles, and only began to make steady progress after Watson. The reflection theorists had difficulty in formulating answers to numerical-prediction questions. Thus the diffraction theorists and the reflection theorists carried out different agendas: the former tried to resolve a mathematical problem of approximation, the latter aimed to explain newly discovered phenomena. This fact explains why atmospheric-reflection theories rarely engaged in any public debate with the surface-diffraction theorists, why some mathematical physicists kept working on diffraction theories regardless of their dubious empirical adequacy, and why an experimenter strongly supporting the reflection models still gave credit to the diffraction models. The diffraction theories and the reflection theories were not competing worldviews.

From the epistemic viewpoint, long-distance wave-transmission research left unexpected legacies to all the participating communities. They started from what they wanted to know, and found what they did not expect to learn. The diffraction theorists found that approximation can be a critical issue in physical problems in which the analytic solution cannot give meaningful quantitative information and direct numerical computation is intractable. The new condition that the wavelength was much shorter than the scatterer's dimension forced them to develop a repertoire of advanced mathematical techniques other than those developed for acoustic scattering for dealing with the approximations of series or integrals. Sommerfeld's integral and Watson's transformation initiated studies of mathematical questions that would become classical problems in mathematical physics: a vertical or horizontal dipole oscillator above or below a homogeneous or layered horizontal plane, a vertical or horizontal dipole oscillator above or below a homogeneous or heterogeneous sphere within a homogeneous or a concentrically layered medium, and so on. These problems did not necessarily correspond to real physical situations. But the mathematicians contentedly investigated the complex-variable techniques to solve the problems for their own sake. The mathematical theory of complex series and integrals prospered from 1930s to 1950s largely owing to the heritage of the German and the British diffraction theorists in the 1900s and 1910s.[81]

The atmospheric-reflection theorists started from the puzzles associated with radio operations, but ended up with a new science of the atmosphere. Their models of the ionosphere were connected with contemporary electron theories of matter. Thus the study of atmospheric effects on radio became incorporated into one of the largest intellectual movements of physics in the early 20th century: the rise of atomic and molecular physics. The radio scientists benefitted from this incorporation: they developed various Maxwellian theories of electromagnetic wave propagation in ionized media. Moreover, the reflection theorists discovered that the radio could be an experimental means to explore atmospheric phenomena. Edward Appleton's experiments of the 1920s, which won him a Nobel Prize, gained "direct" evidence about the physical condition of the ionosphere from radio-interference methods. Meteorology and planetary science became accessible not only through the traditional means of natural history, but also through experiments made possible by efforts of the reflection theorists.[82]

[81] Alfredo Baños, *Dipole radiation in the presence of a conducting half-space* (Oxford, 1966).

The original goal of the American wireless experimenters was to test equipment for the first long-distance radio station of the U.S. Navy. They had a practical engineering problem to solve, but in pursuing it made an important contribution to pure science. The Navy's questionable decision to settle with NESCO's transmitter, the missionary agenda of the Bureau of Standards, and Austin's technical training in German experimental science incorporated meticulous instrumental design systematic operational procedure, and mathematical representation of the data into the investigation. The outcome of their experiments was an empirical law that served as the only quantitative check on theories of long-distance radio-wave transmission in the 1910s. The U.S. Navy did not gain directly from scientific studies of wave transmission, but from the experimental results: it learned that the arc transmitter performed better than the spark-gap transmitter at long distances. The Austin-Cohen formula provided a primary guide for wireless engineers to design long-distance long-wave wireless stations throughout the 1910s. Engineers relied on this simple mathematical relation to select the wavelength and antenna height of a transmitting station for a signal-strength requirement at a given distance. The other face of the empirical law was an engineering formula.

These drastically diverse post-developments enforce the lesson that our three technical communities, working against with different intellectual backgrounds and toward different goals, created a unified study of long-distance radio-wave transmission. They did so by contributing different elements: one offered empirical evidence, another a physical model, and a third a mathematical tool. This episode might be interpreted as confirmation of Peter Galison's estimates of the strength of the constraints on a scientist or engineer within his own communal tradition or of Andrew Pickering's emphasis on the importance of the contingencies a scientist or engineer might confront.[83] More significantly, it warns us not to assume that the intellectual work of different technical communities apparently concerned with the same general phenomena were alternative answers to the same questions. They might have had their eyes on different, and different kinds of questions.

Proceedings of the Institute of Radio Engineers: 1913

THE DAYLIGHT EFFECT IN RADIO TELEGRAPHY.

By A. E. Kennelly.

(Professor of Electrical Engineering, Harvard University.)

It is now generally admitted that the range of radio-transmission of signals is materially influenced by solar radiation; not only in regard to false signals or "X's"; but also in regard to the attenuation of the transmitted electro-magnetic waves.

This attenuating influence of solar radiation on the transmitted waves ordinarily consists of (1) a nearly steady action during the daytime, together with (2) certain marked disturbances occurring near sunrise, or sunset, or both.

In regard to the first or steady effect, we may consider that during the day, whatever the weather may be; i. e., the conditions of wind, temperature, pressure, cloudiness or precipitation in the first few kilometers of air nearest to the ground surface, the sun's rays are steadily falling upon the upper layers of the air; where the air density is relatively very low. It is known from physical laboratory experiments, that ultra-violet light, passing thru attenuated air, ionises it; or decomposes electrically neutral air molecules into positive and negative constituents, the energy of decomposition being absorbed from the radiation. If the ultra-violet radiation is then withdrawn, these constitutents attract each other and recombine, perhaps converting the energy of recombinaion into heat energy or molecular oscillations. For a given intensity of received radiation of assigned wave-length in the ultra-violet region of the spectrum, we may suppose that there exists, in the final state, a certain corresponding number of free electrons per unit of air-volume. It is also reasonable to consider that after the ultra-violet rays in the sunlight have penetrated deeply into the air, they become: (1) scattered and diffusely reflected by the air-molecules, thereby giving us the blue color of the clear sky, and (2) absorbed in decomposition and ionisation of the air-molecules. Consequently, but little ultra-violet light from the sun reaches the ground, after passing thru the atmosphere. The solar spectrum at the ground, or ocean level, may be considered as terminating near to and only a little

CHEN-PANG YEANG

The study of long-distance radio-wave propagation, 1900-1919

ABSTRACT:

At the beginning of the 20th century, scientists and engineers were puzzled by the fact that the long wireless waves could propagate along the earth's curvature without being blocked by the earth. Two explanatory theories were suggested: that the waves are diffracted along the earth's surface and that the waves are reflected back and forth between the earth and a conducting atmosphere. The surface diffraction theory, first proposed by Hector Munro Macdonald in 1901, was continuously elaborated by the British and German mathematical physicists. But its predictions were not consistent with the empirical Austin-Cohen formula obtained from the U.S. Navy's long-distance experiments. The atmospheric reflection theory, first proposed by Arthur Kennelly and Oliver Heaviside in 1901/2, was more commonly believed to be the correct physical model. Yet it had problems yielding quantitative predictions because of its lack of mathematical development. In 1919, the English mathematician, George Neville Watson, developed a mathematical theory of atmospheric reflection that generated predictions consistent with the Austin-Cohen formula based on the analytic techniques established by the surface diffraction theorists.

the one that occurs most commonly—the phenomena vary greatly from day to day—is that one appearing when the sun is setting at a place about half-way between the stations. The minimum is fairly well marked in the sunrise curve shown in fig. 8. The reflections that are so pronounced a feature of Marconi's long-distance observations are not nearly so evident over short distances, according to the author's experience. But fig. 9 shows a case where the variations soon after sunset at Clifden were very decided. The curve does not do full justice to the phenomena, however. As a matter of fact the chief variations were so rapid and so wide that there was not time to measure them; indeed, on occasion, the changes in intensity are startling in their amplitude and swiftness.

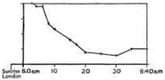

Fig. 8.—Intensity of Signals, January 25, 1912.

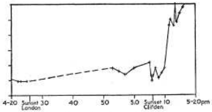

Fig. 9.—Intensity of Signals, January 20, 1912.

It will be noticed that all the curves exhibit a great difference between the strength of the night signals and that of the day signals, although the distance is only 440 miles. Yet it is known that the same signals are heard at Glace Bay as strongly in the day as in the night. We gather from this that the daytime trajectory of the radiation passes well above places relatively near to the sending station and descends again, after overtaking the curvature of the earth, at the greater distance. It is well to recall here that in his recent experiments on the reception of signals from Clifden at distances up to 6000 miles, Marconi found the signals readable only at night at greater distances than 4000 miles—which seems to indicate that the trajectories of the rays in the daytime are such as to bring down within the distance named practically all the radiation starting, at all elevations, from the antenna.

The author desires to tender his thanks to the Government Grant Committee of the Royal Society for a grant in aid of the observations described in this communication.

through the atmosphere can give rise to somewhat regular reflections, so that when it passes over and behind the sending station it changes from being a hindrance to being a help in signalling. This view contains nothing that is fundamentally inadmissible. But the reflecting process was observed to be better with short waves than with long; perhaps the following considerations may in some degree account for this. First, it is known from general electromagnetic principles that when a wave crosses layers of changing refractive index there is a reflected wave propagated backwards, and this reflected wave is the more intense the greater the change in index. Second, let us assume that the surfaces of equal ionisation rise from the day level to the night level in a long slope extending over, perhaps, a hundred miles from east to west through the twilight belt, being rather broken of course, by irregularities in the changing ionisation. On account of the broken character of the belt reflection from the sloping surfaces will be irregular. But it will be more irregular for the more refrangible radiation, that is to say, will be more irregular for waves of low frequency than for waves of higher frequency. Perhaps with this may be conjoined the fact that the frictional absorption suffered by the longer wave is greater than that suffered by the shorter.

The phenomena just discussed are to some extent noticeable over relatively short distances. The following curves are drawn from observations of the intensity of signals from Clifden as heard at the author's laboratory in London, the measurements being made by balancing the intensity of the Clifden signals against the adjustable intensity of locally produced artificial signals of about the same acoustic frequency. On the curves the intensities are plotted in arbitrary units as ordinates, with the times of measurement as abscissæ. The observation had to be snatched, so to speak, at the moments when the station happened to despatch a message, and the points of observation are therefore often rather irregularly distributed. Fig. 7 shows two remarkable minima, which are produced, presumably, by the presence of the ionic curtain between the stations. Of these two minima,

ELECTRICAL WORLD AND ENGINEER.
MARCH 15, 1902. 473

On the Elevation of the Electrically-Conducting Strata of the Earth's Atmosphere.

By A. E. Kennelly.

ACCORDING to the measurements of Professor J. J. Thomson ("Recent Researches in Electricity and Magnetism," p. 101), air at a pressure of 1-100 mm. of mercury has a conductivity for alternating currents approximately equal to that of a 25 per cent aqueous solution of sulphuric acid. The latter is known to be roughly 1 mho-per-centimeter, so that a centimeter cube would have a resistance of about one ohm. Consequently, air at ordinary temperatures, and at a rarefaction 76,000 times greater than that at sea level, has a conductivity some 20 times greater than that of ocean water, although about 600,000 times less than that of copper.

If we apply the ordinary formula for finding the elevation corresponding to a given air-rarefaction, we find that if the air had a uniform temperature of 0 deg. C., the height of this stratum of air with a rarefaction of 76,000, would be

18.39 log 76,000 kilometers above the sea.
or 89.77 kilometers,
or 55.77 miles.

If the air had a uniform temperature of —50 degs. C. this elevation would be reduced 18.3 per cent, or to 73.3 kilometers (45.5 miles). The temperature of the earth's atmosphere has only been measured within a range of a very few kilometers above the surface of the sea, and consequently the materials are not at hand for any precise calculation of the height of electrically conducting strata. It may be safe to infer, however, that at an elevation of about 80 kilometers, or 50 miles, a rarefaction exists which, at ordinary temperatures, accompanies a conductivity to low-frequency alternating currents about 20 times as great as that of ocean water.

There is well-known evidence that the waves of wireless telegraphy, propagated through the ether and atmosphere over the surface of the ocean, are reflected by that electrically-conducting surface. On waves that are transmitted but a few miles the upper conducting strata of the atmosphere may have but little influence. On waves that are transmitted, however, to distances that are large by comparison with 50 miles, it seems likely that the waves may also find an upper reflecting surface in the conducting rarefied strata of the air. It seems reasonable to infer that electromagnetic disturbances emitted from a wireless sending antennæ spread horizontally outwards, and also upwards, until the conducting strata of the atmosphere are encountered, after which the waves will move horizontally outwards in a 50-mile layer between the electrically-reflecting surface of the ocean beneath, and an electrically-reflecting surface, or successive series of surfaces, in the rarefied air above.

If this reasoning is correct, the curvature of the earth plays no significant part in the phenomena, and beyond a radius of, say, 100 miles from the transmitter, the waves are propagated with uniform attenuation cylindrically, as though in two-dimensional space. The problem of long-distance wireless wave transmission would then be reduced to the relatively simple condition of propagation in a plane, beyond a certain radius from the transmitting station. Outside this radius the voluminal energy of the waves would diminish in simple proportion to the distance, neglecting absorption losses at the upper and lower reflecting surfaces, so that at twice the distance the energy per square meter of wave front would be halved. In the absence of such an upper reflecting surface, the attenuation would be considerably greater. As soon as long-distance wireless waves come under the sway of accurate measurement, we may hope to find, from the observed attenuations, data for computing the electrical conditions of the upper atmosphere. If the attenuation is found to be nearly in simple proportion to the distance, it would seem that the existence of the upper reflecting-surface could be regarded as demonstrated.

---

two hours. It then begins to strengthen, and finally reaches a maximum—sometimes a very high one—at the time of sunset at Glace Bay. During the night the signals are very variable in strength, varying from very weak to very strong. Shortly before sunrise at Clifden the signals grow stronger, and reach a high maximum shortly after sunrise; they now dwindle to a marked minimum about two hours after, and then they return gradually to their normal day strength. The ratio of the intensity of the signals during the twilight maximum to the average intensity throughout the day is much greater for a wave 5000 metres long (frequency 60,000 per second) than for a wave 7000 metres long (frequency 43,000 per second), and the long wave signals are uniformly stronger during the day than those of the shorter wave.

Some of these observed facts can be understood by the aid of the hypothesis of ionic refraction. We have only to lay down the principle that the aggregate curvature of the trajectory of the longer waves is nearer to the curvature of the earth than that of the shorter waves, or, in other words, that the daylight trajectory of the longer waves is more suited than that of the shorter waves to the distance between the Irish and Canadian stations. Again, the minimum that occurs at about two hours after sunset at Clifden is readily explained by the conception, already discussed, that in the twilight regions the recombination of ions has consequences equivalent to a somewhat opaque curtain hanging from the top to the bottom of the middle atmosphere. Moreover, at two hours after sunset at Clifden the sun is setting at a place between the stations about 650 miles from Glace Bay. At this place the horizontal plane of Glace Bay passes between 50 and 60 miles overhead. If now we assume that the height of the curtain of irregularly ionised air is of the order 50 miles, thus making no allowance whatever for the bending of the rays from Glace Bay in their progress below that level, we see that the signals transmitted to Clifden are weakest when the curtain comes on the horizon of the sending station. If, on the other hand, we allow for the likelihood of the rays following considerably bent paths even in the lower middle atmosphere, we must take Marconi's results as showing that the ionic curtain reaches effectively to much lower atmospheric levels than 50 miles. All of this applies, *mutatis mutandis*, to the morning minimum produced by the sunrise belt passing between the stations.

In regard to the remaining point quoted from Dr. Marconi, namely, the strong maximum in signals to Clifden at about sunset at Glace Bay, and before sunrise at Clifden, there is more difficulty in finding an explanation. It would seem that the heterogeneous ionisation following the twilight carried on with radiation that had started at considerable upward inclination, and would therefore be accomplished with difficulty. The wave-fronts arriving at the receiving station would also be tilted forward considerably, and consequently the horizontal component of the electric field of the waves might approach the magnitude of the vertical component. In this case an inclined antenna would be a better receiver than a vertical one.

In various parts of the world it has been found that stations on the opposite sides of a mountain chain can communicate in the night with ease, though only with great difficulty, if at all, in the day. This is especially the case if a short wave is in use, and such a pair of stations can sometimes establish day communication by adopting a longer wave-length. It is, in fact, now common knowledge that for communication across hilly country in the daytime, a long wave—a thousand metres or more—should be used. The explanation is obvious on the hypotheses developed above. The rays, starting with sufficient elevation from a sending station in the plains, travel in straight lines through the lower atmosphere past the mountain tops, and then, reaching the middle atmosphere, are deflected downward by refraction in the ionised air. Short waves are refracted much less than long waves, and are therefore not bent so fully into the lower atmosphere as are the long waves. Indeed, the short waves may be entirely lost, and the long waves be bent down abundantly and come to earth again on the far side of the mountains. In the night, however, the ionisation of the middle atmosphere has disappeared, the Heaviside layer is open, and waves of all frequencies are reflected down to earth again. Another fact that emphasises the existence of elevated trajectories is afforded by the experiences of the Alpine receiving stations. These stations commonly receive signals from great distances in all directions—from stations in all parts of Europe and from ships on the Atlantic—so that it has been said that "the Alps attract signals." Stations in the plains do not get these distant signals nearly so often. The fact is that the high mountain stations have, of course, a much better chance of lying on the trajectories of the waves, or, as suggested by Larmor, in a slightly different connection, of "tapping a stronger stratum of radiation."

Recently, in an evening discourse at the Royal Institution, Marconi has described* the striking effects of sunrise and sunset on the strength of signals received from across the Atlantic Ocean. He stated that the intensity of the signals received at Clifden, Ireland, from Glace Bay, Canada, remains fairly steady during the day, but shortly after sunset at Clifden it becomes gradually weaker, and reaches a minimum in about

RADIOTELEGRAPHY.[1]

[With 1 plate.]

By Commendatore G. Marconi, LL.D., D.Sc.

The practical application of electric waves to the purposes of wireless telegraphic transmission over long distances has continued to extend to a remarkable degree during the last few years, and many of the difficulties, which at the outset appeared almost insurmountable, have been gradually overcome, chiefly through the improved knowledge which we have obtained in regard to the subject generally and to the principles involved.

The experiments which I have been fortunate enough to be able to carry out, on a much larger scale than can be done in ordinary laboratories, have made possible the investigation of phenomena often novel and certainly unexpected.

Although we have—or believe we have—all the data necessary for the satisfactory production and reception of electric waves, we are yet far from possessing any very exact knowledge concerning the conditions governing the transmission of these waves through space, especially over what may be termed long distances. Although it is now perfectly easy to design, construct, and operate stations capable of satisfactory commercial working over distances up to 2,500 miles, no really clear explanation has yet been given of many absolutely authenticated facts concerning these waves. Some of these hitherto apparent anomalies I shall mention briefly in passing.

Why is it that when using short waves the distances covered at night are usually enormously greater than those traversed in the day time, while when using much longer waves the range of transmission by day and night is about equal and sometimes even greater by day?

What explanation has been given of the fact that the night distances obtainable in a north-southerly direction are so much greater than those which can be effected in an east-westerly one?

Why is it that mountains and land generally should greatly obstruct the propagation of short waves when sunlight is present and not during the hours of darkness?

---

[1] Reprinted by permission from author's separate of Proceedings of the Royal Institution. Read before Royal Institution of Great Britain at weekly evening meeting, Friday, June 2, 1911.

The general principles on which practical radiotelegraphy is based are now so well known that I need only refer to them in the briefest possible manner.

Wireless telegraphy, which was made possible by the fields of research thrown open by the work of Faraday, Maxwell, and Hertz, is operated by electric waves, which are created by alternating currents of very high frequency, induced in suitably placed elevated wires or capacity areas. These waves are received or picked up at a distant station on other elevated conductors tuned to the period of the waves, and the latter are revealed to our senses by means of appropriate detectors.

My original system as used in 1896 consisted of the arrangement shown diagrammatically in figure 1, where an elevated or vertical wire was employed. This wire sometimes terminated in a capacity or was connected to earth through a spark gap.

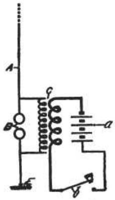

Fig. 1.

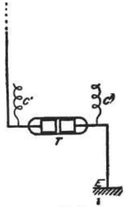

Fig. 2.

By using an induction coil or other source of sufficiently high tension electricity sparks were made to jump across the gap; this gave rise to oscillations of high frequency in the elevated conductor and earth, with the result that energy in the form of electric waves was radiated through space.

At the receiving station (fig. 2) these waves induced oscillatory currents in a conductor containing a detector, in the form of a coherer, which was usually placed between the elevated conductor and earth.

Although this arrangement was extraordinarily efficient in regard to the radiation of electrical energy, it had numerous drawbacks.

The electrical capacity of the system was very small, with the result that the small amount of energy in the aerial was thrown into space in an exceedingly short period of time. In other words, the energy, instead of giving rise to a train of waves, was all dissipated after only a few oscillations, and, consequently, anything approaching good tuning between the transmitter and receiver was found to be unobtainable in practice.

reach the earth again in appreciable amount. This would probably not have happened with longer waves.

As for the night signals, both long and short waves are propagated through the lower and middle atmosphere in straight lines to great heights and reflected at the Heaviside layer, and then they descend to earth again, having suffered comparatively little absorption. The waves may be imagined to creep round this electrical vault of the atmosphere in a manner somewhat analogous to the creeping of sound round a whispering gallery, being plentifully scattered downward in their progress by the irregularities in the reflecting surface, or, to put it another way, we may imagine that a transmitting station "lights up the sky," in an electrical sense, for many degrees below its horizon.

Since in the observations quoted the daylight signals were perceptible at 700 miles, where the horizontal plane of the sender crosses the observer's vertical at a height of 60 miles, we may conclude that the trajectory of the radiation directed horizontally from the sender does not reach higher than 30 miles in the daytime. It may be mentioned at this point that Marconi originally suggested that the phenomenon might be due to a possible discharging action of sunlight on the sending antenna, and J. J. Thomson considered it rather due to the absorption of energy by the ionised air in the immediate neighbourhood of the antenna, but both these explanations ought to make the contrast between day and night signals the same for short distances as for long, which is not the case.

The above considerations suggest that there should exist a best frequency for signalling over great distances. Now the radiation from a Hertzian oscillator is most intense in its equatorial plane, and therefore, from a vertical linear earthed antenna, is most intense in the horizontal plane of the sending station. Hence we conclude that the best frequency is that for which, in a given ionic condition of the atmosphere, the trajectory of the radiation which starts nearly horizontally returns to the earth's surface near the receiving station. Marconi has stated* that a wave-length of 5000 metres is almost always better than one of 4000 metres for Transatlantic signalling—though, he remarks, the shorter wave-length is better than the longer occasionally. In this connection it may be pointed out that, if the transmission of signals be attempted with an exceedingly long wave-length, the aggregate curvature produced by the ionic refraction in the day might be sharper than the curvature of the earth. This would cause the nearly horizontal radiation to be turned down to the earth within a relatively short distance from the radiator. In that case reception at a distance would be exhibit a different frequency; or, in other words, there should be a distinct best frequency at which to adjust the receiving apparatus at each of these stations. This is on account of the difference of trajectory that difference of frequency brings. There is but little experimental evidence bearing on this point, though what there is favours the assumptions; but clearly if dispersion do occur in the sunlit middle atmosphere, and do not occur at night, the weakness of the day strays is fully accounted for without invoking the assistance of absorption.

---

* Nobel Lecture, December, 1909.

Though the hypothesis of propagation round the earth by refraction in the ionised middle atmosphere has now been applied to the problem that prompted it, namely, the explanation of the minimum phenomenon of natural electric waves, yet it seems desirable to enquire how the hypothesis comports itself towards the known facts and properties of the artificial electric waves used in signalling.

The two assumptions on which the discussion has so far been built are, first, that there exists in the atmosphere a permanently conducting upper layer which is somewhat sharply defined, and which therefore reflects waves of every frequency—we may call it Heaviside's reflecting layer; and, second, that in the day (and only to a slight and erratic extent in the night) the atmosphere below this reflecting layer is ionised in nearly horizontal strata, the ionisation diminishing as the earth's surface is approached, with the result that electric waves are given a bent trajectory and the Heaviside layer put out of action. In using these assumptions in what follows, the atmosphere will be supposed at rest.

One of the most important of the facts known concerning the transmission of artificial waves is the difference between day and night signals discovered by Marconi* in 1902 during a voyage from England to New York. He found that there was little difference between day and night signals at distances less than 500 miles from the sending station, but that the day signals were unreadable at distances of 800 miles and more, while the night signals were readable up to distances of 2000 miles. This is possibly due to the same causes as the weakening of the day strays relatively to the night strays, but is most probably due to the failure of the heterogeneously ionised air to bend the waves sufficiently to fit the convexity of the earth. Thus, in explaining the daylight effect observed first by Marconi in 1902, it is only necessary to suppose that the relatively short waves then in use travelled to great heights in the atmosphere on account of the smallness of the curvature of their trajectory, and were not refracted sufficiently to

---

* Marconi, 'Roy. Soc. Proc.,' June, 1902.

Many mechanical analogies could be quoted which show that in order to obtain syntony the operating energy must be supplied in the form of a sufficient number of small oscillations or impulses properly timed. Acoustics furnish us with numerous examples of this fact, such as the resonance produced by the well-known tuning fork experiment.

Other illustrations of this principle may be given; e. g., if we have to set a heavy pendulum in motion by means of small thrusts or impulses, the latter must be timed to the period of the pendulum, as otherwise its oscillations would not acquire any appreciable amplitude.

In 1900 I first adopted the arrangement which is now in general use, and which consists (as shown in fig. 3) of the inductive association of the elevated radiating wire with a condenser circuit which may be used to store up a considerable amount of electrical energy and impart it at a slow rate to the radiating wire.

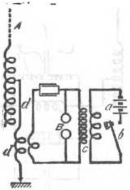

Fig. 3.

As is now well known, the oscillations in a condenser circuit can be made to persist for what is electrically a long period of time, and it can be arranged moreover that by means of suitable aerials or antennæ these oscillations are radiated into space in the form of a series of waves, which through their cumulative effect are eminently suitable for enabling good tuning and syntony to be obtained between the transmitter and receiver.

The circuits, consisting of the condenser circuit and the elevated aerial or radiating circuit, were more or less closely coupled to each other. By adjusting the inductance in the elevated conductor, and by the employment of the right value of capacity or inductance required in the condenser circuit, the two circuits were brought into electrical resonance, a condition which I first pointed out as being essential in order to obtain efficient radiation and good tuning.

The receiver (as shown in fig. 4) also consists of an elevated conductor or aerial connected to earth or capacity through an oscillating transformer. The latter also contains the condenser and detector, the circuits being made to have approximately the same electrical time period as that of the transmitter circuits.

At the long distance station situated at Clifden, in Ireland, the arrangement which has given the best results is based substantially upon my syntonic system of 1900, to which have been added numerous improvements.

An important innovation from a practical point of view was the adoption at Clifden and Glace Bay of air condensers, composed of insulated metallic plates suspended in air at ordinary pressure. In this manner we greatly reduce the loss of energy which would take place in consequence of dielectric hysteresis were a glass or solid dielectric employed. A very considerable economy in working also results from the absence of dielectric breakages, for, should the potential be so raised as to even produce a discharge from plate to plate across the condenser, this does not permanently affect the value of the dielectric, as air is self-healing and one of the few commodities which can be replaced at a minimum of cost.

Various arrangements have been tried and tested for obtaining continuous or very prolonged trains of waves, but it has been my experience that, when utilizing the best receivers at present available, it is neither economical nor efficient to attempt to make the waves too continuous. Much better results are obtained when groups of waves (fig. 5) are emitted at regular intervals in such manner that their cumulative effect produces a clear musical note in the receiver, which is tuned not only to the periodicity of the electric waves transmitted but also to their group frequency.

In this manner the receiver may be doubly tuned, with the result that a far greater selectivity can be obtained than by the employment of wave tuning alone.

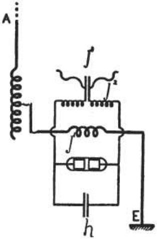

FIG. 4.

In fact, it is quite easy to pick up simultaneously different messages transmitted on the same wave length, but syntonized to different group frequencies.

As far as wave tuning goes, very good results—almost as good as are obtainable by means of continuous oscillations—can be achieved with groups of waves, the decrement of which is in each group 0.03 or 0.04, which means that about 30 or 40 useful oscillations are radiated before their amplitude has become too small to perceptibly affect the receiver.

The condenser circuit at Clifden has a decrement of from 0.015 to 0.03 for fairly long waves.

This persistency of the oscillations has been obtained by the employment of the system shown in figure 6, which I first described in a patent taken out in September, 1907. This method eliminates

---

is sometimes a complete zero lasting for only two minutes or less. Assuming that in this case the source of the natural electric waves and the receiving station lie both on the great circle of twilight, we deduce that the twilight band is at least 30 miles wide, this being the distance the earth rotates eastward in two minutes. In addition, the same assumption would indicate that the principal source of the strays during November, 1909 and 1911, lay in the direction of the eastern portion of the Atlas Mountains.

Again, the observations have shown that the chief twilight minima occur about 10 minutes before sunrise and about 10 minutes after sunset during the same periods. This fact is accounted for by the consideration that the time of sunrise in the middle atmosphere is a little earlier and the time of sunset a little later than at the surface of the earth. In this connection it should be noticed that the electrically effective sunrise at a point in the middle atmosphere, as measured by the ionising power of the sunlight reaching the point, is not coincident in time with the sunrise at the same point as indicated by mere luminosity, that is, with the geometrical sunrise. The rays heralding the sunrise in the latter and ordinary sense must possess very little ionising power, for the reason that in passing the earth tangentially they have traversed so long a path in the lower atmosphere as to have lost their ionising radiation. Thus an observation of the time interval of the stray minimum before geometrical sunrise and after sunset does not determine the height of the electrically disturbed regions. Besides this, the exact time of the stray minimum will be affected to some extent by the obliquity of the ionic curtain to the line of propagation of the waves.

During the day the electric waves travel in the relatively narrow shell of dielectric between some stratum in the middle atmosphere and the surface of the earth. At night they travel in the much wider shell of dielectric between the assumed high conducting layer and the earth. In England, in winter, the day strays are much weaker than the night strays. From this we might conclude either that the aggregate absorption in the thin shell of dielectric is greater than in the deeper night shell, or that the ionisation of the middle atmosphere during the day is sufficiently non-uniform to hinder the propagation of the waves. But another factor must be recognised. The electric disturbance produced by a lightning discharge is doubtless impulsive in character, and is probably either a solitary wave or a very short train of waves. The study of the refraction of such disturbances leads to some well-known theoretical difficulties, but if we assume that the wave undergoes dispersion during its progress through the ionised middle atmosphere, then the disturbance arriving at a given receiving station should exhibit a fairly definite frequency, and that arriving at a station at a different distance should still atmosphere be drawn round the globe they will be nearest the earth at places where the sun is on the meridian, and will rise away from the earth somewhat sharply at places where the sun is rising or setting. The regions in which the change from the day level to the night level takes place form a great circular band round the globe and inclined to the meridians at an angle depending on the season. This region of the atmosphere, since it is perpetually moving with the sun, will be in a highly disturbed electrical condition. Formation of ions is actively proceeding in one half of the great circle and recombination in the other, and these processes doubtless take place somewhat irregularly even in a still atmosphere—with the result that patches or banks of ionised air, analogous to the banks of fog met at sea—will transiently constitute this band in the middle atmosphere. The effect of such patches of variously ionised air on electric waves propagated through the region is, in view of the connection between the velocity of the waves and the concentration of the ions, certain to be difficult. The scattering by repeated refractions will tend to make the region impenetrable to waves directed through it. Hence it may be expected that the regularity of the propagation through the steadily ionised horizontal strata of the daytime will be greatly disturbed by the twilight transitional banks and patches, with the ultimate consequence that the sounds heard in the receiving apparatus will be greatly weakened.

The author's experience up to the present indicates that the existence or non-existence of clouds in the vicinity of the receiving station has but little influence on the intensity and character of the stray minima, or, for that matter (provided the day is not brilliantly clear), on signals received from any distance and any point of the compass. Whence we may conclude that the irregularly ionised band is situated above the ordinary cloud level. The twilight transitional region may therefore be regarded as a sort of curtain enringing the earth and occupying the middle atmosphere and not the lower. Thus it can affect only the trajectories of waves travelling from great distances. The weakening of such long-distance waves will probably be greater or less according as they have to penetrate the curtain more or less obliquely. In the case of the natural electric waves received by an antenna in England during the autumn and winter the origin of the waves must in general lie to the south. It is reasonable to suppose that tropical Africa will supply most of them. In that case, the twilight transitional band must have a very great and a relatively short-lived influence on the intensity of the strays heard in the telephones, for the path of the waves from the suggested source to the receiving station is nearly coincident with the twilight band. These suppositions accord precisely with the observed facts. The minimum

---

almost completely the spark gap and its consequent resistance, which, as is well known, is the principal cause of the damping or decay of the waves in the usual transmitting circuit.

The apparatus shown in figure 6 consists of a metal disk *a*, having copper studs firmly fixed at regular intervals in its periphery and placed transversely to its plane. This disk is caused to rotate very rapidly between two other disks, *b*, by means of a rapidly revolving electric motor or steam turbine. These side disks are also made to slowly turn round in a plane at right angles to that of the middle disk. The connections are as illustrated in the figure. The studs are of such length as to just touch the side disks in passing, and thereby bridge the gap between the latter.

With the frequency employed at Clifden, namely, 45,000, when a potential of 15,000 volts is used on the condenser, the spark gap is practically closed during the time in which one complete oscillation only is taking place, when the peripherical speed of the disk is about 600 feet a second. The result is that the primary circuit can continue oscillating without material loss by resistance in the spark gap. Of course the number of oscillations which can take place is governed by the breadth or thickness of the side disks, the primary circuit being abruptly opened as soon as the studs attached to the middle disk leave the side disks.

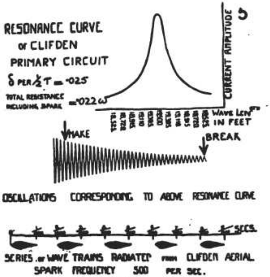

Fig. 5.

This sudden opening of the primary circuit tends to immediately quench any oscillations which may still persist in the condenser circuit; and this fact carries with it a further and not inconsiderable advantage, for if the coupling of the condenser circuit to the aerial is of a suitable value the energy of the primary will have practically all passed to the aerial circuit during the period of time in which the

primary condenser circuit is closed by the stud filling the gap between the side disks; but after this the opening of the gap at the disks prevents the energy returning to the condenser circuit from the aerial, as would happen were the ordinary spark gap employed. In this manner the usual reaction which would take place between the aerial and the condenser circuit can be obviated, with the result that with this type of discharger and with a suitable degree of coupling the energy is radiated from the aerial in the form of a pure wave, the loss from the spark gap resistance being reduced to a minimum.

I am able to show a resonance curve taken at Clifden which was obtained from the oscillations in the primary alone (fig. 5).

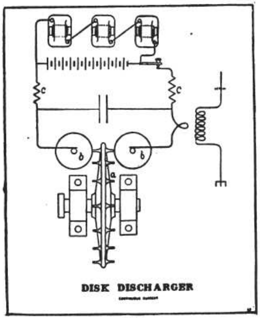

Fig. 6.

An interesting feature of the Clifden plant, especially from a practical and engineering point of view, is the regular employment of high-tension direct current for charging the condenser. Continuous current at a potential which is capable of being raised to 20,000 volts is obtained by means of special direct-current generators; these machines charge a storage battery consisting of 6,000 cells, all connected in series, and it may be pointed out that this battery is the largest of its kind in existence. The capacity of each cell is 40 ampere-hours. When employing the cells alone the working voltage is from 11,000 to 12,000 volts, and when both the direct-current generators and the battery are used together the potential may be raised to 15,000 volts through utilizing the gassing voltage of the storage cells.

For a considerable portion of the day the storage battery alone is employed, with a result that for 16 hours out of the 24 no running

---

0·01. This in turn indicates that the number of ions per cubic centimetre should be about 160,000 when the wave-length is 2000 metres, and about 16,000 when the wave-length is 6000 metres. Such ionic concentrations are not improbable.

It may be objected that there has as yet been no experimental corroboration of this concentration of the energy of the waves into a comparatively thin stratum near the surface of the earth. But as a fact no measurements have as yet been carried out over great distances on the variation of intensity of signals with distance and under unvarying atmospheric conditions; and clearly the measurements that have been made over short distances—which all support the inverse square law as was to be expected—cannot have any bearing on refractions that take place in high layers. When measurements of intensity over distances of 1000 to 2000 miles become available it may be expected that the inverse square law will hold for a distance of three or four hundred miles, and after that a law indicating rather less divergence may hold for several hundred miles more, if the frequency is low enough for the ionic refraction to produce bending at least as great as the convexity of the globe.*

We now proceed to the explanation of the stray minima described earlier. In the first place it is evident that if the surfaces of equal ionisation in a

---

* Since the above was written, an account by L. W. Austin ('Washington Bureau of Standards Bulletin,' October, 1911) of some new measurements of the intensity of signals has come to hand, which appears to strengthen the author's position greatly, so far as the measurements go. The inverse square law for the divergence of energy shows that $I \propto x^{-1}$, where I is the intensity of the current received on an antenna, and x is the distance of the sending station. If the waves were travelling in free space of electrical constitution like that of our lower atmosphere, the absorption would demand a formula of the type

$$I \propto x^{-1}\epsilon^{-\alpha x},$$

where α is independent of the wave-length. Also it has been shown above that if the waves were travelling in free space filled with air highly ionised, the absorption would require a formula of the type

$$I \propto x^{-1}\epsilon^{-\alpha x\lambda^2},$$

where α is again independent of the wave-length. Now, the observations quoted support an empirical formula very different from either of these, namely,

$$I \propto x^{-1}\epsilon^{-\alpha x/\sqrt{\lambda}}.$$

A formula involving the wave-length in this manner is not suggested, and cannot even be accounted for, by absorption in an ionised atmosphere or in a badly conducting surface such as that of land or sea; but it is clearly in rough general accord with the law, developed in this paper, that the desired bending of the rays is better with long waves than with short waves; or, to put it in another way, the loss of radiation by failure to turn the curve of the earth is greater with short waves than with long. The measurements made up to the present by Austin and his collaborators have extended to distances of only 900 miles, involving only very slight bending, and, besides, have not been very numerous.

ions moving up and negative ions moving down, with the result that some parts of the middle atmosphere may remain ionised after the sun has set. If we suppose, however, that the ions do for the most part recombine, then the effect of the change from day to night is to remove a veil, as it were, of ionised air from between the upper conducting layer and the earth.

Since the velocity of the waves in the sunlit middle atmosphere is greater the higher the level at which they are travelling, a ray of electric radiation starting from a point of the earth's surface in a direction inclined slightly upward will pursue a straight path in the lower atmosphere and a slightly bent path, with its concavity downwards, in the middle atmosphere, thus following to a greater or less extent the curvature of the earth. If its curvature in the middle atmosphere is on the average greater than that of the earth—and not otherwise—the ray will be turned down to the lower atmosphere and will again traverse a straight line. In other words, the wave-fronts will be tilted forward as they travel, in a manner quite analogous to the refraction of sound in air when the temperature varies upward. This bending of the rays may be given for shortness the name ionic refraction; it would be very rapid in layers where γ approached unity. Thus the radiations diverging in all directions from a lightning stroke or from a wireless telegraph antenna become confined in the day between the conducting surface of the earth and a certain level in the middle atmosphere. Even the rays that start horizontally from a place on the earth's surface must, owing to the earth's curvature, reach, within 300 miles of the source, to heights where the air may be expected to be strongly ionised, and must then suffer refraction downwards. Since the quantity γ is inversely proportional to the frequency of the transmitted waves, the limiting height of penetration of the waves is smaller the lower the frequency, and therefore low-frequency waves become concentrated nearer to the earth's surface than do higher frequency waves.

The curvature of the trajectory of waves travelling at a height z is $dv/(vdz)$, v being the velocity at the place. But when γ is small $v = (1+\frac{1}{2}\gamma)/\sqrt{(\mu\kappa)}$, and therefore the curvature is $\frac{1}{2}d\gamma/dz$ approximately. If we assume a condition of things in which the radius of curvature of rays at all heights is $r+z$, where r is the radius of the earth, and that $\gamma = 0$ at $z = 0$, we find

$$\gamma = 2\log\frac{r+z}{r} = 2\frac{z}{r}, \text{ approximately.}$$

Though, in fact, the bending of rays in the lower atmosphere is probably not so great as this, the equation indicates that the order of magnitude of γ required in the middle atmosphere at, say, a height of 20 miles is about

---

machinery need be used for operating the station, with the single exception of the small motor revolving the disk.

The potential to which the condenser is charged reaches 18,000 volts when that of the battery or generators is 12,000. This potential is obtained in consequence of the rise of potential at the condenser plates, brought about by the rush of current through the choking or inductance coils at each charge. These coils are placed between the battery or generator and the condenser *c*, figure 6.

No practical difficulty has been encountered either at Clifden or Glace Bay in regard to the insulation and maintenance of these high-tension storage batteries. Satisfactory insulation has been obtained by dividing the battery into small sets of cells placed on separate stands. These stands are suspended on insulators attached to girders fixed in the ceiling of the battery room. A system of switches, which can all be operated electrically and simultaneously, divides the battery into sections, the potential of each section being low enough to enable the cells to be handled without inconvenience or risk.

The arrangement of aerial adopted at Clifden and Glace Bay is shown in figure 7. This system, which is based on the result of tests which I first described before the Royal Society in June, 1906,[1] not only makes it possible to efficiently radiate and receive waves of any desired length, but it also tends to confine the main portion of the radiation to any desired direction. The limitation of transmission to one direction is not very sharply defined, but nevertheless the results obtained are exceedingly useful for practical working.

FIG. 7.

In a similar manner, by means of these horizontal wires, it is possible to define the bearing or direction of a sending station, and also limit the receptivity of the receiver to waves arriving from a given direction.

The commercial working of radiotelegraphy and the widespread application of the system on shore and afloat in nearly all parts of the world has greatly facilitated the marshaling of facts and the observation of effects. Many of these, as I have already stated, still await a satisfactory explanation.

A curious result which I first noticed over nine years ago in long-distance tests carried out on the steamship *Philadelphia*, and which still remains an important feature in long-distance space telegraphy,

---

[1] "On methods whereby the radiation of electric waves may be mainly confined, etc." Proc. Roy. Soc., A, vol. 77, p. 413.

is the detrimental effect produced by daylight on the propagation of electric waves over great distances.

The generally accepted hypothesis of the cause of this absorption of electric waves in sunlight is founded on the belief that the absorption is due to the ionization of the gaseous molecules of the air affected by the ultra violet light, and as the ultra violet rays which emanate from the sun are largely absorbed in the upper atmosphere of the earth, it is probable that that portion of the earth's atmosphere which is facing the sun will contain more ions or electrons than that which is in darkness, and therefore, as Sir J. J. Thomson has shown,[1] this illuminated or ionized air will absorb some of the energy of the electric waves.

The wave length of the oscillations employed has much to do with this interesting phenomenon, long waves being subject to the effect of daylight to a very much lesser degree than are short waves.

Although certain physicists thought some years ago that the daylight effect should be more marked on long waves than on short, the reverse has been my experience; indeed, in some transatlantic experiments, in which waves about 8,000 meters long were used, the energy received by day at the distant receiving station was usually greater than that obtained at night.

Recent observation, however, reveals the interesting fact that the effects vary greatly with the direction in which transmission is taking place, the results obtained when transmitting in a northerly and southerly direction being often altogether different from those observed in the easterly and westerly one.

Research in regard to the changes in the strength of the received radiations which are employed for telegraphy across the Atlantic has been recently greatly facilitated by the use of sensitive galvanometers, by means of which the strength of the received signals can be measured with a fair degree of accuracy.

In regard to moderate power stations such as are employed on ships, and which, in compliance with the international convention, use wave lengths of 300 and 600 meters, the distance over which communication can be effected during daytime is generally about the same, whatever the bearing of the ships to each other or to the land stations —whilst at night interesting and apparently curious results are obtained. Ships over 1,000 miles away, off the south of Spain or round the coast of Italy, can almost always communicate during the hours of darkness with the post-office stations situated on the coasts of England and Ireland, whilst the same ships, when at a similar distance on the Atlantic to the westward of these islands and on the usual track between England and America, can hardly ever communi-

---

molecular size, and the other is that these same agencies also produce, by direct action on the gases of the atmosphere, condensation nuclei consisting of solid or liquid compounds which are not electrically charged when first formed. Evidently, the condensation nuclei can have only slight influence on the value of the quantity γ as compared with the electrical carriers of molecular size. These heavy ions, or condensation nuclei, doubtless frequently become charged by attaching one or more of the light ions, which has the effect of putting such ions out of action for our purposes. The lighter ions are probably in a majority in the higher parts of the middle atmosphere, and the heavy ions in a majority in the lower parts, and also in the lower atmosphere. It may be mentioned that the heavier ions found in the lower atmosphere, whether consequences of solar radiation or not, escape being counted by the kind of apparatus usually used in measurements of atmospheric electricity, on account of their immobility.

So far as the quantity γ is concerned the principal difference between day and night conditions, and between the conditions at different times of the day, is due to the variations of the number of ions per cubic centimetre provided by solar radiation. It is not possible to be precise on this matter, even in the lower atmosphere. But, broadly, it is clear that the value of n in the lower and middle atmospheres must vary considerably with the obliquity of the sun's rays at the place, that is to say, with the season and the time of day, and also must vary profoundly from daylight to darkness. About the time of sunrise at any particular place the process of ionisation by the solar radiation will be occurring at all heights of the atmosphere over an area extending many miles to east and west of the place; at sunset recombination of the ions will occur through a similar space. Of course the layers nearest the earth will be least disturbed in electrical constitution, mainly for the reason that the sun's rays must have been robbed of much of their ionising powers by the time they reach low levels; but it is known from direct observations at various levels up to heights of several miles that the influence of the sun is quite perceptible. But, in fact, it is easily seen from the formula deduced above for the absorption per wave-length, that the normal ionisation observed in the lower atmosphere produces inappreciable absorption of the waves at any time of day over terrestrial distances.

Our knowledge of the conditions ruling in the hours of darkness is even less precise than that of the day conditions. The very rapid rate of recombination of ions when the ionising agent is removed points to the possibility of the middle atmosphere being perfectly free from ions during darkness. But it is probable that there occurs during the day a great sifting of oppositely charged ions under the operation of the earth's vertical electric field, positive

In air under standard conditions $d\xi/dt = 1\cdot5$ cm./sec. in a field having a gradient of 1 volt per centimetre. Take $e = 1\cdot0 \times 10^{-20}$ in electromagnetic units, then $f = 7 \times 10^{-13}$, roughly. Again taking $p = 10^7$ and $m = 2 \times 10^{-21}$ in grammes, then $mp = 2 \times 10^{-14}$. Thus for waves of the order of frequency 1,000,000 per second, the two terms in the denominator of the quantity γ are of about the same order of importance at low levels in the atmosphere. For waves of lower frequency the term f^2 is much more important than the term m^2p^2, which may then be neglected in the denominator of γ. At higher levels, on the contrary, the term f^2 probably becomes negligible in comparison with m^2p^2 since the value of f is known to fall off much faster than that of m as the rarefaction increases. Thus, at high levels, we have

$$\gamma = 4\pi ne^2/\kappa mp^2, \text{ approximately.}$$

At low levels the value of γ works out as $0\cdot55 \times 10^{-14} \times n$ with the numbers already assumed. The number of ions per cubic centimetre at sea level is often given as between 1000 and 10,000. Thus γ is quite negligible compared with unity if this estimate of n and that of f are valid. At high levels, using the last equation, we find $\gamma = 0\cdot6 \times 10^{-11} \times n$ for $p = 10^7$ (corresponding to a wave-length of nearly 200 metres) and $\gamma = 0\cdot6 \times 10^{-9} \times n$ for $p = 10^6$ (corresponding to a wave-length of nearly 2000 metres in ordinary air). It is more than probable, however, that at moderately high levels, where the air is rather rarefied—for example, at a height of 20 miles the pressure is, on the theory of convective equilibrium, about 1/100 of the pressure at sea level—the ion is of much smaller mass, say 100 times smaller, than is assumed above, and this would make the last figure become $\gamma = 0\cdot6 \times 10^{-7} \times n$ for $p = 10^6$.

For convenience in discussion, the portion of the atmosphere below the permanently conducting layer and throughout which the equation

$$\gamma = 4\pi ne^2/\kappa mp^2$$

holds good, that is the portion of the atmosphere which is ionised strongly and directly by the sun, will be called the middle atmosphere. The part below this will be called the lower atmosphere, and here the equation

$$\gamma = 4\pi ne^2 m/\kappa f^2$$

is probably appropriate while n has low values. Of the middle atmosphere and of the upper atmosphere we know nothing directly. Perhaps the best information available is that contained in the memoirs of P. Lenard and C. Ramsauer,* who showed that the ultra-violet light of the sun will produce in air two effects of interest in the present connection. One effect is that the ultra-violet light, and possibly the cathode rays, of the sun produce electrical carriers of

---

* 'Heidelberger Akademie Sitzungsber.,' 1910—11.

cate with these shore stations unless by means of specially powerful instruments.

It is also to be noticed that in order to reach ships in the Mediterranean the electric waves have to pass over a large portion of Europe and, in many cases, over the Alps. Such long stretches of land, especially when including very high mountains, constitute, as is well known, an insurmountable barrier to the propagation of short waves during the daytime. Although no such obstacles lie between the English and Irish stations and ships in the North Atlantic en route for North America, a night transmission of 1,000 miles is there of exceptionally rare occurrence. The same effects generally are noticeable when ships are communicating with stations situated on the Atlantic coast of America.

Although high power stations are now used for communicating across the Atlantic Ocean, and messages can be sent by day as well as by night, there still exist periods of fairly regular daily occurrence during which the strength of the received signals is at a minimum.

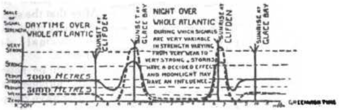

FIG. 8.

Thus in the morning and the evening, when, in consequence of the difference in longitude, daylight or darkness extends only part of the way across the ocean, the received signals are at their weakest. It would almost appear as if electric waves, in passing from dark space to illuminated space and vice versa, were reflected and refracted in such a manner as to be diverted from the normal path.

Later results, however, seem to indicate that it is unlikely that this difficulty would be experienced in telegraphing over equal distances north and south on about the same meridian, as, in this case, the passage from daylight to darkness would occur more rapidly over the whole distance between the two stations.

I have here some diagrams which have been carefully prepared by Mr. H. J. Round. These show the average daily variation of the signals received at Clifden from Glace Bay.

The curves traced on the diagram (fig. 8) show the usual variation in the strength of these transatlantic signals on two wave lengths —one of 7,000 meters and the other of 5,000 meters.

The strength of the received waves remains as a rule steady during daytime.

Shortly after sunset at Clifden they become gradually weaker, and about two hours later they are at their weakest. They then begin to strengthen again, and reach a very high maximum at about the time of sunset at Glace Bay.

They then gradually return to about normal strength, but through the night they are very variable. Shortly before sunrise at Clifden the signals commence to strengthen steadily, and reach another high maximum shortly after sunrise at Clifden. The received energy then steadily decreases again until it reaches a very marked minimum, a short time before sunrise at Glace Bay. After that the signals gradually come back to normal day strength.

It can be noticed that, although the shorter wave gives on the average weaker signals, its maximum and minimum variations of strength very sensibly exceed that of the longer waves.

Figure 9 shows the variations at Clifden during periods of 24 hours, commencing at 12 noon throughout the month of April, 1911, the vertical dotted lines representing sunset and sunrise at Glace Bay and Clifden.

Fig. 9.

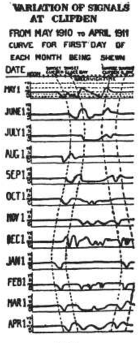

Fig. 10.

Figure 10 shows the curve for the first day of each month for one year, from May, 1910, to April, 1911.

I carried out a series of tests over longer distances than had ever been previously attempted, in September and October of last year, between the stations of Clifden and Glace Bay, and a receiving station placed on the Italian Steamship *Principessa Mafalda*, in the course of a voyage from Italy to Argentina (pl. 1, fig. 1).

Eliminating β and ζ among these three equations, we have

$$\frac{\partial^2 Z}{\partial x^2} = \mu\kappa \frac{\partial^2 Z}{dt^2} + \frac{4\pi\mu ne^2}{mip+f}\frac{\partial Z}{\partial t}.$$

There is a solution of the form

$$Z = \epsilon^{-lx+ip(t-x/v)}$$

for waves of frequency $p/2\pi$, if the velocity

$$v = \frac{mp}{\gamma f}\sqrt{\left(\frac{2(1-\gamma)}{\mu\kappa}\right)}\left\{\sqrt{\left[1+\left(\frac{\gamma f}{mp(1-\gamma)}\right)^2\right]}-1\right\}^{\frac{1}{2}}$$

and the absorption factor $l = \frac{\mu\kappa\gamma f}{2m}v.$

Here γ has been put for the quantity

$$\frac{4\pi ne^2 m}{\kappa(m^2p^2+f^2)},$$

which, it will be shown, is usually smaller than unity. In addition, the quantity $\gamma f/mp(1-\gamma)$ is usually very small compared with unity, hence, approximately,

$$v = \frac{1}{\sqrt{(\mu\kappa)}}(1+\tfrac{1}{2}\gamma), \qquad l = \frac{\sqrt{(\mu\kappa)}f}{2m}\gamma(1+\tfrac{1}{2}\gamma);$$

or the absorption coefficient per wave-length is

$$l' = \frac{\pi}{1-\gamma}\frac{\gamma f}{mp}.$$

It should be mentioned that, in forming the equations, it has been implicitly assumed that the ions are so heavy that they acquire only small velocities and make very small excursions under the action of the waves. That is to say, the ions are supposed to be collections of molecules, or, at the smallest, single molecules. The absorption in the case of very small ions, that is, electrons, has been worked out by J. J. Thomson,* and involves different considerations from those appropriate here.

Rough estimates of the various magnitudes involved in the last equations may be obtained by using the results of laboratory experiments on ionised gases, though, unfortunately, there are as yet but very few data available on the ionisation of air by solar radiation. First notice that the friction coefficient f can be estimated from experiments on the terminal velocities of ions in various gases. From the equation of motion of an ion we see that its terminal velocity under a steadily applied electric field Z is

$$\frac{d\zeta}{dt} = \frac{e}{f}Z.$$

* 'Phil. Mag.,' August, 1902, p. 253.

other recorded facts of long-distance transmission be explained. The writer has therefore investigated another, and closely related, possibility, which, it turns out, throws light on the causes of the stray minimum, as well as on many of the observed facts of long-distance transmission. To these new considerations we now turn.

The hypothesis to be introduced is based on the influence of the ionisation of the air on the propagation of electric waves through it. It is well known that, under normal conditions, the air at the sea-level is only slightly ionised even in strong sunshine, and that at a height of a few miles above the earth's surface the ionisation is, according to observations from balloons, sometimes 20 times as great as at the surface. Higher still the ionisation doubtless increases further, on account of the more and more intense ionising action of the solar radiation, which, it is plain, must be greater in these higher and rarer regions than in the dense regions below. No law can be legitimately assigned for the computation of this gradual transition from low conductivity to high conductivity, yet, for the purpose in hand, it is necessary to form some idea of the effect of this heterogeneity on the propagation of electric waves.

It is first necessary to examine the effect of charged ions of molecular mass on the velocity of the waves, and here we may follow, with suitable modifications, the standard methods applied to the study of optical dispersion in media containing electrons. Let e be the charge, m the mass, of each ion, and let n be the number of ions per cubic centimetre at a point whose co-ordinates are x, y, z, referred to a right-handed rectangular frame of axes with the axis of z vertical. Suppose that electric waves are advancing through the medium in the positive direction of the x axis, and with electric force Z, magnetic force β, at the point x, y, z. Then if μ be the permeability of the medium and κ the dielectric constant of the unionised air,

$$\frac{\partial Z}{\partial x} = \mu \frac{d\beta}{dt} \quad \text{and} \quad \frac{\partial \beta}{\partial x} = \kappa \frac{dZ}{dt} + 4\pi ne \frac{d\zeta}{dt},$$

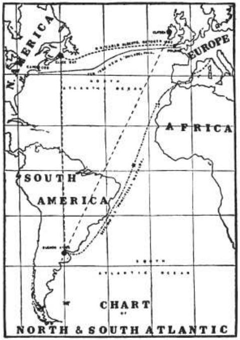
where ζ indicates the displacement of each ion from its original position produced by the waves. The equation of motion of an ion is

$$m \frac{d^2\zeta}{dt^2} + f \frac{d\zeta}{dt} = eZ,$$

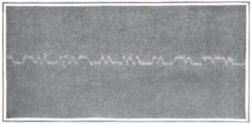
where f is a frictional constant of viscous type.

If the time factor in Z be ϵ^{ipt}, this equation becomes

$$\frac{d\zeta}{dt} = \frac{eZ}{mip+f}.$$



1. Long Distance Wireless Tests in 1910.



2. Record of Wireless Signals.

During these tests the receiving wire was supported by means of a kite, as was done in my early transatlantic tests of 1901, the height of the kite varying from about 1,000 to 3,000 feet. Signals and messages were obtained without difficulty, by day as well as by night, up to a distance of 4,000 statute miles from Clifden.

Beyond that distance reception could only be carried out during nighttime. At Buenos Aires, over 6,000 miles from Clifden, the night signals from both Clifden and Glace Bay were generally good, but their strength suffered some variations.

It is rather remarkable that the radiations from Clifden should have been detected at Buenos Aires so clearly at nighttime and not at all during the day, whilst in Canada the signals coming from Clifden (2,400 miles distant) are no stronger during the night than they are by day.

Further tests have been carried out recently for the Italian Government between a station situated at Massaua in East Africa and Coltano in Italy. Considerable interest attached to these experiments, in view of the fact that the line connecting the two stations passes over exceedingly dry country and across vast stretches of desert, including parts of Abyssinia, the Soudan, and the Libyan Desert. The distance between the two stations is about 2,600 miles.

The wave length of the sending station in Africa was too small to allow of transmission being effected during daytime, but the results obtained during the hours of darkness were exceedingly good, the received signals being quite steady and readable.

The improvements introduced at Clifden and Glace Bay have had the result of greatly minimizing the interference to which wireless transmission over long distances was particularly exposed in the early days.

The signals arriving at Clifden from Canada are as a rule easily read through any ordinary electrical atmospheric disturbance. This strengthening of the received signals has moreover made possible the use of recording instruments, which will not only give a fixed record of the received messages, but are also capable of being operated at a much higher rate of speed than could ever be obtained by means of an operator reading by sound or sight. The record of the signals is obtained by means of photography in the following manner: A sensitive Einthoven string galvanometer is connected to the magnetic detector or valve receiver, and the deflections of its filament caused by the incoming signals are projected and photographically fixed on a sensitive strip, which is moved along at a suitable speed (pl. 1, fig. 2). On some of these records, which I am able to show, it is interesting to note the characteristic marks and signs produced amongst the signals by natural electric waves or other electrical disturbances of

---

diffraction has been thoroughly settled by the investigations of Rayleigh, Poincaré, Macdonald, Nicholson, and others, whose work has shown irrefutably that the energy propagated round a quarter of the globe by the process of diffraction would be utterly inappreciable. Heaviside has suggested that, in the type of waves used in wireless telegraphy, the Faraday lines of electric force are attached, as it were, to the earth, and slide along its surface, and that therefore they cannot leave it; but this view, in fact, throws us back on the diffraction result. Again, in 1906, Zenneck added to this suggestion a consideration based on a well-known illustration of Poynting's theorem. In his original memoir* on the propagation of energy in the electromagnetic field, Poynting gives as an illustration of the theorem the case of a wire possessing resistance and carrying an electric current. Heaviside,† referring to this illustration, showed that the moving electric field cannot be purely radial; in other words, the Faraday lines belonging to the flowing electricity must lean forward as they move along the wire—so that the energy vector shall have a component perpendicular to the surface of the wire. This particular case has been worked out in great detail since the date of the memoir, but Zenneck's application was to the simple case of the propagation of a plane wave over a badly conducting solid, such as the earth, with a plane boundary. His suggestion is, briefly, that the tilting forward of the wave fronts near the conductor will lead to a general slow turning downward of the waves towards the earth, so that a large proportion of the energy of the waves will be deflected round the bend of the earth instead of being propagated linearly into space. This suggestion does not in reality assist the pure diffraction theory at all.

Another hypothesis was put forward by Heaviside in 1900, when he suggested that the attenuated gases of the upper atmosphere might provide a conducting surface concentric with the earth, between which and the surface of the earth itself the waves might spread with two-dimensional divergence. This hypothesis has not yet been supported or denied by any trustworthy experiments or observations. Such experiments or observations will necessarily have to be made on waves that have travelled long distances, for the upper layers of the atmosphere cannot be greatly concerned in short-distance transmission. But it will be perceived, from the remarks already made on the minima of natural electric waves, that this upper conducting layer might supply the explanation of the phenomenon, and thereby gain some support. On examination, however, it appears that the phenomenon cannot be explained by means of the bare hypothesis, and still less can the practically as perfect in strong sunlight as in the dark. On all these counts, therefore, the supposition that the minima phenomena under discussion can be explained by ionisation of the lower layers of the atmosphere must be discarded as untenable.

---

* 'Phil. Trans.,' Jan. 10, 1884.

† 'Electrical Papers,' vol. 2, p. 94.

We must therefore turn to the possibility of alterations in the resistance of the ground round the antenna, alterations of such a nature that the waves are absorbed much more freely during a certain few minutes of twilight than before or after. Here we may at the same time consider a subordinate possibility, namely, that the resistance of the ground within a few yards of the earth plates of the antenna might vary through a minimum value during twilight. If this really happened there would be extra dissipation near the earth plate of the energy of the oscillations excited on the antenna by the incoming waves. Both of these views have been negatived by the author's observations on signals coming from short distances, which show that signals originating at distances of less than 50 miles do not undergo appreciable diminution in strength, even on days when the stray minimum is well marked. But, to make certain of the non-existence of the subordinate possibility just referred to, a long series of determinations was made, during the past autumn, of the high-frequency resistance of the antenna and its earth connection at various frequencies and at various times of the day; and especially at the twilight periods. These measurements were carried out by two distinct and trustworthy methods. The details of the determinations need not be given here; it is sufficient to state that the results leave no doubt that the local earth resistance does not vary in the rapid manner, nor to the wide extent, that is required to explain the twilight minima of the strays.

Another point that supports the view that the stray minimum is not produced by strictly local causes may be stated here. It is very noticeable that the twilight minima are easier to observe when the receiving apparatus is adjusted for long waves (say 6000 metres) than when it is adjusted for short waves (say 1000 metres). This is of obvious significance when taken with the fact that signal waves of great length are most suitable for communication over great distances. Now the most striking difference between signals received from long and from short distances is that in the former case the curvature of the earth may exert appreciable, perhaps very great, influence on the signal intensity.

This immediately raises the question of the manner of propagation of long electric waves round the earth. The fact is now thoroughly established that signal-bearing waves can travel a quarter of the way round the globe and still be easily perceptible. That this is not a manifestation of ordinary

---

the atmosphere, which, on account of their doubtful origin, have been called "X's."

Although the mathematical theory of electric wave propagation through space was worked out by Clerk Maxwell more than 50 years ago, and notwithstanding all the experimental evidence obtained in laboratories concerning the nature of these waves, yet so far we understand but incompletely the true fundamental principles concerning the manner of propagation of the waves on which wireless telegraph transmission is based. For example, in the early days of wireless telegraphy it was generally believed that the curvature of the earth would constitute an insurmountable obstacle to the transmission of electric waves between widely separated points. For a considerable time not sufficient account was taken of the probable effect of the earth connection, especially in regard to the transmission of oscillations over long distances.

Physicists seemed to consider for a long time that wireless telegraphy was solely dependent on the effects of free Hertzian radiation through space, and it was years before the probable effect of the conductivity of the earth was considered and discussed.

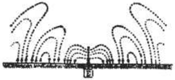


FIG. 11.

Lord Rayleigh, in referring to transatlantic radiotelegraphy, stated in a paper read before the Royal Society in May, 1903, that the results which I had obtained in signaling across the Atlantic suggested "a more decided bending or diffraction of the waves round the protuberant earth than had been expected," and further said that it imparted a great interest to the theoretical problem.[1] Prof. Fleming, in his book on electric wave telegraphy, gives diagrams showing what may be taken to be a diagrammatic representation of the detachment of semiloops of electric strain from a simple vertical wire (fig. 11).

As will be seen, these waves do not propagate in the same manner as does free radiation from a classical Hertzian oscillator, but instead glide along the surface of the earth.

Prof. Zenneck[2] has carefully examined the effect of earthed receiving and transmitting aerials, and has endeavored to show mathematically that when the lines of electrical force, constituting a wave front, pass along a surface of low specific inductive capacity—such as the earth—they become inclined forward, their lower ends being retarded by the resistance of the conductor, to which they are attached. It therefore would seem that wireless telegraphy as at present practiced is, to some extent at least, dependent on the conductivity of the earth, and that the difference in operation across long distances of sea compared to over land is sufficiently explained by the fact that sea water is a much better conductor than is land.

---

[1] Proc. Roy. Soc., vol. 72, p. 40.

[2] "Annalen der Physik," vol. 23, p. 846, "Physikalische Zeitschrift," 1906, pp. 50, 553.

The importance or utility of the earth connection has been sometimes questioned, but in my opinion no practical system of wireless telegraphy exists where the instruments are not in some manner connected to earth. By connection to earth I do not necessarily mean an ordinary metallic connection as used for wire telegraphs. The earth wire may have a condenser in series with it, or it may be connected to what is really equivalent, a capacity area placed close to the surface of the ground. It is now perfectly well known that a condenser, if large enough, does not prevent the passage of high-frequency oscillations, and therefore in this case, when a so-called balancing capacity is used, the antenna is for all practical purposes connected to earth.

I am also of opinion that there is absolutely no foundation in the statement which has recently been repeated to the effect that an earth connection is detrimental to good tuning, provided of course that the earth is good.

Certainly, in consequence of its resistance, what electricians call a bad earth will damp out the oscillations, and in that way make tuning difficult; but no such effect is noticed when employing an efficient earth connection.

In conclusion, I believe that I am not any too bold when I say that wireless telegraphy is tending to revolutionize our means of communication from place to place on the earth's surface. For example, commercial messages containing a total of 812,200 words were sent and received between Clifden and Glace Bay from May 1, 1910, to the end of April, 1911; wireless telegraphy has already furnished means of communication between ships and the shore where communication was before practically impossible. The fact that a system of imperial wireless telegraphy is to be discussed by the imperial conference, now holding its meetings in London, shows the supremely important position which radiotelegraphy over long distances has assumed in the short space of one decade. Its importance from a commercial, naval, and military point of view has increased very greatly during the last few years as a consequence of the innumerable stations which have been erected, or are now in course of construction, on various coasts, in inland regions, and on board ships in all parts of the world. Notwithstanding this multiplicity of stations and their almost constant operation, I can say from practical experience that mutual interference between properly equipped and efficiently tuned instru-

---

may be regarded as very small in itself. But, in the present case, the result is so completely inexplicable by the ordinary conceptions of the propagation of electric waves through the atmosphere, that we are compelled by its refusal to fit into the accepted scheme of things to attempt an extension of that scheme. Now, in searching for an explanation of these twilight minima, we have to notice that there are two main alternative possibilities. In the first place, the atmospheric discharges that produce the strays may themselves, for some reason, become temporarily infrequent at twilight; and, in the second place, the space through which the waves travel may become temporarily less easily traversed in twilight. The former alternative, when taken in conjunction with the author's experience over nearly 20° of longitude that it is the receiving station's local time which is concerned, implies that the bulk of the strays received at a given station are produced by atmospheric discharges occurring in regions of the atmosphere that have the same sunset and sunrise as that station; or, in other words, implies that the strays observed have their origin at places on (roughly) the meridian of the receiving station. Evidence has been already quoted, however, to show that the larger proportion of the strays observed at any station usually originate at a great distance from the station; hence the alternative under discussion leads to the unlikely conclusion that every station receives its strays from atmospheric discharges occurring at a great distance along its own meridian, and from that place solely.

We turn, therefore, to the other alternative, that the propagation of electric waves towards any place is hindered by some unknown effect of twilight. That this latter alternative is really the correct one is strongly indicated by observations (to be described later) on artificial electric waves coming from considerable distances.

Electric waves travelling near the earth's surface might conceivably be affected by the presence or absence of the sun at a point of observation in two obvious ways: First, light may ionise the air locally in sufficient degree to cause considerable absorption of the energy of the waves; and, secondly, sunlight might affect the electrical resistance of the ground within, say, 50 miles round the antenna, and thus have an effect on the absorption of the waves when they run over this region. Considering the former hypothesis first, the atmospheric absorption by ionisation due to solar radiation must, if it exists, be greater in strong sunshine than during twilight, which is contrary to observation. In point of fact, the absorption arrived at in this manner is, as will be shown incidentally later, much too small at any time of day to produce the effects actually observed. Moreover, it has long been known that the propagation of electric waves over short distances is aggregate area of the representative marks in any convenient intervals of time. The value of this time integral taken over, say, two minutes, is treated as the ordinate corresponding to the middle moment of the interval, which is taken as abscissa and a smooth curve drawn. But an even rougher method, consisting of counting the number of marks in each two minutes' interval, and using these numbers as ordinates corresponding to the mid-times, may suffice in many cases. Of course, a theoretically more perfect procedure would be to pass the detector currents through a sensitive galvanometer possessing a heavy moving system. A time record of the deflections indicated by the instrument would, at first sight, give a better quantitative result than the hand-made record just described; but actual trials show that there is an increase of accuracy only when the strays are very numerous, more numerous, in fact, than on the average occasion. Adopting, then, the method already described, we obtain curves such as that of fig. 6. These observations were made at the author's laboratory in London.

The scientific value or importance of an isolated result like the present one

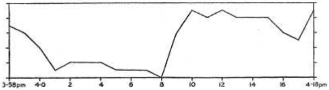

FIG. 6.—Integral Intensity Curve, Sunset, December 9, 1911.

ments has so far been almost entirely absent. Some interference does without doubt take place between ships, in consequence of the fact that the two wave lengths adopted in accordance with the rules laid down by the international convention, are not sufficient for the proper handling of the very large amount of messages transmitted from the ever increasing number of ships fitted with wireless telegraphy. A considerable advantage would be obtained by the utilization of a third and longer wave to be employed exclusively for communication over long distances.

In regard to the high-power transatlantic stations, the facility with which interference has been prevented has to some extent exceeded my expectations. At the receiving station situated at a distance of only 8 miles from the powerful sender at Clifden, during a recent demonstration arranged for the Admiralty, messages could be received from Glace Bay without any interference from Clifden when this latter station was transmitting at full power on a wave length differing only 25 per cent from the wave radiated from Glace Bay, the ratio between the maximum recorded range of Clifden and 8 miles being in the proportion of 750 to 1.

Arrangements are being made to permanently send and receive simultaneously at these stations, which, when completed, will constitute in effect the duplexing of radiotelegraphic communication between Ireland and Canada.

The result which I have last referred to also goes to show that it would be practicable to operate at one time, on slightly different wave lengths, a great number of long-distance stations situated in England and Ireland without danger of mutual interference.

The extended use of wireless telegraphy is principally dependent on the ease with which a number of stations can be efficiently worked in the vicinity of each other.

Considering that the wave lengths at present in use range from 200 to 23,000 feet, and moreover that wave group tuning and directive systems are now available, it is not difficult to foresee that this comparatively new method of communication is destined to fill a position of the greatest importance in facilitating communication throughout the world.

Apart from long-distance work, the practical value of wireless telegraphy may perhaps be divided into two parts, (1) when used for transmission over sea and (2) when used over land.

Many countries, including Italy, Canada, and Spain, have already supplemented their ordinary telegraph systems by wireless-telegraphy installations, but some time must pass before this method of communication will be very largely used for inland purposes in Europe generally, owing to the efficient network of land lines already existing which render further means of communication unnecessary; and

therefore it is probable that, at any rate for the present, the main use of radiotelegraphy will be confined to extra-European countries, in some of which climatic conditions and other causes absolutely prohibit the efficient maintenance of land-line telegraphy. A proof of this has been afforded by the success which has attended the working of the stations recently erected in Brazil on the upper Amazon.

By the majority of people the most marvelous side of wireless telegraphy is perhaps considered to be its use at sea. Up to the time of its introduction, ships at any appreciable distance from land had no means of getting in touch with the shore throughout the whole duration of their voyage. But those who now make long sea journeys are no longer cut off from the rest of the world; business men can continue to correspond at reasonable rates with their offices in America or Europe; ordinary social messages can be exchanged between passengers and their friends on shore; a daily newspaper is published on board most of the principal liners, giving the chief news of the day. Wireless telegraphy has on more than one occasion proved an invaluable aid to the course of justice—a well-known instance of which is the arrest, which took place recently through its agency, of a notorious criminal when about to land in Canada.

The chief benefit, however, of radiotelegraphy lies in the facility which it affords to ships in distress of communicating their plight to neighboring vessels or coast stations; that it is now considered indispensable for this reason is shown by the fact that several governments have passed a law making a wireless-telegraph installation a compulsory part of the equipment of all passenger boats entering their ports.

---

connected to an earth plate. The inductance was usually about 6×10^6 cm., and the natural period of the antenna was about 50,000 per second—which corresponds to a wave-length of about 6000 metres. This frequency was selected merely because it was of the same order of magnitude as that of the Marconi Transatlantic stations, signals from which were also being measured from time to time. The antenna inductance engaged inductively with another coil forming part of a secondary circuit that could be tuned to the antenna by aid of a variable condenser in it. A detector and telephone were connected with the circuit in the ordinary way. The Pickard zincite-chalcopyrite detector was used.

With such apparatus several ways of making and recording observations present themselves. The easiest and most obvious method consists in listening at sunrise and sunset to the noises made in the telephone by the natural electric wave trains; other methods involve the use of a galvanometer in place of a telephone receiver. The observations in this paper were practically all made with the telephone. A careful listener will find that on a typical morning the following phenomena appear:—First, starting to listen about half an hour before sunrise, the strays heard in the telephone are loud and numerous and much as they have been all night; then about 15 minutes before sunrise a change sets in, the strays get weaker and fewer rather quickly, till at about 10 minutes before sunrise a distinct lull occurs, of perhaps a minute's duration. At this period there is sometimes complete silence. Then the strays begin to appear again, and within 10 minutes of the lull they have settled down to the steady stream proper to the daytime. These day strays are weaker and fewer than the night strays, except on rare occasions. The lull is sometimes very pronounced, and at other times there is no lull at all. It is usually more marked at sunset than at sunrise.

The simplest way of representing these events, just as they are heard in the telephone, is by a hand-written record of the sounds. With practice, it becomes easy to make pencil marks on paper ruled in convenient units of time in such a way that the height of the mark represents the intensity of the sound, and the general shape of the mark the duration and character of the sound. Some of the records that have been obtained in this way are reproduced in figs. 2 to 5. These are selected out of a large number of records as examples of the different kinds of minima obtained at both sunrise and sunset. It will be noticed that at sunset the minimum is about 10 minutes after the calendar time of setting. Records such as these can be made to yield quantitative results of sufficient accuracy for the discussion of so irregular a phenomenon, by plotting rough estimates of the time integral of the intensity of the strays, that is, by estimating the radius of two or three hundred miles of the receiving station.) During the winter months, on the contrary, the number and intensity of the strays are relatively regular. The study of the phenomena belonging to the strays of distant origin may clearly be more favourably pursued in the winter than in summer, since the confusing feature of local lightning discharge is absent in winter. Besides the seasonal variations in the number and the intensity of the strays there is at every station a well-marked diurnal variation. Leaving out the irregularities due to local storms, we may say that the strays are in general more frequent and numerous during the night hours than during the day hours. The variations may be represented graphically as a curve in any of the methods indicated below and then they appear as shown in fig. 1, which may be regarded as a typical 24 hours' continuous record of the integral of number and intensity. These diurnal variations have not yet been investigated thoroughly. The author has not been able to find any account of observations in which the effects of local storms have been eliminated.

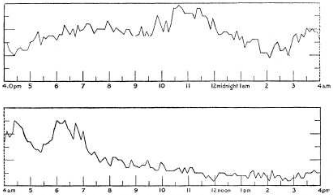

Fig. 1.—Twenty-four hours' Continuous Record of Integral Intensity of Strays, November 14 and 15, 1910.

From what has been said it is plain that the most interesting parts of the diurnal curve are those at which day and night conditions meet and change one into the other. To investigate these important parts of the curve the ordinary apparatus of a wireless telegraph station may be utilised. The apparatus employed by the author consisted of an antenna of 12 wires sloping from south to north at an angle of about 45° from a height of 170 feet, connected at the bottom to a coil of variable inductance, which was in turn

SOME QUANTITATIVE EXPERIMENTS IN LONG-DISTANCE RADIOTELEGRAPHY

By L. W. Austin

During December, 1909, and the spring and summer of 1910 the Navy Department carried on long-distance wireless tests between the scout cruisers *Birmingham* and *Salem* and the large Fessenden station at Brant Rock, which was leased by the Government for this purpose. These tests were primarily for the determination of the range of communication between the two cruisers and between the cruisers and the Brant Rock station. The United States Naval Wireless Laboratory had charge of the taking of certain quantitative measurements in connection with these tests, and this enabled us to obtain scientific data in regard to the laws which govern the radiation and reception of electrical waves, and, what was of especial interest, to study the course of the so-called atmospheric absorption up to a distance of about one thousand miles. The following paper contains the results of this work.

It was shown by Duddell and Taylor[1] in experiments carried on between a land station and the steamer *Monarch* in the Irish Sea that the received current over water fell off very nearly in proportion to the distance. This law has since been verified by Tissot.[2]

As the data obtained during the July experiments were by far the most full and accurate, all the theoretical deductions have been based on these results and the others have been employed only for comparison and verification. The Brant Rock station, situated directly on the shore 20 miles south of Boston, employs for its antenna a steel tower 420 feet high and 3 feet in diameter thoroughly insulated at its base. From the top of the tower extend four arms 50 feet in length and from each of these two 300-foot cylindrical cages are drawn out by means of guys at an angle of

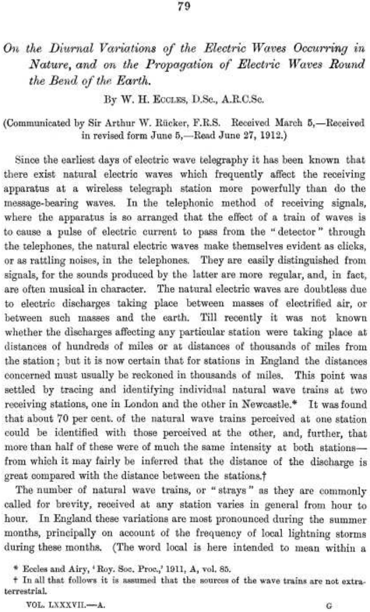
Proceedings of the Royal Society of London 1912



On the Diurnal Variations of the Electric Waves Occurring in Nature, and on the Propagation of Electric Waves Round the Bend of the Earth.

By W. H. Eccles, D.Sc., A.R.C.Sc.

(Communicated by Sir Arthur W. Rücker, F.R.S. Received March 5,—Received in revised form June 5,—Read June 27, 1912.)

Since the earliest days of electric wave telegraphy it has been known that there exist natural electric waves which frequently affect the receiving apparatus at a wireless telegraph station more powerfully than do the message-bearing waves. In the telephonic method of receiving signals, where the apparatus is so arranged that the effect of a train of waves is to cause a pulse of electric current to pass from the "detector" through the telephones, the natural electric waves make themselves evident as clicks, or as rattling noises, in the telephones. They are easily distinguished from signals, for the sounds produced by the latter are more regular, and, in fact, are often musical in character. The natural electric waves are doubtless due to electric discharges taking place between masses of electrified air, or between such masses and the earth. Till recently it was not known whether the discharges affecting any particular station were taking place at distances of hundreds of miles or at distances of thousands of miles from the station; but it is now certain that for stations in England the distances concerned must usually be reckoned in thousands of miles. This point was settled by tracing and identifying individual natural wave trains at two receiving stations, one in London and the other in Newcastle.* It was found that about 70 per cent. of the natural wave trains perceived at one station could be identified with those perceived at the other, and, further, that more than half of these were of much the same intensity at both stations—from which it may fairly be inferred that the distance of the discharge is great compared with the distance between the stations.†

The number of natural wave trains, or "strays" as they are commonly called for brevity, received at any station varies in general from hour to hour. In England these variations are most pronounced during the summer months, principally on account of the frequency of local lightning storms during these months. (The word local is here intended to mean within a

† In all that follows it is assumed that the sources of the wave trains are not extra-terrestrial.

7 to 30 amperes antenna heights 37 to 130 feet, wave lengths from 300 to 3750 meters, and distances up to 1000 nautical miles.

In regard to the value of the day absorption it is only possible to say that the above expression is satisfied within the limits of error of the observations. It is quite possible that when observations are made at distances of 2000 to 3000 miles, the value of the absorption coefficient will have to be corrected by 10 or even 20 per cent, as this amount of error could exist without discovery at the distances covered in these experiments. It is also possible that the square root law relating the absorption with the wave length is only an approximation.

U. S. Naval Wireless Telegraphic Laboratory,
Washington, February 1, 1911.

---

about 45°. This forms a system of eight conductors spaced symmetrically about the tower. These cages are approximately 4 feet in diameter and consist of four wires each, separated by a system of hoops. The cages are insulated at the bottom and electrically connected to the steel tower at its top, thus forming a type of umbrella antenna. The inductance of the complete antenna system amounts to 0.055 millihenry, and the capacity is 0.0073 microfarad. The closed circuit was inductively coupled to the antenna just loosely enough so that but one wave length[3] was radiated. The closed circuit condensers were of the well-known Fessenden compressed-air type, and for a wave length of 3750 meters the capacity was 0.18 microfarad. The spark gap was of the Fessenden synchronous rotary type with two fixed electrodes and a system of rotary electrodes mounted on the shaft of the generator. The generator was rated at 100 kilowatts at 500 cycles, thus producing 1000 sparks per second. It was not possible to run the generator at full power with the steam engine available at the time of the experiments, the actual power expended being 50 to 60 kilowatts.

The scout cruisers were provided with flat top antennas supported by steel masts surmounted by wooden topmasts. The antenna dimensions were: Length 116 feet, breadth 40 feet, number of longitudinal wires 14, cross wires 15. During the December test, the height above the water was approximately 112 feet, but this height was increased in the three later tests to 130 feet. The capacity was about 0.0018 microfarad and the inductance 0.038 millihenry. During the May experiments the capacity of the *Birmingham* was increased by two 70-foot cages forward and two 80-foot cages aft set at an angle of approximately 30° with the vertical. These cages were similar to those forming the umbrella of the Brant Rock tower. This increased the capacity to about 0.0025. In the midst of the July tests, cages were added to the *Salem* also, but the change resulted in no observable variation in the intensity of the signals, the increase in capacity being apparently counterbalanced by the decrease in effective height. The closed circuit was coupled to the antenna, so that but one wave length was radiated, and the closed circuit capacity was 0.036 microfarad at 3750 meters, and 0.018 microfarad at 1000 meters wave length. The motor generators were 500-cycle machines rated at 10 kilowatts, and the spark gap was of the same type as that used at Brant Rock but of smaller dimensions.

---

[3] Experience has shown that when the closed circuit is properly designed—that is, without undue waste of energy from brushing, etc.—the greatest range is obtained by a coupling loose enough to give but one wave length in the antenna.

JULY EXPERIMENTS

I_s. Sending antenna current in amperes.
I_R. Received antenna current through 25 ohms.
N. Night observations.
K. Received antenna current at 1 kilometer distance.
d. Distance in kilometers.
h. Height of flat top antenna.
α. Day absorption coefficient = 0.0015.
λ. Wave length.
H. Stat. Heavy static = atmospheric discharges preventing reception of signals.
Miles. Nautical mile = 1.85 kilometers.
For good communication. $I_R = 40 \times 10^{-6}$ amperes through 25 ohms = 4×10^{-8} watts.
For audible signals. $I_R = 10 \times 10^{-6}$ amperes through 25 ohms = 2.5×10^{-9} watts.

Preliminary experiments were begun early in July, the scout cruisers lying at anchor in the harbor at Provincetown, 22 miles from Brant Rock. The path of the waves between the ships and the shore station, except for a narrow strip of sand hills bounding Provincetown Harbor, lay entirely over water. Later, when the ships put to sea, it was found that this strip of land made no appreciable difference in the received signals. Careful measurements were made on the intensity of the received antenna current at Brant Rock for the two wave lengths 1 000 meters and 3 750 meters. This current was measured either by means of a hot-wire ammeter of 15 ohms resistance, provided with a mirror for mirror and scale readings,[4] or by a tellurium constantan thermo-element,[5] also of 15 ohms resistance. The hot wire ammeter gave a scale deflection of about 0.2 millimeter for 1 milliampere oscillatory current in the antenna and 9.4 millimeters for 10 milliamperes. One millimeter galvanometer deflection with the thermo-element was equivalent to 263 microamperes, and the deflections

---

heights of from 30 to 80 feet and wave lengths from approximately 1500 to 4000 meters.

(*c*) Taking account of the influence of antenna height and wave length equation (2) may be extended and a general day transmission formula written as follows

$$(3) \quad I_R = 4.25 \frac{I_s\, h_1\, h_2}{\lambda d} e^{-\frac{0.0015\, d}{\sqrt{\lambda}}}$$

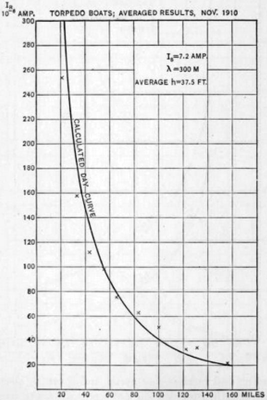

Fig. 28

where the currents are given in amperes and all lengths in kilometers.[19] This formula has been tested for sending currents from

---

[19] From this it would appear that it is advisable to rate stations according to the magnitude of the antenna current, or perhaps better, according to the product of the current into the height.

Variations also appear to occur during the daytime, but these are probably in general small.

(*b*) The received antenna currents between two stations with salt water between are proportional to the product of the heights[18] of the sending and receiving antennas and inversely proportional to the wave length, provided the antenna resistances remain constant. These experiments were carried on with flat-top antenna

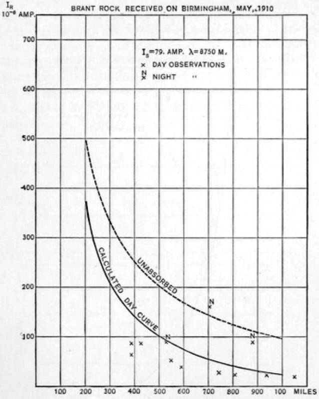

Fig. 27

---

[18] The experiments indicate that for the greatest efficiency of a flat-top antenna the vertical lead wires should be bunched so as to reduce their capacity as much as possible and concentrate the capacity at the greatest height.

---

were, as nearly as could be determined, directly proportional to the square of the oscillatory current. For the 1000-meter wave length a variable air condenser was placed in series with the Brant Rock antenna, and in this way it was possible to adjust the antenna resistance for both wave lengths to about 25 ohms. From a number of observations it was determined that the received current at Brant Rock for a wave length of 1000 meters was 10 500 microamperes for the *Birmingham*, with a sending antenna current of 33 amperes,[6] and 11 000 microamperes for the *Salem*, corresponding to a sending antenna current of 27 amperes. For a wave length of 3750 meters the received currents were 3200 microamperes for the *Birmingham* and 4100 microamperes for the *Salem*, corresponding to sending antenna currents of 27 and 24 amperes.

After the ships had attained distances too great to permit the reading of the received signals at Brant Rock by means of thermoelements, a chalcopyrite zinkite rectifier with galvanometer was employed whenever the atmospheric disturbances permitted. This was connected in a secondary circuit coupled to the antenna and calibrated by means of a thermoelement in the antenna and an exciting buzzer circuit which could be tuned to the wave length used.[7]

Throughout the experiments, both at Brant Rock and on shipboard, shunted telephone readings were taken on the incoming signals. The detectors used for the shunt readings were of the free wire electrolytic type and the head telephones connected in series were each of 600 ohms resistance,[8] the shunt being placed across one of these according to the Fessenden method. The circuits for the galvanometer and for the shunt readings at Brant Rock are shown in Fig. 1.

An extended comparison of antenna currents through circuit A and the shunt readings as taken in circuit B was made, and the

---

[6] It will be noticed that while the radiation current of the *Birmingham* is considerably greater than that of the *Salem*, the strength of received signal is slightly less. It is possible that the apparently greater radiation of the *Birmingham* was due to a deck insulator which gave trouble throughout the July test. It is not improbable, therefore, that the actual antenna current was not greater than that of the *Salem*. The mean of the readings of the two ships, 30 amperes at a wave length of 1000 meters, has been taken as a basis for calculation.

[7] See this Bulletin, **7**, p. 295.

[8] The inductive resistance of each telephone used in calculating the shunt ratio was 2000 ohms.

This is true in general for day transmission. The absorption at night is entirely irregular varying from zero to the day value,[17] but is on an average much less during the winter than in summer.

---

[17] The great variations in night absorption make useless all attempts to judge the quality of wireless apparatus from night distances. For this purpose only observations on the average day range have any value.

SUMMARY AND CONCLUSIONS

Quantitative measurements have been carried out in long distance wireless telegraphy up to 1000 miles for the purpose of determining the law of the variation of strength of signal with distance.

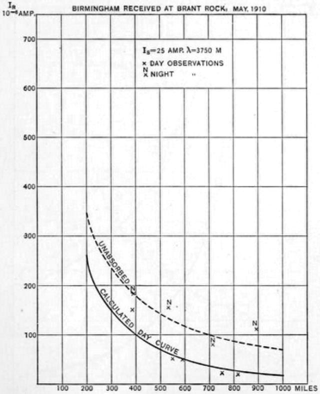

Fig. 25

Supplementary work was also done on the effect of height of antenna and wave length on sending and receiving.

The results are given briefly as follows:

(*a*) Over salt water the electrical waves decrease in intensity in proportion to the distance as found by Duddell and Taylor. In addition they are subject to an absorption which varies with the

---

results are shown in Table I. The table shows the amount of current in an antenna having a total resistance of 25 ohms which would correspond to the telephone shunt readings on a detector coupled to the antenna with the degree of coupling capable of drawing the maximum amount of energy into the detector.[9]

Shunt readings are very difficult to take even under the best circumstances. In a quiet laboratory it has been found possible to make them agree among themselves with average errors in the single observations not greater than 10 per cent. In a wireless station, with its varying degree of noise, especially if the station is on shipboard, the errors are much greater than this, amounting under ordinary circumstances with good operators to from 20 to 40 per cent; while in a stormy time, or when the atmospheric discharges are heavy, the observed strength of signal will often be only a small fraction of that which would have been observed under normal conditions. It is evident that most of these sources of error tend to decrease the observed value of the signal. Occasionally, however, a loose contact or a loose plug where plug resistance boxes are used, will produce abnormally high values. Then, too, the difference in ear sensitiveness of different operators produces variations in the record. For this reason it is necessary that a very large number of observations be taken to make the results of much value.

As the received currents given in the curves and tables are proportional to the square root of the loudness of signal, the percentage errors are of course smaller than the errors in taking the shunt readings.

The standard of audibility taken in this work is that strength of signal which permits a clear differentiation of the dots and dashes.

The *Birmingham* sailed from Provincetown early on the morning of July 14, taking a course nearly south until she had attained a distance of about 1200 miles from Brant Rock. The *Salem*

---

[9] The actual amount of current in the antenna for the same intensity of signal in the detector varies with the effective resistance, which in turn depends on the wave length and amount of tuning inductance. The energy in the detector, required to produce given signals is constant, however. This energy is what is actually measured in taking shunt readings, and for convenience of comparison its square root is put in terms of micro amperes through 25 ohms which was the resistance actually employed in the thermoelement readings at Brant Rock, and which is approximately the effective resistance of a properly coupled ship's antenna of moderate size at a wave length of 1000 meters.

curve as calculated from Table XVI for antenna heights of 37.5 feet, a sending current of 7.2 amperes, and a wave length of 300 meters. The agreement is remarkable, considering the fact that the table from which the theoretical curve was calculated was based on data derived from ships with 130-foot masts working at a wave length of 1000 meters and employing a spark frequency of 1000 per second. These results show, as has often been observed in our laboratory, how little the ratio of sending currents and received signals depends on the spark frequency, the telephones apparently never showing the added sensitiveness for high frequencies exhibited in the case of sinusoidal alternating currents.

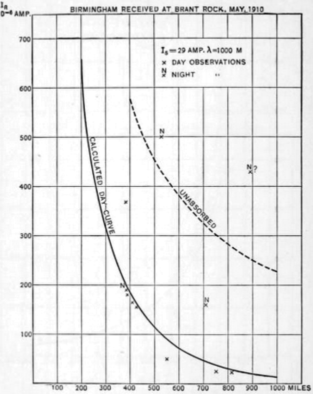

Fig. 24

mately 1.12. The telephones on both boats were of approximately the same sensitiveness and were of 2000 ohms resistance with an inductive resistance under working conditions of about 4000 ohms.

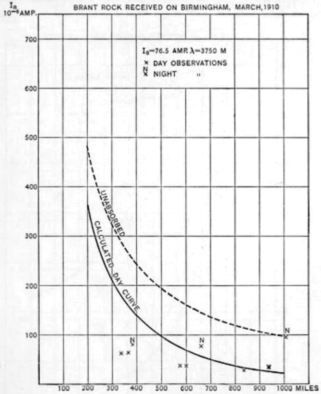

Fig. 23

The observations of these tests, shown in Table XVII, were taken with great care, the engines being stopped during the time of observation. Each one is the mean of a number of readings.

In the last column are given the received currents averaged for both boats corrected to a sending current of 7.2 amperes and to the readings of the electrolytic detector. In Fig. 28 is shown the

followed on the morning of July 15 and proceeded slowly to a point about 450 miles from Brant Rock. The courses of the two ships are shown in figure 2. Regular sending and receiving periods were observed at the three stations. At Brant Rock the signals were received as far as possible on the thermoelement and a few readings were taken with the rectifier, but while the preceding week had been almost completely free from atmospheric disturbances, unfortunately, soon after the ships sailed, strong disturbances set in which precluded the possibility of galvanometer measurements, so that for the rest of the experiments all the readings had to be taken by the shunted telephone method. On the ships no attempt was made to use deflection methods, although

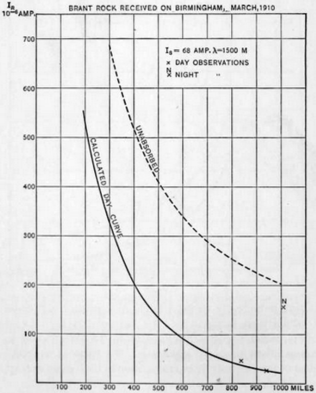

Fig. 22

The antenna of the *Stringham* consisted of four wires 2 feet apart, 135 feet long, and 48.5 feet above the water. Its capacity was 0.00134 microfarad. The closed circuit condenser was the same as that of the *Bailey*. The length of the *Stringham's* radiated wave was 340 meters. The receiving apparatus of both boats was of the latest inductively coupled type, and perikon detectors were used which were standardized by comparison with electrolytic detectors, which experiments have shown to have a constant sensitiveness when properly adjusted. The ratio of current sensitiveness of the electrolytic to the perikon in both cases was approxi-

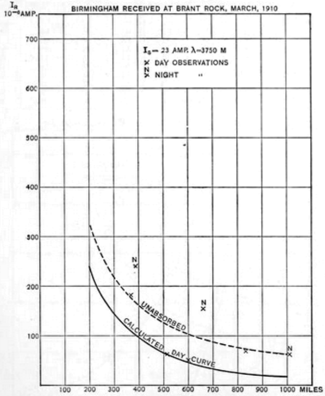

Fig. 21

---

it is possible that satisfactory measurements could have been taken by means of marine galvanometers. Tables II to VI contain the data of the experiments, the received signals being reduced to terms of current through 25 ohms antenna resistance.

* Telephone readings

Wherever possible the readings taken by the deflection method are used. During the experiments the atmospheric disturbances were heavy most of the time, especially at night and at the longer wave length. These frequently entirely prevented the reception of the signals as indicated by the blanks in the received current column. No table is given for Brant Rock received on the *Salem*, because during a great part of the time the signals were too strong for accurate shunt readings. No tables are given for the work between the two cruisers at a wave length of 3 750 meters, as their antennas seemed too small to work successfully at this wave length and only a few unsatisfactory shunt readings were obtained.

For determining the law of the decrease of the intensity of the signal with the distance a smooth curve was drawn through the observed day readings and points on this were taken as the

---

with small 120-cycle directly connected sending sets which, however, could be coupled loosely enough so that but one wave length was radiated. The flat-top antenna of the *Bailey* consisted of four wires 2 feet apart, 80 feet long, 32 feet above the water. The antenna capacity was 0.000875 microfarad; the closed circuit condenser consisted of Leyden jars in air having a capacity of 0.015 microfarad. The length of the wave radiated by the *Bailey* was 280 meters.

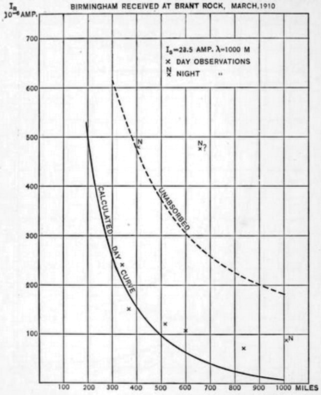

Fig. 20

of long range night communication must be considered exceptional so late in the year, though perhaps it would not be so considered in midwinter.

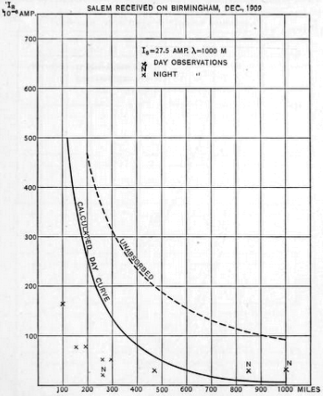

Fig. 19

TORPEDO-BOAT TESTS

In order to test the validity of equation (3) for very short wave lengths and small antennas, the torpedo boats *Stringham* and *Bailey* were detailed to carry out a series of tests in Chesapeake Bay during the month of November, 1910. The two boats were fitted

observed values for purposes of calculation. It was assumed from the results of Duddell and Taylor and Tissot that the received currents would be inversely proportional to the distance provided no absorption existed. The observed curve indicated that this was approximately true up to a point between 100 and 200 miles, but beyond this point the currents evidently dropped much more rapidly. The simplest assumption in regard to absorption is that it is proportional to the distance. Joining this to the Duddell and Taylor law we have as an expression for the received current

$$I_R = \frac{K}{d} e^{-Ad} \qquad (1)$$

where d is the distance, K the received current at unit distance, e the base of the natural logarithms, and A a constant. Dr. Louis Cohen of the National Electric Signaling Co., while testing the validity of this formula made the discovery that A was inversely proportional to the square root of the wave length within the limits of accuracy of the observations. Then, writing $A = \frac{\alpha}{\sqrt{\lambda}}$ the expression becomes

$$I_R = \frac{K}{d} e^{-\frac{\alpha d}{\sqrt{\lambda}}} \qquad (2)$$

α is the absorption coefficient and in these experiments equals 0.0015, the distance and wave length being expressed in kilometers.

Tables VII to XI contain a comparison of the calculated values with those taken from the smoothed observation curves. It is seen that the agreement is exceedingly good in the case of the signals between the *Birmingham* and the *Salem* and those of the *Salem* received at Brant Rock. In the case of the signals between Brant Rock and the *Birmingham*, however, the observed values fall somewhat below the calculated, from 300 to 600 miles. As the observed curve has the same form both for the signals received on the *Birmingham* and those received at Brant Rock the divergence is probably not accidental, and is probably due to a temporary increase of absorption accompanying a marked change in the weather at about this time. The effect is not observed in the *Salem* signals received at Brant Rock because the *Salem* at this time had not attained a great enough distance to make the absorption play an important part.

---

and the short wave at 1305 miles. Night signals from Brant Rock were first received at 2776 miles and were heard without interruption from that point on. Both waves from the *Birmingham* were received faintly in the daytime at Brant Rock at 2090 miles, and the long wave again at 1315 miles, no other day signals being received until the distance was reduced to 815 miles. Night signals were received by Brant Rock from the *Birmingham* first at 2418 miles and continued nightly for the rest of the voyage, though very irregular in intensity. This remarkable continuation

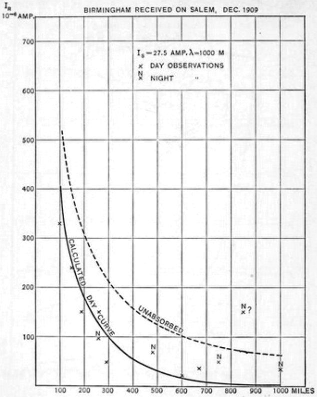

Fig. 18

errors of observation, or possibly to some kind of reflection from the upper atmosphere.[16] Beyond the range of the curves abnormal signals were again observed, faint day signals of the Brant Rock long wave being received on the *Birmingham* at 2330 miles,

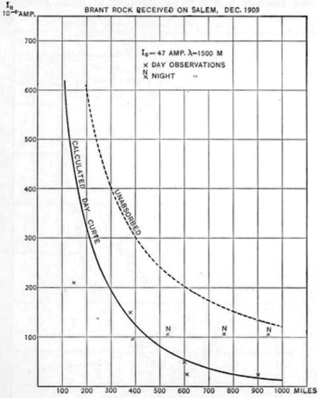

Fig. 17

---

[16] There can be no doubt that at times something of the nature of a reflection of signals from the upper atmosphere takes place. During the past winter the Norfolk station sending at a wave length of 1000 meters and with an antenna current of 10 or 12 amperes and antenna height below 200 feet was distinctly heard at night at the Mare Island Navy Yard in San Francisco, a distance of approximately 2000 nautical miles across the continent. Although it is possible that over sea water a clearing up of the atmospheric absorption would have explained this phenomenon, when we take into account the ground absorption which is probably independent of day and night and generally much greater than the atmospheric absorption, this explanation becomes untenable.

The curves of figures 3 to 10 give the results in graphic form. The dotted line gives the strength of signal which would have been received if the K/d law had obtained; that is, if there had been no absorption. The continuous curve gives the theoretical day values as calculated from equation 2, while the individual observations are represented by crosses. Observations taken by the deflection method are indicated by circles around the crosses, while night observations are accompanied by the letter N. It is seen that the day observations correspond approximately to the values of the calculated curve, but that the night signals are entirely irregular,

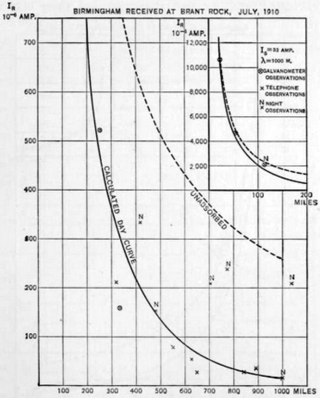

Fig. 3

Birmingham at 2550 miles, while on the same night both waves from the *Birmingham* were received at Brant Rock.

MAY EXPERIMENTS

During the month of May the *Birmingham* returned from Liberia to Hampton Roads, and the results of the telephone observations taken during this voyage are shown in figures 24 to 27.

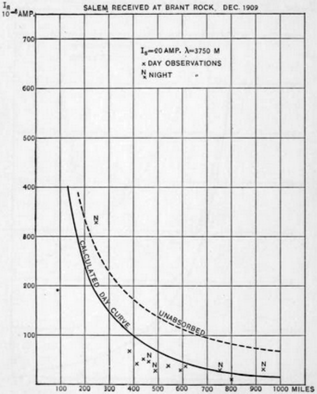

Fig. 16

Within the range covered by the curves the day observations are not as irregular as during the March voyage, although, as was also the case in March, some of the night observations lie above the curve calculated for zero absorption. As has already been said in describing the July experiments, these may be due to

In some of the curves it is seen that the observations are exceedingly irregular, the day signals showing as much variation as the night signals during the July tests. In addition to the observations shown on the curves, faint day signals from the *Birmingham* were received at Brant Rock at a distance of 1325 miles, and again at 1720 miles, while the Brant Rock short wave was received faintly on the *Birmingham* at 1325 miles. All of these observations are beyond the range of calculated day audibility and show that there was an abnormally low absorption on these days.

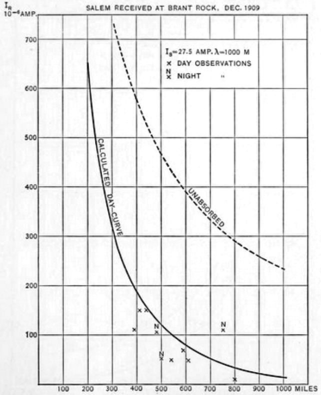

Fig. 15

Night signals during this voyage were also heard at times at great distances, the Brant Rock short wave being received on the

---

being in general stronger than the day signals, as was first observed by Marconi. Sometimes they lie close to the K/d curve, indicating that the absorption has disappeared, while at others they are practically of the same strength as the day readings. In a very few cases, night signals were observed considerably stronger than the calculated value for zero absorption, but these may very probably be due to errors of observation, since it is not observed that the remarkable strength of signal is reciprocal between the two stations. If the observations are genuine, however, it would perhaps indicate some kind of reflection from the upper layers of the atmosphere.

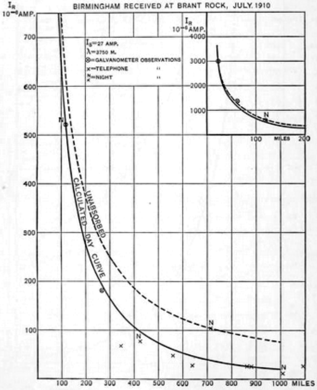

Fig. 4

THE CAUSE OF THE ABSORPTION

According to the calculations of Zenneck,[10] the conductivity of air at moderate heights can not explain the magnitude of the observed absorption, neither can the sea-water absorption be of the proper magnitude, according to the same author. But as the wave front at any considerable distance from the sending station must extend far into the upper layers of the atmosphere, it does not seem improbable that this is the region of absorption. If

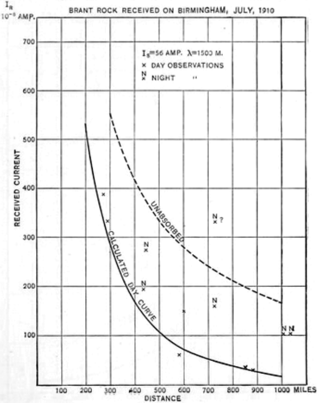

Fig. 5

---

[10] Zenneck, Ann. d. Phys., 23, p. 846; 1907.

The arrangement of the apparatus on the cruisers was highly unsatisfactory, largely on account of lack of space. In addition to this the weather was extremely tempestuous much of the time. In the light of all this, it is not surprising that the observed received currents fell below the calculated values.

The results are shown in the curves of Figs. 12 to 19.[15]

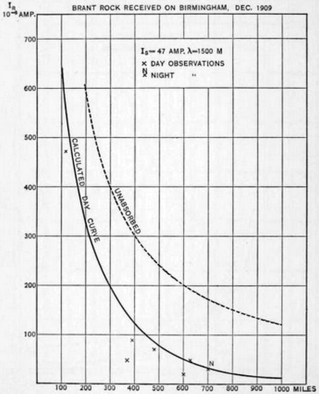

Fig. 14

MARCH EXPERIMENTS

In March the *Birmingham* was sent to Liberia, and during the voyage current measurements were made on the ship and at Brant Rock. The results are shown in Figs. 20 to 23.

---

[15] Neither of the cruisers was able to take any satisfactory measurements on the 3750-meter wave.

all this into account, the results of these earlier tests can not by any means be considered to have the same weight as those in July. But as it is desirable to obtain all the light possible on the validity of the transmission formula, the following observations are given.

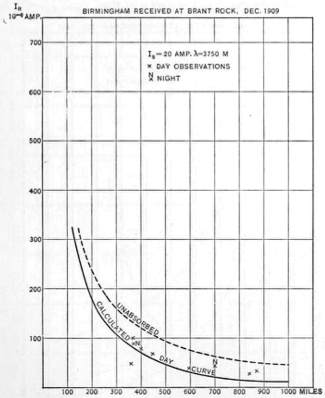

Fig. 13

DECEMBER EXPERIMENTS

The December experiments were made shortly after the installation of the sets on the cruisers, the *Birmingham* taking an easterly course from Provincetown, while the *Salem* sailed to the southward. At the greatest distance attained the two ships were distant from each other and from Brant Rock approximately 1000 miles.

---

the conductivity is increased by the sun's rays at these heights, this would also explain the differences in the strength of the day and night signals. The observations would indicate, if this explanation is true, that the excessive ionization may, especially in summer, persist through many nights. The general experience of wireless telegraphy would indicate that during the colder months the absorption dies out more uniformly at night. The day absorption appears from the data obtainable to be fairly uniform

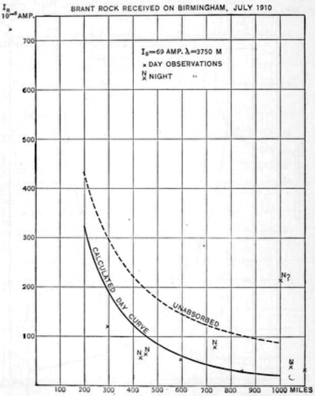

Fig. 6

throughout the year, at least in the portion of the ocean covered by our observations, although there are undoubtedly variations at times, as has been already mentioned in regard to the *Birmingham*-Brant Rock signals. There are well-authenticated instances when, for a day or two, the absorption seems to nearly disappear in the daytime. A case in point is that of the long-distance day signals between the *Birmingham* and Brant Rock on the return voyage from Liberia mentioned on page 351.

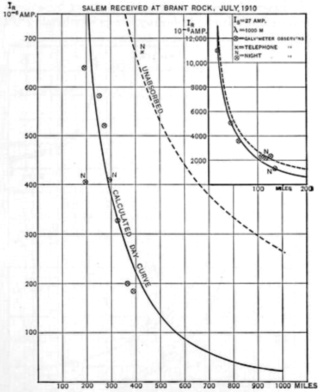

Fig. 7

OTHER LONG-DISTANCE WORK

In all of the experiments with the cruisers excepting those carried on during the month of July the calculated received currents at unit distance were estimated from the ratio of the sending currents to those observed at the corresponding stations in July, account of course being also taken of the change in antenna heights on the cruisers from 112 feet to 130 feet after the close of the December tests. This calculation is somewhat arbitrary, since there were many changes in the arrangement of the apparatus which very probably had an influence on the efficiency of the sets. Taking

SUPPLEMENTARY MEASUREMENTS

PROPORTIONALITY OF SENDING AND RECEIVING CURRENTS

It was thought possible that when the antennas were used with the highest power, especially at the longer wave lengths, there might be losses of energy, either by brushing or by leakage over the insulators, which might destroy the proportionality between

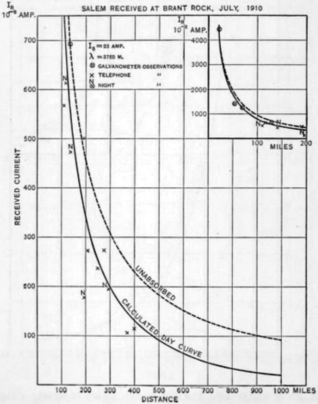

Fig. 8

sending antenna current and received antenna current. To settle this question, the station at Brant Rock sent with varying powers at a wave length of 3750 meters. The signals were received on the antenna at the Bureau of Standards at Washington, D. C., 380 miles away. The receiving antenna was of the harp form, 180 feet high at top, 40 feet high at bottom, and 18 feet wide, with 8 wires. The capacity was approximately 0.0012 microfarad. A chalcopyrite zinkite rectifier, with a sensitive galvanometer, was connected in a tuned secondary circuit coupled to the antenna inductance so as to give maximum deflection, the circuits being those shown under circuit A in Fig. 1. The results are shown in the curve of Fig. 11. The galvanometer deflections are proportional to the square of the current, hence the square roots of the deflections expressed in microamperes of received antenna current are compared with the sending antenna current at Brant Rock.

currents and four wave lengths. The table shows the great advantage of long wave lengths for very distant stations. It is seen that for good communication at a distance of 2500 miles not less than 240 amperes[13] must be used at a wave length of 6000 meters, though one-fourth of this would be audible.

For the purpose of easily calculating the probable day working distance for various sending currents, heights, and wave lengths according to equation (3) Tables XVI and XVI-A are given. Table XVI gives the current which may be expected to be received through 25 ohms for an antenna height at both stations of 130 feet and a sending antenna current of 30 amperes. Table XVI-A gives the sending currents which will be required for various heights of the sending and receiving antennas h_1 and h_2 to give the values of the received currents as shown in Table XVI. To determine the current which will be received for any antenna height, wave length, and distance for a given sending current, multiply the value, given in Table XVI for the given distance and wave length, by the given current, divided by the value of I_s in Table XVI-A for the given antenna heights.[14] In Table XVI it may be assumed that 40×10^{-6} ampere insures good communication and that 10×10^{-6} ampere is just audible.

---

[13] From the experience of the Marconi transatlantic stations it would appear possible that for the same antenna current the distances given in the table could be obtained with a smaller antenna height provided a bent antenna were used.

[14] Example: If $h_1=200$ feet, $h_2=130$ feet, $\lambda=600$ meters, distance=500 miles, and $I_S=12$ amperes, then $I_R=60.2 \times 12/19.5=37.0 \times 10^{-6}$ ampere. The above tables have been given in this convenient form for calculation largely with the hope that they will be tested by the experience of the various wireless companies. It is very common in wireless stations to have an antenna meter for the measurement of the sending current. When this is used with a shunt, the multiplying value of the shunt for the given frequency may easily be obtained by connecting a like unshunted hot-wire meter in the antenna in series with the regular instrument and sending with reduced power so that the needle of the unshunted meter just remains on the scale. The ratio of the readings of the two meters then gives the multiplying value. When only one meter is available an approximate calibration may be obtained by sending with reduced power and observing the reading of the meter without the shunt and then with the shunt connected. Of course this calibration must be carried out with the same wave length used in regular work. The range of good daylight communication with another flat-top antenna of known height over sea water can be compared with the values in the table for the given wave length, distance, and sending current, provided the sending station radiates but a single wave length. If the equation is correct, the tables should indicate a current of from 20 to 40 microamperes.

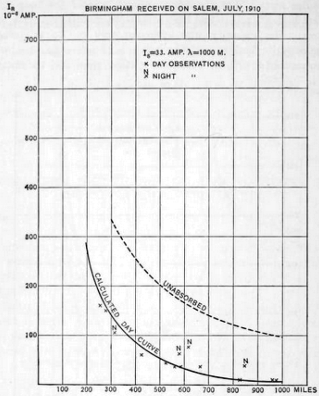

Fig. 10

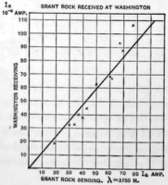

Fig. 11

The proportionality is fairly good. It is possible that in the changes of adjustment of the circuits at Brant Rock the tuning became somewhat deranged, or that the change of the coupling at Brant Rock produced a change in the damping of the waves, which was not compensated for by a change in the coupling at Washington. A few observations were taken at Brant Rock on signals sent from the *Birmingham* when coming into Newport, R. I., both at wave lengths of 1000 meters and 3750 meters. From these it was concluded that there was no marked overloading of the sending antenna, although there were slight indications in this direction at the wave length of 3750 meters.

THE EFFECT OF ANTENNA HEIGHT AND WAVE LENGTH IN SENDING AND RECEIVING

At the close of the test with the scout cruisers, a flat top antenna was erected at Plymouth, 11 miles from Brant Rock, for the purpose of investigating the relationship of height of antenna and wave length to sending and receiving. Except for a narrow sand spit the whole path of the waves between the two stations lay over water. The antenna was swung between two noninsulated steel masts in order to reproduce as fully as possible the conditions on board ship. The Plymouth antenna had a length of 110 feet and consisted of 11 wires 2 feet apart. The capacity was approximately 0.001 microfarad. The Plymouth station was furnished with a 2-kilowatt, 500-cycle Fessenden sending set, and a somewhat larger 500-cycle set used at Brant Rock. The currents were measured at both stations by means of 15-ohm thermoelements with galvanometers as described on page 317. The experiments were begun by my assistants, but were completed by Dr. Cohen of the National Electric Signalling Co.

SENDING

Table XII gives the results of observations taken by Dr. Cohen and his assistants, Plymouth being the sending station and Brant Rock the receiving. This table is for the most part self-explanatory. The deflections of the galvanometer connected to the thermoelement are proportional to the square of the current, so that the square roots of these deflections are taken as proportional to the current itself. The deflections are in arbitrary units. For

much as 30 per cent under ordinary conditions. This difference in the value of the constant does not, however, make a very great difference in the range of communication, although for short distances it would make a considerable difference in the loudness of signal. To show the variation in range of communication with different antenna currents, Table XIV is given, showing the range of communication between two flat top antennas 130 feet high at a wave length of 1000 meters for various values of the sending antenna current, assuming that 40×10^{-6} ampere assures good communication. A quarter of the indicated current would produce audible signals under favorable conditions. The table shows how very slowly the range increases with increasing sending current. Increasing the current from 30 to 60 amperes increases the distance only from 565 miles to about 725 miles, while even with 10 amperes, corresponding to a moderately efficient 2-kilowatt set, 345 miles is easily reached.

In columns 3 and 5 are given the distances attainable for regular communication and audibility on the assumption that there is no atmospheric absorption; that is, the extreme range of night communication.[12]

TABLE XV

Good Working Distance and Sending Current for Two Stations with Flat Top Antennas 450 Feet High

Nautical Miles	$\lambda=1000$ m	$\lambda=2500$ m	$\lambda=3750$ m	$\lambda=6000$ m
1000	15 amp.	13.5 amp.	15 amp.	17 amp.
1250	38	27	27	30
1500	91	49	44	46
1750	200	95	77	74
2000	490	155	122	105
2250		245	200	160
2500		470	314	235
2750			500	335
3000			775	500

In Table XV is given the estimated day range of two large stations with flat-top antennas 450 feet high for various antenna

---

[12] Excluding the possibility of the effects of reflection from the upper atmosphere.

We may write this equation as follows:

$$I_R = 4.25 \frac{I_s h_1 h_2}{\lambda d} e^{-\frac{\alpha d}{\sqrt{\lambda}}} \qquad (3)$$

where I_R represents the current received through 25 ohms resistance, I_s the sending current, h_1 the height of one antenna, h_2 that of the other, d, the distance between the stations, and λ the wave length, where all the lengths are taken in kilometers and the currents in amperes. α is the absorption coefficient, which in our experiments was found to be equal to 0.0015. This disregarding the absorption term $e^{-\frac{\alpha d}{\sqrt{\lambda}}}$, corresponds in form to the Herzian equation for the electromotive force in a vertical resonator at a distance from the oscillator.

TABLE XIV

Calculated Relation between Antenna Current and Distance for Two Ships with Antenna Heights of 130 Feet

$\lambda=1000$ m

Antenna Current I_S	Working Distance 40.10^{-6} amp.		Extreme Distance of Audibility 10.10^{-6} amp.	
	Day	Night (Zero Absorption)	Day	Night (Zero Absorption)
1 amp.	75 miles	90 miles	200 miles	360 miles
2	135	180	300	720
3	180	270	375	1080
5	235	450	475	1800
7	280	630	550	2520
10	345	900	630	3600
15	420	1350	725	5400
20	475	1800	790	7200
25	525	2250	840	9000
30	565	2700	900	10800
40	630	3600	970	14400
50	685	4500	1025	18000
60	725	5400	1150	21600

In our formula the constant 4.25 applies strictly only to ship antennas with the same losses due to masts, rigging, etc., both in sending and receiving, as found on the scout cruisers. On other ships the value of the constant might probably differ by as

---

comparison, the square roots of the deflections were reduced to a uniform sending antenna current. These values are given under I_R in the next to the last column, while the last column gives this quantity divided by the height. Although there is considerable

TABLE XII

Plymouth Received at Brant Rock

$\lambda=3900$ m

Antenna Plymouth h	I_S	Deflection Receiving D	$I_R = \sqrt{D}$ reduced to $I_S=4.7$ amp.	$\frac{I_R}{h}$

2400	4.75	13.6	3.26	7830
1985	5.1	26.3	4.22	8400

Shorter wave lengths were not used on account of the long natural wave length of the Brant Rock station.

variation in the values of this column it is evident that there is no systematic variation, and for the individual wave lengths we must consider that the received current is proportional to the height of the sending flat-top antenna. The receiving antenna was tuned by means of a variable inductance in series with the thermoelement.

In the last section of Table XII the results show the variation with wave length, and in this case the equivalent received current is multiplied by the wave length and the product is seen to be approximately constant. Thirty-five ohms was introduced into the receiving antenna to nullify the changes in the resistance of the inductance during the process of tuning. This table shows that the received antenna current is proportional to the height of the sending attenna and inversely proportional to the wave length.

RECEIVING

Table XIII gives similar data in regard to the Plymouth antenna used for receiving, the sending station being Brant Rock. This table shows that the same relationship holds for receiving as for sending; that is, for a constant sending antenna height and current the received current is proportional to the height of the receiving antenna and inversely proportional to the wave length.[11]

While it appears that the sending and receiving relations for a flat-top antenna are reciprocal, this is apparently not the case for an umbrella antenna. It is seen from the observations that the scout cruisers, sending with 10 kilowatts, were received at Brant Rock with almost the same strength as that with which Brant Rock, sending with 60 kilowatts, was received on the cruisers. Comparing the strength of the sending and receiving currents, it appears that the umbrella antenna at Brant Rock for sending is only equivalent to a flat-top antenna 170 feet high, which is not far from the height of the lower ends of the umbrella, while for receiving its equivalent height is much greater. A few experiments have also been made on an umbrella and flat top at Plymouth, which also showed that an umbrella is a better receiver than radiator.

---

[11] This will not strictly hold in the case where the radiation resistance of the receiving antenna is comparable with the rest of the antenna resistance. See R. Ruedenberg, Ann. d. Phys., 25, p. 446; 1908.

TABLE XIII

Brant Rock Received at Plymouth

$\lambda = 4000$ m

Antenna Plymouth h	I_S	Deflection Receiving D	$I_R = \sqrt{D}$ reduced to $I_S = 7.0$ amp.	$\frac{I_R}{h}$
80 ft.	7.0 amp.	8.4	2.90	0 0362
70	10.0	12.4	2.46	.0352
60	9.4	8.0	2.10	.0350
50	9.75	6.0	1.76	.0352

$\lambda = 1980$

h	I_S	D	I_R ($I_S = 7.4$ amp.)	$\frac{I_R}{h}$
80 ft.	7.4 amp.	26.0	5.1	0.0637
70	7.6	24.0	4.77	.0682
60	11.1	41.1	4.28	.0713
50	10.9	22.6	3.22	.0644
40	10.4	15.5	2.80	.0700

h = 70 ft.
35 ohms added in receiving antenna

λ	I_S	D	I_R ($I_S = 10$ amp.)	$I_R \times \lambda$
4000 m	10.0 amp.	4.3	2.07	8300
3550	9.1	4.8	2.41	8560
2980	8.6	6.0	2.85	8500
2510	9.9	12.9	3.63	9110
1984	7.6	10.0	4.16	8240

Uniting the experimental data contained in the last two tables with the data obtained from the experiments with the cruisers, we may write an equation which will cover the normal day received current over salt water through 25 ohms for two stations with flat-top antennas of any height, with any value of sending current and any wave length, provided the sending station is so coupled as to give but one wave length.

NOTES:

INTRODUCTION

This handbook explores radio in general and crystal radio from the standpoint of RF Resonance. I again begin things with a brief walk down memory lane with an introduction to the subject of resonance and coupled circuits by Dr Hoag written in 1942. This represents an early, but already well-developed notion on the theory and application of resonance to radio apparatus.

The next few articles explore general theory concerning resonance with a strong emphasis on the mathematical base in order to help the reader better apply these concepts in theory own work, especially with respect to setting up excel spreadsheets. Note that while I like the pretty plots from SPICE simulations, I see this as a black box because authors almost never present the equations that make the plots possible, they are canned inside the program, bad form. I feel that, if I can plot it myself, I must be understanding it pretty well.

Then included are general discussion articles on resonance and coupled circuits. Most crystal radios of any pretentions to good performance will be coupled with separate antenna tuning. These articles should help explore this aspect of your radio!

I finally follow with an article on impedance matching and resonance as these are closely-related and need to be thought of together when designing, or at least understanding your radio.

Of general note, the web is a marvelous source of data and information. Many long-time crystal set builders, and many others have created dedicated sites to disseminate information and resources, to share their creations and knowledge. I am eternally in your debt. All of the material in this handbook is copyright for which I have not sought permission. Therefore this is not presented for publication or copy. It is only my personal resource. I encourage anyone finding this copy to pursue ON THE WEB the web pages identified within. I include the name of the author and web address of each section. I wish to sincerely thank every author presented for their excellent pages and ask forgiveness for my editing into this handbook.

NOTES:

as shown in Fig. 24*b*. It will be noted that the use of link coupling has the effect of reducing the equivalent primary and secondary inductance, and hence of raising the resonant frequencies. In other respects, the use of link coupling gives the same behavior as obtainable from ordinary inductive coupling.

6. Coupled Circuits with Resonant Primary and Secondary Tuned to Slightly Different Frequencies.—When two circuits resonant at slightly different frequencies are coupled together, the behavior depends upon the coefficient of coupling and the relative and absolute circuit Q's. When $Q_p = Q_s$, the response curve of secondary current (or voltage) has a shape of the same type as would be obtained if the two circuits were both resonant at the same frequency and coupled with an increased coefficient of coupling. In other words, the effect of detuning the circuits for the case of equal Q's is equivalent, as far as shape is concerned, to increasing the effective coupling. The only difference is that detuning causes the absolute magnitude of the response curve to be less than when the same shape is obtained without detuning.

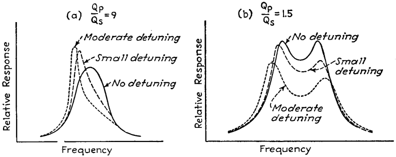

FIG. 25.—Curves illustrating the effect produced on the shape of the response curve by detuning primary and secondary circuits when the primary and secondary circuits do not have identical Q's.

Analysis shows that when $Q_p = Q_s$ the shape with detuning is as though the circuits were both tuned to the same frequency and coupled by an amount[1]

$$\left.\begin{array}{r}\text{Equivalent coupling}\\ \text{corresponding to}\\ \text{detuned operation}\end{array}\right\} = \sqrt{k^2 + \left(\frac{\Delta}{f_0}\right)^2} \qquad (43)$$

where k = actual coefficient of coupling.
Δ = difference between resonant frequency of primary and secondary circuits.
f_0 = frequency midway between primary and secondary resonant frequencies.

In the more general case where the circuit Q's are not the same, the secondary response curve is no longer symmetrical about the mean frequency, as shown in Fig. 25. In cases where unsymmetrical peaks are obtained, the low-frequency peak will be depressed when the secondary is tuned to a higher frequency than the primary and the secondary Q is higher, or when the secondary is tuned to a lower frequency and the secondary Q is the lower. Otherwise the high frequency peak will be depressed.

Detuning produces much more effect upon the shape of the primary current curve than upon the secondary response, and if the detuning is at all large the primary

circuit, as shown in Fig. 17. In many cases where coupled resonant circuits are employed, the excitation of the primary circuit is obtained by applying the voltage in parallel with the primary circuit through a resistance, as shown in Fig. 23*a*. This arrangement can be termed *parallel excitation*, and corresponds to the case when the coupled circuits are excited from a vacuum tube.

FIG. 23.—Actual and equivalent circuits for the case of parallel excitation of two coupled circuits.

The parallel excited circuit of Fig. 23*a* can be reduced by Thévenin's theorem to the equivalent arrangement shown in Fig. 23*b*. This is accomplished by considering that the portion of the circuit to the left of the dotted line is the equivalent generator circuit supplying the remainder of the circuit. The principal effect of parallel excitation is to introduce an added resistance in series with the primary circuit that becomes greater the lower the series resistance R used in the parallel feed. The equivalent series voltage also varies somewhat with frequency, but in a limited range, such as the region in which the resonance phenomena occur, can be considered as being substantially constant.

CHAPTER 6

RESONANT CIRCUITS

6.1 Series Resonance. When two bodies, or two currents, or two voltages, oscillate at the same frequency they are said to be in resonance.

A series *LCR* circuit can be built which resonates to a generator of given frequency. Then the current which flows through the circuit will have its greatest effective value. This is accomplished by choosing the inductive and capacitive reactances equal to each other. From the equations for the reactances, it is easily proven that the resonant frequency is given by

$$\boxed{f_r = \frac{1}{2\pi\sqrt{LC}} \times 10^9}$$

where f_r is in cycles per second, $2\pi = 6.28$, $10^6 = 1$ million, L is the inductance in microhenries (μh), and C is the capacitance in micromicrofarads ($\mu\mu$f). This is one of the most important equations in radio. Note that the resistance of the circuit does not appear in the equation. At resonance, the only opposition to the flow of the current is that due to the resistance, i.e., $I_r = E/R$ and not $I = E/Z$.

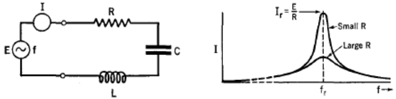

FIG. 6 A. A series circuit and its resonance curve

The current in the "tuned" or resonant series circuit is indicated at the peak of the "resonance" curve of Fig. 6 A. Note that if the total resistance of the circuit is large, the curve is broader and flatter, and vice versa.

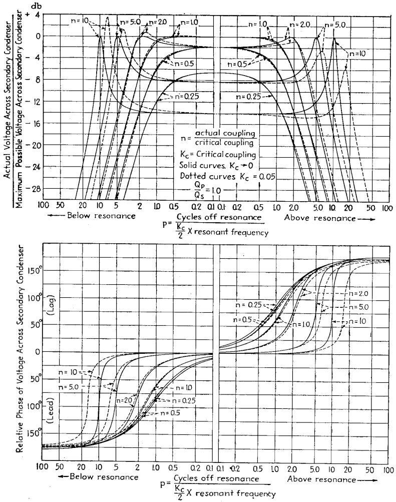

FIG. 22a.—Universal curves giving the phase and relative magnitude of the voltage across the secondary condenser for the case of two coupled circuits resonant at the same frequency and having a Q ratio of unity.

many cycles as do the peaks, this can be readily obtained by neglecting the circuit resistance and using Eq. (34).

When $Q_p = Q_s$, the value of E_c/E approximates the maximum possible response that can be obtained, as given by Eq. (38). On the other hand, when $Q_p \neq Q_s$, the peaks always have a height less than the maximum possible response in the secondary.

The ratio of the mean of the responses at the two peaks to the response at resonance is plotted in Fig. 21 for a number of Q ratios.

Universal Response Curves.—Equations (33) and (38) can be combined to give

$$\frac{\left\{\begin{matrix}\text{Actual voltage across}\\ \text{secondary condenser}\end{matrix}\right\}}{\left\{\begin{matrix}\text{Maximum possible volt-}\\ \text{age across secondary}\\ \text{condenser with}\\ \text{optimum coupling}\end{matrix}\right\}} = \frac{2n}{\left(1+\frac{pk_c}{2}\right)^2\left[(n^2+1)-(mp)^2+j(mp)\left(\sqrt{\frac{Q_p}{Q_s}}+\sqrt{\frac{Q_s}{Q_p}}\right)\right]} \tag{42a}$$

where $n = \dfrac{k}{k_c} = \dfrac{\text{actual coefficient of coupling}}{\text{critical coefficient of coupling}}$.

$$p = \frac{\text{cycles off resonance}}{\left(\frac{k_c}{2}\right) \times \text{resonant frequency}}.$$

$$m = \frac{1+\frac{pk_c}{4}}{\left(1+\frac{pk_c}{2}\right)^2}.$$

Universal curves based on Eq. (42*a*) are given in Figs. 22*a* and 22*b* for $k_c = 0$, and $k_c = 0.05$. These curves, especially when considered in conjunction with Figs. 18, 19, and 21, provide a complete and accurate picture of the response that can be expected when two resonance circuits are tuned to the same frequency and coupled together.

Figure 22 shows that when both primary and secondary circuits have the same Q, the response curve separates into double peaks whenever the coefficient of coupling exceeds the critical value, and these peaks maintain a substantially constant height irrespective of their location. On the other hand, when the two circuits have different Q's, then if the coupling exceeds the critical value by only a small amount, the response curve still has a single peak, but with reduced response at resonance. Double humps do not occur until the coupling exceeds the critical value by an amount that depends upon the ratio Q_p/Q_s, and the peaks become slightly lower as the coupling increases.

Practical Calculation of Coupled Systems Involving Two Resonant Circuits Tuned to the Same Frequency.—When it is desired to obtain the response curve of a given system, the relative shape of the curve of voltage developed across the secondary condenser can be determined with an accuracy sufficient for all ordinary purposes by the use of the universal curves of Fig. 22, interpolating between these in accordance with the Q ratio involved. The absolute magnitude of the curve can then be obtained by calculating the response at the resonant frequency with the aid of Eq. (35).

An alternative procedure for the case where the curve shows two peaks is to calculate the response at resonance by Eq. (35), determine the location and height of the peaks by Figs. 19 and 21, or Eqs. (40) and (42), and then to note that the response beyond the peaks falls to the response at resonance when the frequency is $\sqrt{2}$ times as far from resonance as the coupling peaks. This information is sufficient to define the shape of the double peaked curve in the vicinity of resonance. If quantitative information is desired at frequencies differing from resonance by at least twice as

---

6.2 Parallel Resonant Circuits. Fig. 6 B shows a parallel circuit and its impedance curves. The curves are of the same shape as the current curves of a series circuit. Note that the impedance across the terminals of a parallel circuit is a maximum at resonance,[1] whereas it is a minimum for the series circuit. The current in the *LCR* circuit itself is often very large at resonance and can cause considerable heating.

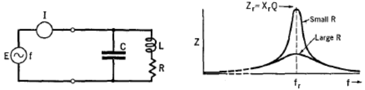

Fig. 6 B. A parallel circuit and its impedance curve

The impedance of a parallel circuit at resonance is given by

$$Z_r = \frac{(2\pi f_r L)^2}{R} = (2\pi f_r L)Q = X_r Q = \frac{L}{RC}$$

if all the resistance is in the coil (which is very nearly true in practice). The meaning of Q is given in Section 6.4. The resonant frequency f_r is given by the same equation as for a series circuit provided R is small in comparison with X. This is often true in radio frequency circuits.

6.3 Selectivity. The sharpness of the resonance curves is greater when the resistances are smaller. Sharpness of tuning is also called "selectivity." It shows the ability of the circuit to discriminate between voltages of different frequencies.

6.4 Q of a Circuit. As current surges back and forth in a resonant circuit, the electrical energy is alternately shifted back and forth between the magnetic field of the coil and the electric field of the condenser, losing a certain proportion of the total into the resistance at each alternation. In order to maintain oscillations, the generator must supply a small amount of energy each cycle. This is analogous to the small push we give to a swing; only a little push is needed at the end of each swing to keep it going. Electrically, the interest lies in the comparison between the total energy in the circuit to that which is dissipated (and must be re-supplied by the generator). This ratio is called the "Q" (quality) of the circuit. In practice, nearly all of a circuit's resistance is in the coil. It may then be shown that

---

[1] There are really three different ways of defining resonance in the case of a parallel circuit, but, if the resistance is low, the resonant frequency in all three cases is practically identical.

$$\boxed{Q = \frac{2\pi fL}{R} = \frac{X_L}{R}}$$

Practical radio frequency coils have Q's from 50 to 200 and occasionally 500. Audio frequency coils range from 1 to 10 and occasionally are as low as 1/2. The higher the Q, the better.

The rate at which current dies down in a resonant circuit, after the source has been disconnected, is called the damping of the circuit, whose measure is called " the decrement " δ. $Q = \pi/\delta$. A high Q circuit is lightly damped, has a small decrement, a sharp resonance peak, and a high selectivity.

6.5 The L to C Ratio. In order that a circuit shall resonate to a given frequency f_r, the product LC must have a definite value given by $LC = 1/(2\pi f_r)^2$. This does not tell us, however, whether the product shall be made up of a large L and a small C or vice versa. Within limits, an increase in the number of turns of wire in a coil increases its reactance faster than its resistance. Hence, for circuits alone, or for those connected to high load resistances, such as a vacuum tube, the coils should be made with a relatively large inductance, i.e., the L/C ratio should be large.

FIG. 6 C. If R is small, the LC circuit will be heavily loaded and will have a low Q. Making the ratio L/C small helps to keep Q large

When the load on a resonant circuit (R in Fig. 6 C) is small, say only a few thousand ohms, as in transmitters and induction heaters, a majority of the energy loss takes place in the load. The coil's resistance plays only a negligible role. In this case, it can be shown that L should be comparatively small and C large if Q is to be satisfactorily high.

6.6 Resonant Voltages. At resonance, the voltage across the inductance is numerically equal to that across the condenser, although they are always of opposite polarity. This voltage, at resonance, is equal to Q times the voltage in series with the circuit. The condenser must be built with an insulator which will not be punctured by this voltage.

6.7 Crystal Resonators. A properly cut and ground piece of quartz, located between two metal plates and placed in series with a high frequency generator, has a natural vibrational period dependent largely upon its thickness. It is equivalent to a series resonant circuit of very high Q.

Furthermore, in the very common case when the coefficient of coupling is small, Eq. (41a) becomes

$$\frac{\text{Frequency at peak of secondary voltage}}{\text{Resonant frequency of tuned circuits}} = 1 \pm \frac{k}{2} \qquad (41b)$$

In practical work, one is commonly interested in the frequency band over which the response in the secondary circuit equals or exceeds the response at resonance. This band is illustrated schematically in Fig. 20, and can be shown to be equal to $\sqrt{2}$ times the width of the frequency band between coupling peaks.[1]

The height of the peaks of response in the secondary circuit can be obtained by substituting the value of γ_p from Eq. (40) into Eq. (33). This gives

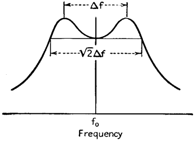

FIG. 20.—Relationship between band width, and width between secondary peaks existing when two circuits resonant at the same frequency are coupled together.

Value of $\frac{E_c}{E}$ at peaks

$$= \frac{1}{\gamma_p^2}\sqrt{\frac{L_s}{L_p}}\frac{\sqrt{Q_pQ_s}}{\left[\sqrt{\frac{Q_p}{Q_s}} + \sqrt{\frac{Q_s}{Q_p}}\right]\left[1 - \frac{k_c^2}{4k^2}\left(\sqrt{\frac{Q_s}{Q_p}} - \sqrt{\frac{Q_p}{Q_s}}\right)^2\right]^{1/2}} \qquad (42)$$

It will be noted that the lower frequency peak is the highest peak. However, since γ_p differs only slightly from unity in ordinary cases, it is customary to consider that the peaks are identical.

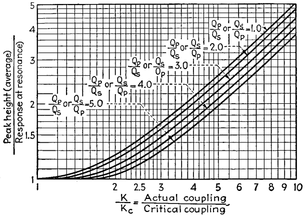

FIG. 21.—Universal curves giving the ratio of actual peak height to the response at resonance as a function of the coefficient of coupling for two coupled circuits resonant at the same frequency.

---

[1] See Aiken, *loc. cit.*

is given in Fig. 19 for various conditions, in terms of a parameter *g* given by the lower part of Fig. 19.

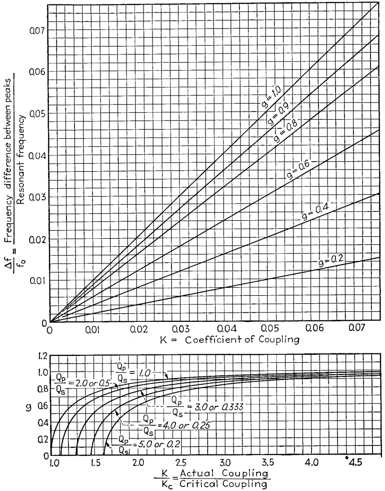

FIG. 19.—Curves from which the separation between peaks can be determined for the case of two coupled circuits resonant at the same frequency.

When the circuit *Q*'s are not too unequal, and the coefficient of coupling greatly exceeds the critical value, Eq. (40) reduces to

$$\frac{\text{Frequency at peak of secondary voltage}}{\text{Resonant frequency of tuned circuits}} = \frac{1}{\sqrt{1 \pm k}} \qquad (41a)$$

CHAPTER 7

COUPLED CIRCUITS

7.1 Introduction. It is sometimes desirable to transfer electrical energy from one circuit to a neighboring circuit. This can be accomplished, as in Fig. 7 A, by means of a transformer, wherein the source of energy is in the primary circuit and the load is in the secondary circuit. There are other coupling methods which employ a link circuit between the primary and the secondary. In still other types of coupling, the primary and the secondary circuits are actually connected together, using a coil or a condenser or a resistance, as the element common to both primary and secondary circuits.

FIG. 7 A. Typical coupling methods

The *transformer*, as shown in Fig. 7 A, differs in its action from the iron core transformer discussed in the chapter on a.c. circuits, in that only a few of the lines of force of the primary cut the wires of the secondary coil. The simple voltage step-up and impedance ratios applicable to the iron core case no longer hold true. The extent to which the lines of force of the primary cut the secondary is measurable, and is called the *mutual inductance*. Its symbol is M and its unit is the *henry*. When the secondary coil is placed close to the primary and on the same axis, the *coupling* will be great and M will be large. If the secondary coil is rotated, or is moved farther away from the primary, the voltages set up in it will be smaller, the coupling will be less, and M will represent a smaller number.

The coefficient of coupling is defined by the equation,

$$k = M/\sqrt{L_1L_2},$$

where the L's are the self-inductances of the primary and secondary circuits. If all of the lines of force from the primary were to cut the secondary, k would be equal to unity; the coefficient would be 100 per cent. This is the "tightest" possible coupling.

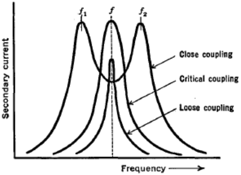

FIG. 7 B. Transformer coupling. The primary and secondary circuits were independently tuned to the same frequency (f)

When the circuits are tuned to the same frequency and are so related that but little energy is transferred from the primary to the secondary, they are said to be *loose coupled*. As the coupling is increased, the secondary increasingly "loads" the primary; and also, the primary increasingly loads the secondary. This loading action broadens the resonance curves of both circuits. At *critical coupling,* maximum energy is transferred and the resonance curve has quite a broad peak, as in Fig. 7 B. If the circuits are still closer coupled, the energy transferred from one circuit to the other decreases, and the resonance curve will have two peaks, one on either side of the single

---

This coupling k_c is often termed the *critical coupling*. The corresponding mutual inductance is

$$\omega M = \sqrt{R_pR_s} \tag{37}$$

With the mutual inductance for critical coupling, the resistance coupled into the primary circuit at resonance by the presence of the secondary equals the primary resistance. This gives the maximum possible secondary current. The resulting maximum possible voltage across the secondary condenser is

$$\text{Maximum possible } \frac{E_c}{E} = \frac{1}{2k_c}\sqrt{\frac{L_s}{L_p}} = \frac{\sqrt{Q_pQ_s}}{2}\sqrt{\frac{L_s}{L_p}} \tag{38}$$

where k_c is the critical coupling as given by Eq. (36). The voltage developed across the condenser at resonance with other couplings is less than value given by Eq. (38) by an amount depending upon the ratio of actual to critical coupling, as shown in Fig. 18.

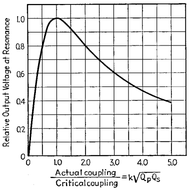

FIG. 18.—Relative output voltage obtained at resonance as a function of coefficient of coupling in the case of two circuits tuned to the same frequency and coupled together.

Conditions for Existence of Double Peak —Height, Location, and Width of Peaks.—The curve of response in the secondary circuit exhibits double peaks whenever the coefficient of coupling is sufficient to cause the right-hand side of Eq. (33) to show two maxima. This occurs when[1]

$$\frac{\text{Actual coefficient of coupling}}{\text{Critical coefficient of coupling}} \geqslant \left[\frac{1}{2}\left(\frac{Q_p}{Q_s} + \frac{Q_s}{Q_p}\right)\right]^{1/2} \tag{39}$$

It will be noted that when $Q_p = Q_s$, double peaks occur whenever the coupling exceeds the critical value, but if the Q's are different, double peaks do not occur until the coupling exceeds the critical value by an amount determined by the Q ratio.

When double humps occur, the location of the peaks in relation to the resonant frequency depends upon the actual coupling, the critical coupling, and the Q ratio. Analysis based upon Eq. (33) shows that to an accuracy sufficient for all ordinary purposes the location of the peaks is given by[2]

$$\left.\frac{\text{Frequency at peak of secondary voltage}}{\text{Resonant frequency of tuned circuits}}\right\} = \gamma_p = \frac{1}{\sqrt{1 \pm k\left[1 - \frac{k_c^2}{2k^2}\left(\frac{Q_p}{Q_s} + \frac{Q_s}{Q_p}\right)\right]^{1/2}}} \tag{40}$$

where k_c is the critical coefficient of coupling as given by Eq. (36) and the remaining notation is the same as above. The ratio represented by the spacing between coupling peaks to the resonant frequency, as a function of the coefficient of coupling,

---

[1] Equation (39) assumes that the γ^2 multiplying the denominator of Eq. (33) is constant. The approximation that results is so small as to be of negligible consequence, but results in enormous simplification of the equations.

[2] Eq. (40) involves the same approximation as does Eq. (39), but again the error introduced is negligible and the simplification considerable.

The curve of secondary current is then somewhat broader in the immediate vicinity of the resonant frequency than the resonance curve of the secondary circuit, and the primary curve shows double peaks. With still greater coupling, the double humps in the primary current curve become more prominent, and the peaks spread farther apart. At the same time the secondary current curve begins to show double humps, with the peaks becoming progressively more pronounced and farther apart as the coefficient of coupling is increased.[1]

Basic Equations.—In practical work, the most important property of the coupled system under consideration is the ratio of voltage developed across the condenser in the secondary circuit to the voltage applied in series with the primary circuit. A useful expression for this important ratio is obtained by rearranging Eqs. (22) and (23) to give the relation[2]

$$\frac{\text{Voltage across secondary condenser}}{\text{Voltage applied in series with primary}} = \frac{E_c}{E}$$

$$= \frac{-1}{\gamma^2}\sqrt{\frac{L_s}{L_p}}\,\frac{k}{\left[k^2 + \frac{1}{Q_pQ_s} - \left(1 - \frac{1}{\gamma^2}\right)^2 + j\left(1 - \frac{1}{\gamma^2}\right)\left(\frac{1}{Q_p} + \frac{1}{Q_s}\right)\right]} \tag{33}$$

where $\omega = 2\pi$ times frequency.

$\omega_0 = 2\pi$ times resonant frequency.

$\gamma = \frac{\omega}{\omega_0} = \frac{\text{actual frequency}}{\text{resonant frequency}}$.

E = voltage applied in series with primary.

$Q_p = \omega L_p/R_p$ for primary circuit.

$Q_s = \omega L_s/R_s$ for secondary circuit.

$k = M/\sqrt{L_pL_s}$ = coefficient of coupling.

L_p = total inductance of primary circuit.

L_s = total inductance of secondary circuit.

This equation involves no approximations, other than assuming that the circuits are resonant at the same frequency.

In the special case where the circuit losses are zero, or where the frequency differs sufficiently from the resonance frequency to allow the losses to be neglected, Eq. (33) takes the form

$$\frac{E_c}{E}\text{ for zero losses} = \frac{-1}{\gamma^2}\sqrt{\frac{L_s}{L_p}}\,\frac{k}{\left[k^2 - \left(1 - \frac{1}{\gamma^2}\right)^2\right]} \tag{34}$$

Effect of Coupling on Response at Resonance—Critical Coupling.—The response at resonance is obtained by substituting $\gamma = 1$ in Eq. (33), which gives

$$\frac{E_c}{E}\text{ at resonance} = -\sqrt{\frac{L_s}{L_p}}\,\frac{k}{\left[k^2 + \frac{1}{Q_pQ_s}\right]} \tag{35}$$

This expression is maximum when the coefficient of coupling has the value

$$k_c = \frac{1}{\sqrt{Q_pQ_s}} \tag{36}$$

---

[1] When the circuit Q's are not equal, double humps do not appear in the curve of secondary current until the coupling is somewhat greater than the critical value. This is illustrated in the universal curves of Fig. 22.

[2] For derivation, see Terman, *op. cit.*, p. 81.

---

frequency to which the circuits were originally tuned. The closer the coupling, the greater the frequency separation of these peaks.

If the two circuits are not exactly tuned to the same frequency, their effect upon each other is not only to increase the effective resistance (the Q of the circuit decreases) but also to reduce the self-inductance. Hence the peak of the resonance curve shifts to a different frequency.

7.2 The Effect of " Neighboring Bodies." The secondary circuit need not necessarily consist of a coil, condenser, and resistance, as in the cases we have just discussed, but can consist of any metallic, and even a dielectric body, in the neighborhood of the circuit containing the alternating current. A piece of metal placed inside a coil will have small *eddy currents* induced in it. These currents, in turn, react upon the primary circuit to increase its resistance, i.e., lower its Q, and *decrease* its inductance and hence increase its resonant frequency. Because of the increased resistance, the generator must supply an additional amount of power (current squared, times resistance). Thus, if we use the symbol $R_1{}^1$ for the *effective resistance* of a circuit (its actual resistance plus that which is " reflected " from the load), we may write

$$\underbrace{I_1^2R_1{}^1}_{\text{Total Heat}} = \underbrace{I_1^2R_1}_{\text{Prim. Heat}} + \underbrace{I_2^2R_2}_{\text{Sec. Heat}},$$

where the term on the left side represents the total power which the source must supply. The first term on the right-hand side of the equation represents the heat developed in the primary circuit, and the second term represents the heat developed in the secondary, or load — be it a circuit or a metallic body or an insulator. Now, this state of affairs may be good or it may be bad. For example, it is " good " when the circuit is used as an *induction heater,* which consists of a radio frequency generator with a tuned circuit, the coil of which consists of a few turns of heavy copper wire. The coil is placed around a body which is to be heated; such, for example, as the metal electrodes sealed inside a vacuum tube during its process of manufacture, or of a human body in which it is desired to develop an " artificial fever." The eddy currents set up in the conductive parts of the body inside the coil cause the body to heat up and, in some cases, to an extent such as to melt it completely.

If an insulator is placed inside the coil, the high frequency electrostatic fields cause the electrical charges in its atoms and molecules to oscillate back and forth about their normal positions. This requires energy which can only come from the primary circuit. This causes the dielectric to heat up, and is spoken of as *dielectric loss*. That energy should be absorbed from a circuit by a neighboring dielectric is, in general, undesirable. The resistance of the primary circuit is effectively increased by these losses.

We may generalize the concept of resistance by defining it in the following manner:

$$\text{Generalized Resistance} = \frac{\text{Watts Lost}}{\text{Current Squared}},$$

where the "watts lost" include the heat losses in the circuit itself and in neighboring bodies (as ohmic, eddy current, or dielectric heating); in general, lost in any form whatsoever from the source of power.

7.3 Shielding. A metal shield can be used to prevent coupling between two circuits. Capacitive or electrostatic coupling can be prevented by shielding either the primary or secondary, or both, circuits with an enclosing metal container. The shield should be grounded and be made of material of low resistance. Also, metal shields can be used at radio frequencies to prevent magnetic coupling. Here, the eddy currents in the shield have magnetic fields which oppose the original field and more or less completely keep it out of the inside of the shield. The shielding effect is greater at the higher frequencies, is greater for more conductive materials, and also depends upon the thickness of the shielding material. At low frequencies, the eddy currents are so feeble that this method is not satisfactory. The best that can be done in this case is to surround the circuit with a complete shield of soft iron. This will partially divert the magnetic fields.

A shield changes the resonant frequency and the Q of the circuit being shielded. In shielding a coil, the spacing between the sides of the coil and the shield should be equal to at least half the diameter of the coil, and the distance of the shield from the end of the coil should be not less than the diameter of the coil. Copper and aluminum are satisfactory metals for shields.

7.4 Introduction to Filters. Various combinations of coils and condensers are used:

1. To separate currents of different frequencies from each other.
2. As a coupling unit between two circuits whose impedances are not equal to each other.

---

5. Two Resonant Circuits Tuned to the Same Frequency and Coupled Together.[1] When two circuits resonant at the same frequency are coupled together, the resulting behavior depends very largely upon the coupling, as shown in Fig. 17. When the coefficient of coupling is small, the curve of primary current as a function of frequency approximates closely the series resonance curve of the primary circuit considered alone. The secondary current at the same time is small and varies with frequency according to a curve having a shape approximating the product of the resonance curves of primary and secondary circuits taken alone. As the coupling is increased, the curve of primary current becomes broader and the peak value of primary current is reduced. At the same time, the secondary current becomes larger and the sharpness of the secondary current curve is reduced. These trends continue until the coupling is such that the resistance that the secondary circuit couples into the primary at resonance is equal to the primary resistance. This coupling is called the *critical coupling*, and causes the secondary current to have the maximum possible value that it can attain.

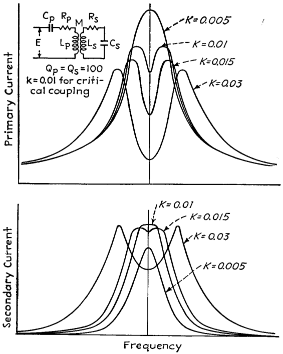

Fig. 17.—Curves showing variation of primary and secondary current with frequency for different coefficients of coupling when the primary and secondary are separately tuned to the same frequency.

---

[1] A very complete discussion of this subject is given by C. B. Aiken, Two-mesh Tuned Coupled Circuit Filters, *Proc. I.R.E.*, Vol. 25, p. 230, February; p. 672, June, 1937. See also E. S. Purington, Single and Coupled-circuit Systems, *Proc. I.R.E.*, Vol. 18, p. 983, June, 1930.

When ωL_p is not negligible compared with the primary resistance, the response curve still has the shape of a resonance curve, but the peak is shifted to a slightly higher frequency. This shift in location of the peak is due to the fact, expressed by Eq. (26), that maximum secondary current occurs when secondary is sufficiently detuned that its coupled reactance neutralizes the reactance of the primary. When the primary reactance is not negligible, this detuning is appreciable. The coupling required for maximum secondary current is also greater as the ratio $\omega L_p/R_p$ is increased.

(b) Curve of Voltage Across C_S

FIG. 15.—Inductively coupled circuit with tuned secondary and untuned primary.

Analysis of the output of coupled systems with untuned primary and tuned secondary can be most conveniently carried out by using the equivalent secondary circuit of Fig. 12*d*. Such equivalent circuits are shown in Fig. 16. These show how the association of the primary with the resonant secondary has the effect of increasing the effective secondary resistance and hence of lowering the effective Q, and also that an inductive primary neutralizes some of the secondary inductance and so raises the resonant frequency.

3. To shift the phase between voltage and current.
4. To alter the magnitude of voltage or current.

Figure 7 C shows some of the filters with which we are already familiar, together with their curves of output current at different input frequencies, their basic equations, and their names. See also Figs. 5 A and 5 B. More complicated combinations will serve better in separating neighboring frequencies and in more completely suppressing others. In other words, there are filters which have a *sharper cutoff*.

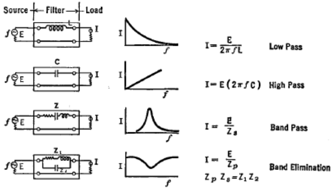

FIG. 7 C. Crude filters. Low-pass types use series inductance (top figure). High-pass use series capacitance. Band-pass use series *LC* circuits. Band-elimination use parallel *LC* circuits (bottom figure)

Of the host of possible *LC* combinations, a few simplified forms have been developed under the following assumptions and simplifications:

1. The resistances of all parts of the filter circuits are to be kept as low as possible. We shall assume that the resistances are zero. Such filters are called " ideal " or *non-dissipative.*
2. There shall be no batteries or other sources of electromotive force, nor vacuum tubes with their attendant amplification, in the filter. Such filters are said to be *passive.*
3. The inductances of all coils which contain iron cores shall be assumed to be the same for any of the currents which flow through them. Filters constructed with such inductances are said to be *linear.*
4. There shall be no magnetic coupling of the lines of force from any of the coils to any other coils in the circuits.

5. The output or load circuit shall consist of pure resistance (no coils or condensers), whose value shall be the same as that of the generator or input circuit.

It is possible to describe the characteristic of filters in terms of the output current as in Fig. 7 C, or in terms of the *ratio* of output to input currents, or the ratio of the output voltage across the load to the input voltage, or the ratio of the power output to the power input, or, as is more common and as we shall now do, in terms of the *attenuation* of the filter. The attenuation is expressed in decibels (Sec. 2.6) and is proportional to the logarithm of the ratio of the output to the input currents or voltages or powers. It is a measure of the losses which take place in the filter at the different frequencies.

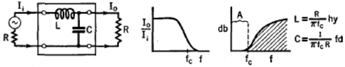

FIG. 7 D. An L-section, low-pass filter. The lower frequencies in the range "A" pass through, while those of higher value are more or less attenuated or lost in the filter

7.5 Low-Pass Filters. The circuit of Fig. 7 D is called an L-type, low-pass filter. It contains a series inductance and a shunt capacitance. From the attenuation (db.) curve in this figure, it can be seen that the choking action of the coil, aided by the bypass action of the condenser, has materially sharpened the curve over that of a single series inductance (Fig. 7 C), especially in the neighborhood of the *cutoff frequency*, f_c. In the equations given in Fig. 7 D, L is in henries, C is in

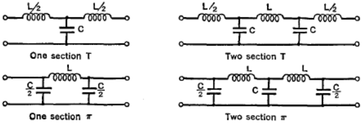

FIG. 7 E. — T- and π-type, low-pass filters

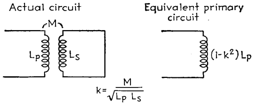
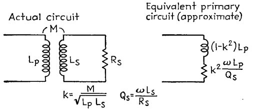
---

resistance of the tube. When the secondary is a resonant circuit, the curve of coupled impedance $(\omega M)^2/Z_s$ with variation in frequency has substantially the same shape and characteristics as the parallel impedance curve of the secondary, but the absolute magnitude is determined by the mutual inductance.

The important characteristic of this circuit is the curve of voltage developed across the secondary condenser as a function of frequency under conditions where $R_p >> \omega L_p$. Such a characteristic is shown in Fig. 15*b*, and has substantially the same shape as a resonance curve with the peak at the resonant frequency of the secondary and an effective Q somewhat lower than the actual Q of the secondary circuit.



(a) Untuned reactive secondary with zero losses



Actual circuit
Equivalent primary circuit (approximate)
M
Lp
Ls
Rs
(1-k²)Lp
$k^2 \frac{\omega L_p}{Q_s}$
$k = \frac{M}{\sqrt{L_p L_s}}$
$Q_s = \frac{\omega L_s}{R_s}$

(b) Untuned secondary with small losses

FIG. 14.—Inductively coupled circuits with untuned secondaries.

On the assumption that $R_p >> \omega L_p$, the response at resonance is

$$\frac{\left\{\begin{matrix}\text{Voltage across secondary} \\ \text{condenser at resonance}\end{matrix}\right\}}{\text{Voltage applied to primary}} = \frac{\omega M}{R_p R_s + (\omega M)^2} \times \omega L_s \tag{30}$$

With given primary and secondary circuits, the response at resonance is maximum when the coupled resistance equals the primary resistance, *i.e.*, when

$$\omega M = \sqrt{R_p R_s} \tag{31}$$

With greater or less coupling, the response is less.

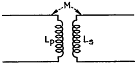
The relationship between the effective Q of the response curve and the actual Q of the secondary circuit is, still assuming that $R_p >> \omega L_p$

$$\frac{\text{Effective } Q \text{ of amplification curve}}{\text{Actual } Q \text{ of tuned circuit}} = \frac{1}{1 + \frac{(\omega M)^2/R_s}{R_p}} \tag{32}$$

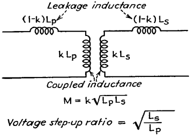
The effective Q of the response curve approaches the actual Q of the secondary circuit when the coupling is very small, and is exactly one-half of the actual Q when the coupling corresponds to the value giving maximum response.

Inductive Coupling Considered as a Transformer.—Two coils inductively coupled represent the general case of a transformer, and can be reduced to the equivalent transformer circuit of Fig. 13. Here the primary and secondary inductances are divided into leakage and closely coupled components. The leakage inductances correspond to magnetic flux lines that produce no linkages to any secondary circuit, while the coupled inductances are taken as having unity coefficient of coupling.

In a conventional transformer with iron core, the coefficient of coupling between primary and secondary is so large that the leakage inductances represent only a very small fraction of the total circuit inductances. Under these conditions it is convenient to analyze the behavior in terms of the turn-ratio, leakage inductance, etc., as is commonly done with 60-cycle power transformers. However, in the more general case where the coefficient of coupling may be small, most of the inductance is leakage, and turn ratio has relatively little significance. It is then preferable to use the general method of analysis given above.



(a) Actual circuit



(b) Same circuit shown as transformer

FIG. 13.—Equivalent circuit of a transformer expressed in terms of primary and secondary inductances and coefficient of coupling.

4. Analysis of Some Simple Coupled Circuits. *Untuned Secondary Consisting of a Pure Reactance.*—This case corresponds to a coil serving as the primary, with a metal mass of low resistivity serving as the secondary. In this case, which is illustrated in Fig. 14*a*, one has

$$\text{Coupled reactance} = -\frac{(\omega M)^2}{\omega L_s} = -k^2\omega L_p \qquad (29)$$

where k is the coefficient of coupling between the coil and the secondary. The presence of the secondary reduces the inductance as viewed from the coil terminals to an equivalent value $(1 - k^2)L_p$.

It will be noted that the amount of reduction in inductance is determined solely by the coefficient of coupling and not by the number of primary turns, etc. It will be also observed that the effect of the secondary decreases rapidly as the coefficient of coupling becomes small.

Untuned Secondary Having Both Resistance and Reactance.—This corresponds to the practical case of a coil in a shield, or near a metal panel or other mass, with the resistance of the metal secondary taken into account. For such a secondary, the coupled impedance as given by Eqs. (24) and (25) consists of a resistance and a negative reactance. The effect of the secondary upon the primary is hence to lower the equivalent inductance and increase the equivalent resistance of the primary coil as viewed from its terminals.

Under practical conditions, a secondary consisting of a shield or other metal object is usually of copper or aluminum, so that the secondary reactance is considerably greater than the secondary resistance. Under these conditions, the equivalent primary circuit has the values and form given in Fig. 14*b*.

Tuned Secondary, Untuned Primary.—This circuit, illustrated in Fig. 15*a*, is of importance because it represents the equivalent circuit of the transformer-coupled tuned radio-frequency amplifier, with the primary resistance R_p representing the plate

---

farads, R is in ohms, and f_c is in cycles per second. Note that the generator and the load both have the same resistance.

Referring to Fig. 7 E, we see that several " T "-sections or " π "-sections can be connected in series with each other to form two, three, or more section filters. The cutoff becomes increasingly sharp the more sections used. Then, of two frequencies near f_c, the lower one will get through and the higher one will not. The same design equations are used as for the L-section low-pass filter. Note that, in Fig. 7 E, only one-half the inductance or one-half the capacitance is used in certain places while the full value is used at others.

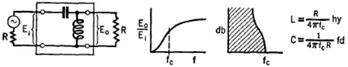


FIG. 7 F. An L-section, high-pass filter. L is in henries, C is in farads, R is in ohms and is the same at the input and output. The cutoff frequency, f_c, is in cycles per second

7.6 High-Pass Filters. Whereas the low-pass filters of the preceding section permitted the passage, more or less, of all frequencies below the cutoff value, and attenuated or suppressed, more or less, all frequencies above this value, high-pass filters do just the reverse. A single L-section high-pass filter is shown in Fig. 7 F and is seen to con-

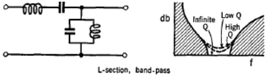
One section T　　Two section T

One section π　　Two section π

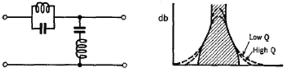
FIG. 7 G.—T- and π-type, high-pass filters

sist of a series condenser, whose reactance is large for low frequencies and small for higher frequencies, and a shunt inductance, which readily bypasses low frequencies but forces the higher frequencies to continue on out to the load R.

Figure 7 G shows T- and π-type, one- and two-section high-pass filters which offer greater discrimination to frequencies near the cutoff. The design equations are the same as for the L-section.



L-section, band-pass



L-section, band-elimination

FIG. 7 H. Simple band-pass and band-elimination filters

7.7 Band-Pass and Band-Elimination Filters. It is possible to transmit a certain range of frequencies through a *band-pass filter*, and more or less completely suppress all lower and all higher frequencies. A simple filter of this type, together with its attenuation curve, is given in Fig. 7 H.

It is also possible to construct filters which will, more or less, transmit all frequencies except those which lie within a certain range. A simple form of *band-elimination* or *band-suppression filter* is also given in Fig. 7 H, together with its attenuation curve.

With multi-section filters of these types, the separation of adjacent frequencies can be made much sharper than with the simple L-section. On the other hand, in practice, the coils are not pure inductances but have some resistance. Now Q is our measure of the inductive-ness versus resistance of a coil, i.e., $Q = 2\pi fL/R$. In Fig. 7 H, the dotted lines show in what manner the attenuation is affected when low- and high-Q coils are used. Similar unsharpening effects occur in practice with all filters.

---

circuit leads to the same results as the first form, since the extra voltage that is considered as acting in the second case is just compensated for by the voltage drop in the extra impedance considered as existing in the secondary circuit.

The resistance and reactance components of the coupled impedance are

$$\text{Resistance component} = \frac{(\omega M)^2}{R_s^2 + X_s^2} R_s \tag{24}$$

$$\text{Reactance component} = -j \frac{(\omega M)^2}{R_s^2 + X_s^2} X_s \tag{25}$$

where R_s and X_s are, respectively, the resistance and reactance components of the secondary impedance Z_s. The effect that the secondary has on the primary circuit is exactly as though the resistance and reactance given by Eqs. (24) and (25) had been inserted in series with the primary circuit. The energy and reactive volt-amperes consumed by the primary current flowing through this hypothetical resistance and reactance represent the energy and reactive volt-amperes that are transferred to the secondary circuit.

Conditions for Maximum Secondary Current.[1]—In dealing with coupled circuits, it is desirable to keep in mind the adjustments giving maximum secondary current. The behavior in the more important cases is summarized below for the case of two circuits inductively coupled, with resistance and reactance in each circuit.

Case 1. Maximum Secondary Current with Variation of Secondary Reactance.—When frequency, mutual inductance, primary impedance, and secondary resistance are constant, the secondary current is maximum when

$$X_s = \frac{(\omega M)^2}{R_p^2 + X_p^2} X_p \tag{26}$$

where X_p and X_s = reactance of primary and secondary circuits, respectively.
R_p and R_s = resistance of primary and secondary circuits, respectively.
ω = 2π times frequency.
M = mutual inductance.

Case 2. Maximum Secondary Current with Variation of Primary Reactance.—If the primary rather than secondary reactance is varied, maximum secondary current is obtained when

$$X_p = \frac{(\omega M)^2}{R_s^2 + X_s^2} X_s \tag{27}$$

Case 3. Maximum Possible Secondary Current.—The secondary current has its maximum possible value when the adjustments are such that the resistance and reactance coupled into the primary circuit by the secondary are equal to the resistance of the primary circuit and the negative of the primary reactance, respectively; *i.e.*, when

$$\begin{aligned} \frac{(\omega M)^2}{R_s^2 + X_s^2} R_s &= R_p \\ -\frac{(\omega M)^2}{R_s^2 + X_s^2} X_s &= -X_p \end{aligned} \tag{28}$$

It will be noted that in order to obtain maximum possible secondary current, it is necessary that two independent variables be adjusted. One of these is commonly the mutual inductance; the other, the reactance of one or both circuits. Unless the mutual inductance satisfies the relation $\omega M \geqq \sqrt{R_pR_s}$, it is impossible to satisfy the condition for maximum possible secondary current.

---

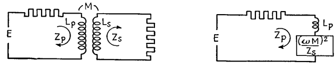
[1] For a more detailed discussion, see G. W. Pierce, "Electric Oscillations and Electric Waves," Chap. XI, McGraw-Hill, New York, 1920.

circuit as a result of a voltage applied to that circuit produces magnetic flux that induces a voltage in the coupled circuit, resulting in induced currents and a transfer of energy from the first or primary circuit to the coupled or secondary circuit.

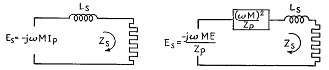
Analysis of Inductively Coupled Circuits.—The behavior of inductively coupled circuits can be determined by making use of the following principles:[1] *First,* as far as the primary circuit is concerned, the effect of the presence of the coupled secondary circuit is exactly as though an impedance $(\omega M)^2/Z_s$ had been added in series with the primary, where

M = mutual inductance.
$\omega = 2\pi f$.
Z_s = series impedance of secondary circuit when considered by itself.

Second, the voltage induced in the secondary circuit by a primary current of I_p has a magnitude of ωMI_p and lags the current that produces it by 90°. *Third,* the secondary current is exactly the same current that would flow if the induced voltage were applied in series with the secondary and if the primary were absent.



(a) Inductively coupled circuit (b) Equivalent primary circuit



(c) Equivalent secondary circuit (d) Alternative form of equivalent secondary circuit

FIG. 12.—Inductively coupled circuit and also equivalent primary and secondary circuits.

The preceding analysis shows that the actions taking place in the primary and secondary circuit are as though one had the equivalent circuits shown in Figs. 12*b* and 12*c*. Here the primary circuit consists of the actual primary impedance Z_p in series with an additional impedance $(\omega M)^2/Z_s$ that takes into account the effect the secondary produces on the primary current. This extra impedance $(\omega M)^2/Z_s$ is termed the *coupled impedance.* The equivalent secondary circuit of Fig. 12*c* consists of the voltage $-j\omega MI_p$ induced in the secondary by the primary current, in series with the secondary impedance Z_s as shown.

An alternative form of equivalent secondary circuit is given in Fig. 12*d*. This is obtained by applying Thévenin's theorem and noting that when the secondary is opened, the open circuit voltage that appears is $-j\omega MI_p$, while when the applied voltage is short-circuited, the equivalent impedance as viewed from the opened secondary terminals is $Z_s + (\omega M)^2/Z_p$. This second form of the equivalent secondary

---

[1] These rules for handling coupled circuits are direct consequences of the mesh equations, which for this case can be written as

$$E = I_pZ_p + j\omega MI_s \tag{22}$$
$$\text{Induced voltage} = -j\omega MI_p = I_sZ_s \tag{23}$$

It is well known that a quartz slab cut from its crystal in proper fashion and mounted between two metal plates acts like a circuit of very high Q. Hence, in circuits where the frequency of the currents is comparable with the natural vibrational frequency of the quartz, it is possible to obtain very sharp cutoff filters of all types.[1]

Introduction

There are lots of books, articles and websites describing Software Defined Radio (SDR). My goal, in this introductory work, is to give you blazing fast access to a working set of concepts you can use to decide when and how SDR will be useful to you. It will start simply and build essential ideas step-by-step. This book has two goals. The first is to provide a working overview of SDR. The second is to make hardware and software prototyping easier for the uninitiated.

This will not be a mathematically intensive development but rather a plug and "play" approach. Each chapter will start with interactive simulation and end with real devices - devices you can explore and interconnect. The interested reader should visit the references provided in the final chapter to clarify the more sophisticated ideas. Running each simulation is easy and highly recommended.

The book is divided roughly in half. In the first chapters, essential radio hardware issues will be discussed. For the foreseeable future SDR has not eclipsed the entire radio. Front-end RF hardware is still required to gather, sample and downconvert the signal. In the latter chapters we will transition to software-based concerns, while keeping an eye on hardware and instrumentation that will make our lives easier and our understanding more complete.

To demonstrate hardware concepts, we will be using a set of PostCardKits™. The pattern is this. We will use simulation to understand the theory behind each PostCardKit™. Then we mix and match the postcards to configure different kinds of radios. Pretty fun and exciting! Later we will mix and match software blocks to accomplish the same objective.

Figure 2: Mix and Match Postcards for Chapter 1

In the second chapter on amplifiers the crystal radio card is improved using an audio amplifier PostCardKit™, an RF amplifier PostCardKit™, and two kinds of power cards. One power card features rechargeable lithium batteries; the other uses solar cells for recharging and direct power. How green is that?! PostCardKits™ are flat, lead-free evaluation cards, printed on high quality paper with conductive ink. PostCardKits™ can be stamped and mailed, or mailed in envelopes to maintain pristine appearance. The first chapter is introduced with a crystal radio set. This card functions without any external or battery power. It receives AM radio stations. A first attemp on a file card pulled in stations from Asia and Central America.

You can hear fainter stations if you add an audio amplifier card. You can receive more stations if you add the RF amplifier. These additional cards require power. We will reuse the audio, RF amplifier and power cards in later chapters in novel ways. For example, the audio card is a stereo amplifier used for a special kind of station hunting called binaural radio.

Laterwe will develop radio software on a PC. Towards the end, we will extend the power of the hardware and software and reach for the stars.

The first PostCardKit™, Crystal Radio, utilizes a germanium diode for signal detection. It demonstrates the simplest effective combination of discrete components. It consists of an inductor, a capacitor, a resistor, a germanium diode detector and a piezoelectric crystal earphone.

Just for fun, I let solver run with k, Ca, E, Cb, R1 and R2. Adding R1 to solver's program really allowed it to nail the data with a close-fit model. The price? Look at the resistivity values it chose. R1 = -439 ohms and R2 = 719 ohms. Well, at least R2 is not negative! These results may be telling me something important, but as yet I am too dense to understand. Or, they may be just what they appear, totally bogus.

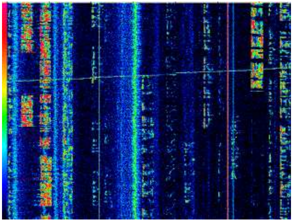

Figure 4: Visualization of Radio Spectrum

The Crystal Radio PostCardKit™

The crystal radio is the simplest of all radios. In World War II, Allied GI's used paper clips set against rusty razor blades to form crude diode junction receivers that the Nazi forces could not detect. These were dubbed "Foxhole receivers". Crystal radios have a long and colorful history documented in Wikipedia and various radio collections documented on the web.

Attach the earphone provided to the jack in the upper left corner of the postcard. You probably won't hear anything unless you live close to a powerful AM radio station. An antenna and a ground will improve your reach considerably. Just as a picture in the dark cannot be seen, a radio without an antenna cannot be heard. Lighting is half of art. The antenna is half of radio. You can learn more about antennas in the ARRL Antenna Book. It is highly recommended.

Putting Up the Litz

There is one errand to run before heading back to the easy chair. It is essential to route the Litz wire provided around a wall or ceiling to create an antenna. With antennas, bigger is usually better. I use a fold of masking tape to make a tiny hangar that holds the antenna on the wall. You can stick a clear pushpin through the tape to secure the antenna. Suspend the wire from the four corners of the room so it is up and out of the way. The wire provided is fine, so it is a quite aesthetic. When you are done, tin or sand the ends of the wire so that all the strands are conducting and install them in the connector provided. Now you have an antenna.

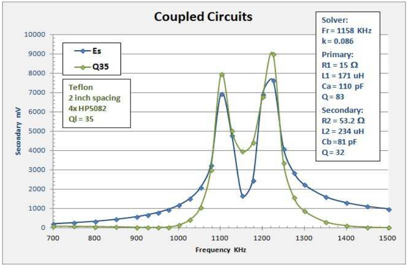
This square wire loop is a versatile omnidirectional antenna. If you wrap the antenna more than once around the room, the inductance will increase and the resonant frequency will drop according to:

$$f_{resonant} = \frac{1}{2\pi\sqrt{LC}}$$

Formula: Resonant Frequency

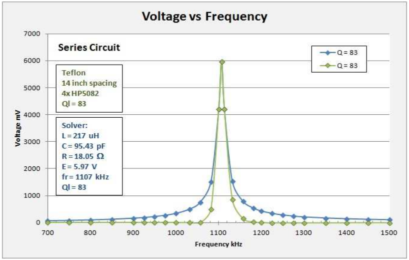
This formula informs us that those stations you manage to receive will be lower in the band, and lower in frequency. Start with one trip around the average sized room. Take your time getting this antenna right, it will serve you well. If you live on top of a hill, you will get better reception, but since radio waves bounce off the ionosphere, you will usually hear something unless you live in a salt mine. Using the clip provided, attach your antenna to the upper left hand corner your PostCardKit™ by the ANT. symbol. That was the hard part. You will also need a good ground. Grounding is

happens at the -3dB point. My simulation suggests a resistive loss of 18 ohms and reproduced the Q = 83. Pretty interesting. But, before congratulating myself too quickly...



Here I look at the over coupled case. As before, I am just unable to reproduce the steep flanks of my measured data with such a simple coupled circuit model. At a 2 inch separation, and looking only at the lower peak (recall my re-peaking), I had measured a Q = 35. The model does a fairly poor job of simulating this circuit. Note that in my simulation, I kept the known values of inductance for the two coils. Additionally I found that solver gave unacceptable values for R1 and so I pegged it at 15 ohms. I had solver look for k, Ca, E, Cb, and R2.

The first thing to note on the above plot is that the over-coupled curve is not centered with respect to the loosely coupled curves. This is a result of my A) not knowing at the time about exactly how the resonance curve splits with over coupling and B) my technique of re-peaking the set before each set of measurements. It is obvious that after moving the ATU to 2 inches separation, on re-peaking the output, I must have subtracted capacitance shifting the curve upward in frequency until the I got a peak at my desired measurement frequency of 1100 KHz. I should have made my resonance study earlier!



Looking now at just the measured data from the 14 inch spacing and comparing it to a curve generated with my series resonance spreadsheet. The data in green is my radio which, at this spacing gave me a set loaded Q = 83. I used excel's Solver routine on the central three datapoints to search for model parameters L, C and R. The steep flanks of the measured data were impossible to reproduce, but at least I could see what

discussed in an essential book on radio: The ARRL Radio Amateur's Handbook.

Figure 5: Ideal Reception

Using the Crystal Radio

Now that the radio has a good antenna, you should be able to hear more stations. You can tune the radio with the knob in the center. Remarkably, it needs no power! You might want to keep a logbook of the signals you hear, the time of day along with any tweaks you have made to the radio or antenna. Low frequency signals travel better at night than in the daytime. Some high frequency signals are the opposite. Where do we look when an aircraft is lost? The radio logbook.

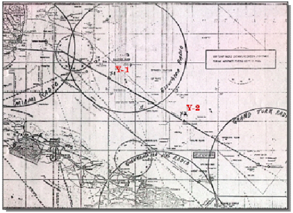


Figure 6 – Keeping a log enables discovery.

After you log a few entries it will be time to improve the radio. We will do that with the amplifiers mentioned above. Now for a little about how the crystal radio works.

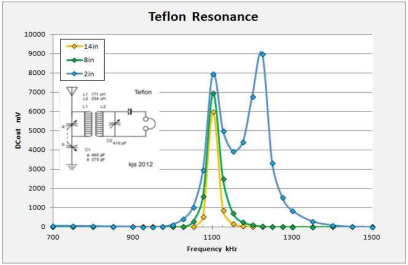
Basic Parts

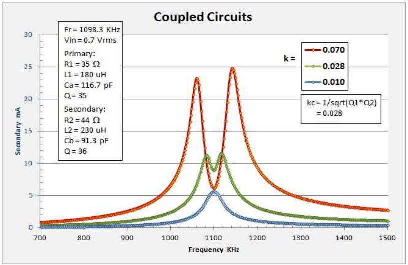
Picking up the card and shining the light on it you will notice it contains but five parts! The radio contains a diode, a resistor, an inductor, and two capacitors. Here is the schematic for the crystal radio including the Tidy TINA meter for RF power gain. The meter is used to optimize performance – it doesn't appear in the final circuit.

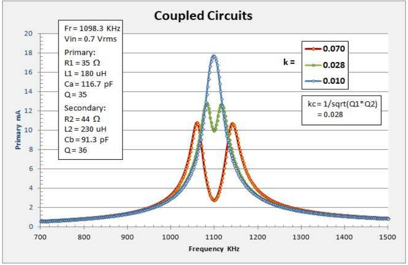
should give pause to note just how little signal one deals with in crystal sets. Note that critical coupling is when the secondary current attains its greatest value, not necessarily where the double hump disappears. Kc = 1/sqrt(Qp*Qs).

A copy of the coupled circuit spreadsheet can be found here: Coupled_kjs.xlsx

What else can one do with these spreadsheets? One of my motivations in building spreadsheets is that it allows me to compare measurements from actual radios to their theoretical counterparts. This allows me to better understand my sets and approach a best guess on certain parameters I might not otherwise be able to measure. The following few plots take data from a double tuned set that I have made frequency versus DC out at three differing coupling distances, 2 inches between coils (over coupled), 8 inches (presumed near critical), and 14 inches (under coupled).







In each plot I show curves with coupling factors of 0.070 (over-coupled), 0.028 (critically coupled), and 0.010 (loosely coupled). I find it amazing just how quickly the induced secondary current falls off with lowered coupling. These plots look quite different from most "generic" cartoon plots and

Re = 20 MOhm high impedance earphone
```

Example 0: Crystal Radio Schematic and Values

Just as in the Richter scale of earthquakes and the Fujitsu scale of tornadoes, we use a logarithmic scale when comparing the intensity of radio signals. This scale is measured in decibels (dB). This makes for much more reasonable comparisons. If two signals differ by a factor of two, they are about 3 dB apart. If they differ by a factor of four, they are 6 dB, and so on. Logarithmic scales turn multiplication into addition. This is useful when we want to talk about very large or small numbers. To convert a factor of 1000 to dB, you first count zeros to get 3. This corresponds to log(1000) = 3. Then you multiply by 10. 3 x 10 = 30 dB. So if two signals differ in power by a factor of 1000, then they are 30 dB apart:

In short dB = 10log(P), where P is power. Can you feel the power?

Tip - Use dB to compare the power of radio signals.

The resistor Re and capacitor Ce simulate the earphone. To really understand the crystal radio, we must understand the principles of the parts. If you are already an expert skip this quick review, but you might want to glance at the gain curves for voltage, current and power.

Resistors (units: Ohms) dissipate energy as heat. They impede the flow of electrical current, causing a voltage drop across the terminal ends. I once asked my dad if it wouldn’t be better if a circuit had no resistors at all because of this energy loss. He said “No” and then paused for a moment and said, “Yes”. The voltage drop E across a resistor is R times the current I, using Ohm’s law. You can think of an Ohm of resistance as the volt of force required to make an ampere of current flow.

$$\boxed{E=R\times I}$$

Formula: Ohm’s Law

Power (Watts) is voltage times current. Is your resistor rated for the power passing through it? Touch it and see, but don’t get burned.

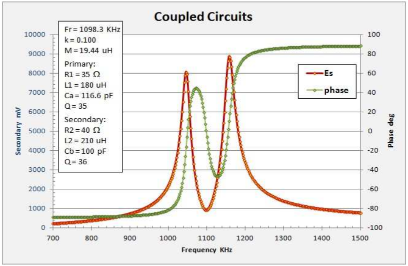
$$\boxed{P=E\times I}$$

Formula: Power

With Ohms Law and Power, you can derive six others! Two other handy resistor formulas:

Xs = wLs - 1 / (wCs)
Rcoupl = (wM)^2 * Rs / (Rs^2 + Xs^2)
Xcoupl = -1 * (wM)^2 * Xs / (Rs^2 + Xs^2)
Real = Rp + Rcoupl Imag = wLp + Xcoupl - 1/(wCp)
w = 2pi * frequency

Where the subscripts "s" means secondary circuit and "p" means primary circuit. M is the Mutual Induction of the two circuits defined as: M = sqrt(Lp*Ls) and is measured in Heneries. The Coupling Coefficient k indicates the amount of inductive coupling. This is a fractional value between 0 (no coupling) and 1 (perfect coupling). The Coupling Factor for the circuit then is defined as follows: M = k * sqrt(Lp*Ls).

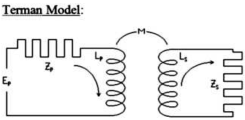


The plot above presents a generic coupled circuit with loose coupling (k = 0.1). I show the current induced in the secondary and the phase of the circuit impedance. Below are two interesting plots with the secondary current and primary current each at three different coupling factors.

value, reactance consists of inductive XL and capacitive XC parts. The parts are not necessarily the same and so adding them together does not necessarily equal zero. Note that, at resonance, they are equal in magnitude but opposite in sign (by convention, XC is negative) and they do add to zero. Where they have differing magnitudes, the combined impedance Z is the vector sum of the resistance and total reactance (XL + -XC). Z is the hypotenuse of a right triangle with an interior angle phi. This is the phase of the circuit. Where the phase is negative the circuit is capacitive, where the phase is positive the circuit is inductive. Where XL-XC is very large with respect to R, the phase approaches (but never reaches) plus or minus 90 degrees.

A copy of the parallel circuit spreadsheet can be found here: Parallel_kjs.xlsx

Time to move to the big leagues with coupling of two circuits. Here I am afraid my skills prove inadequate and I have turned to Mike Tuggle for help and, ultimately, a spreadsheet to make the needed calculations. For this I wish to publically acknowledge and thank Mike. Also to apologize to him for the significant liberties I have taken with said spreadsheet.



The model is based on Terman 1947 p149, shown at left. Mike builds a number of equations, the essential ones of which I used as follows:

Add two resistors in series to obtain the equivalent resistance:

$$\boxed{R_{series} = R_1 + R_2}$$

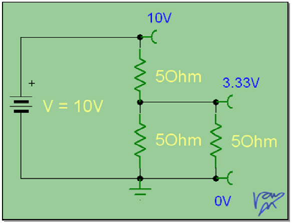
Formula: Series Equivalent Resistance

Use the product over sum for resistors in parallel:

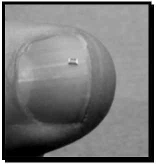
$$\boxed{R_{parallel} = \frac{R_1 R_2}{R_1 + R_2}}$$

Formula: Parallel Equivalent Resistance

The current flow in circuit loops and the voltage drop across circuit elements can be computed using Kirchoff's Laws and Thevenin Equivalent circuits. The programming of these laws is already done for you in a tidy program called TINA-TI, a free download from the TI web site. I highly recommend it. Here is a classic voltage divider, simulated in TI's TINA-SPICE



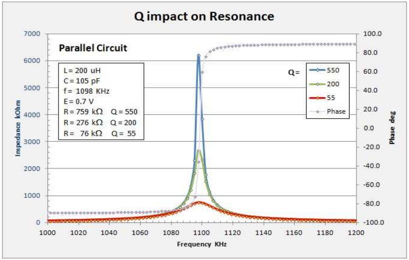
Circuit 1: Classic Voltage Divider Solved in Tidy TINA.



- Ordy

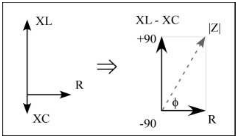
Figure 7: No room for color codes on surface mount resistors!

w = 2pi * frequency



This plot above for a parallel circuit looks, as it ought, just like that for the series circuit with the same values of L and C. Note though that parallel R is significantly higher than in the series case. Parallel resistance is not a measure of the circuit loss but rather how "tight" it is, (spoken as a non-engineer). You should see that Q values now go up with increasing value of parallel resistance.

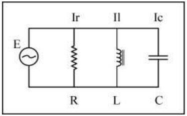
Additionally in this plot I include the phase of the impedance (for the Q = 550 case). The diagram at left indicates why it is necessary to keep track of the real (resistance R) and imaginary (reactance X) parts of the equations. While resistance is a "real"



plot on the chart the current versus frequency for the same tank with three variations of resistivity which gives three different values of Q. It is immediately clear that keeping resistance in the circuit low good of the quality of the set.

A copy of the series circuit excel spreadsheet can be found here: Series_kjs.xlsx

Having proved that I can simulate a simple series circuit it is time to take it up a notch with a PARALLEL circuit. Analysis of a parallel is inherently more complicated as it involves imaginary, or complex numbers. It is necessary to keep close track of the real and imaginary parts of the calculations. Also, the math dealing with complex numbers is different, especially the rules for multiplication and division. See my Appendix at the bottom of this page.



I take the tack of starting with the impedances (Z) of the components and combining them in parallel. The symbol "||" means to combine in parallel. Formulas for this computation as follows:

Zs = Zc || Y
R || Zl
Y = (R * Zl) / (R + Zl)
Zs = (Zc * Y) / (Zc + Y)

Where:
Zl = jwL and
Zc = -j / wC

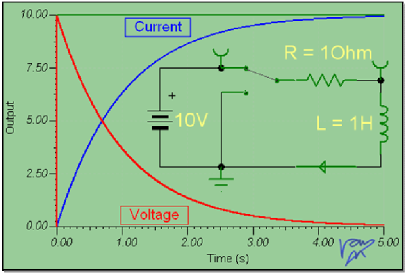
Notes on Resistors.
1) Always measure the value of a resistor before using it in a prototype circuit. Make sure your volt-ohm meter has a fresh battery.

2) In radio sections that operate at high frequencies we want resistors whose value does not vary with frequency. Thin-film and metal film resistors are preferred to wirewound resistors, which are really just lossy miniature inductors! Speaking of inductors…

Inductors (units: Henries)
store energy as a magnetic field. They are usually coils of wire or other conductive material in various shapes. Inductors have a direct current (DC) response and an alternating current (AC) response. These responses can be steady state or transient. Let's throw the switch!

When the switch is closed on the circuit below, an equal and opposite voltage is "induced" in the inductor. This is induced voltage is called "back EMF". After several time constants, the circuit reaches its "steady state". The magnetic field is established and this opposing voltage disappears. If the switch is opened, the magnetic field collapses and sparks can ensue! There was an old saying, "nature abhors a vacuum". Magnetic fields don't like suddenly open switches. This is an important principle when working with sensitive semiconductor components. Fried!

To track voltage in Tidy TINA we add a pin connection . To track current we add an arrow connection seen at the bottom of the circuit. By convention positive current flows from positive to negative. Electron vacancies or “holes” move in this direction, but real electrons flow the other way. Thanks Ben Franklin!

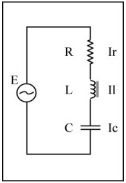


Circuit 2: Inductor Transient DC Response

Tidy TINA shows us two curves if we request a Transient Analysis. The top curve shows the current in the circuit. Since a coil is a conductor, keeping the switch on drains the battery. The bottom curve shows the induced voltage as it decays over time. This transient DC response ends with the steady-state DC response. What about AC, the stuff of which radio signals are made?

Consider the same circuit as before, but this time, we replace the DC battery with an AC signal generator and simplify the circuit to obtain:

Starting with a series RLC circuit. This circuit is straightforward and the math is pretty easy. The formula for the current through a SERIES circuit is:

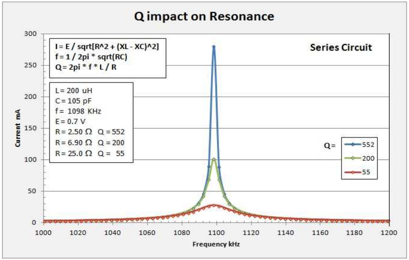


I = V / sqrt[R^2 + (XL - XC)^2]

Since reactances XL = 2pifL and XC = 1/2pifC, the above formula becomes:

I = V / sqrt[R^2 + (2pifL - 1/(2pifC))^2]

The resonance response with input values often discovered in a crystal set, L = 200 uH, C = 105 pF, and R = 6.9 ohms peaks at a frequency of 1098 KHz with a Q factor of 200.



The above plot shows first that it is indeed straightforward to evaluate a circuit in excel, a series circuit anyway. Further, it gives an indication as to what visualizations can be made. I increases with frequency while capacitive reactance decreases. Resonance is that frequency where the two reactance's cancel each other leaving only resistance in the circuit. A little fun derivation may be in order.

Looking at reactance's where f = frequency, L = inductance, and C = capacitance:

XL = 2pifL ... Inductive reactance
XC = 1/2pifC ... Capacitive reactance, so:
2pifL = 1/2pifC ... condition of resonance

taking f out of the denominator:
2pif^2L = 1/2piC

divide both sides by 2piL
f^2 = 1/2^2pi^2LC

take the square root of each side
f = sqrt(1) / sqrt((2pi)^2LC)

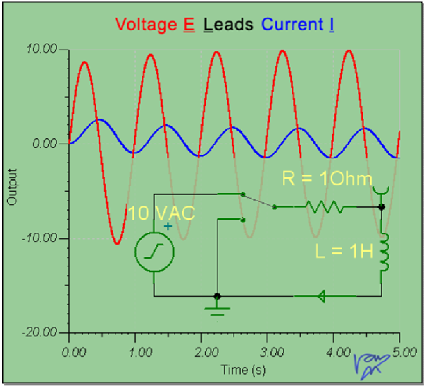
and simplifying...

f = 1 / 2pi sqrt(LC)

This is the general formula for resonance.

In all the plots from here on I will show sweeps of frequency with impedance or current as the dependant variable. The point of resonance on each plot should be apparent as that point where the dependant variable reaches its maximum value.

The AC signal causes the inductor's magnetic field to repeatedly collapse and expand in alternating directions. Ohm's law is constantly running, but now there is a delay. This delay is caused by the union of magnetic field workers whose boss is Maxwell and whose contact is binding. Forget that. Remember this. Voltage E Leads Current I in an inductor.



Circuit 3: Inductive AC Response

ELI the ICE man reminds us that voltage leads current by 90□ in an inductor. This is called phase shift. Radio is all about keeping track of phase. We draw voltage in red and current in blue on the same graph so we can see their relationship in time. But what about frequency?

Frequency Response: What Happens When Inductance and Resistance Change?
Now we can play with the inductor and resistor values and see what happens in our circuit. We will measure this by comparing the gain of various configurations. Gain is the amplitude of the signal in a circuit. Gain comes in three flavors, voltage gain, current gain and power gain. Power gain is voltage gain times current gain. We want to know how the gain changes as we change the frequency of our input signal. We can determine this quickly with Tidy TINA. First, we fix the resistor at 1 Ohms and set the inductor to 1 microHenries. Then we ask TINA to compute the AC Transfer Characteristics. Voila! We get a graph that yields major insight.

A graphical look at Resonance

Kevin Smith

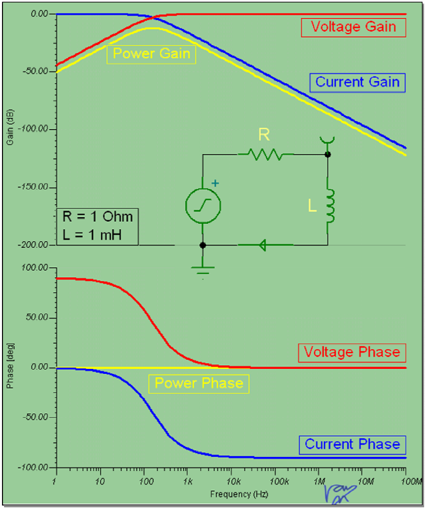
http://www.lessmiths.com/~kjsmith/crystal/resonance.shtml

I write this page in order to review, in my own mind mostly, those things which go into radio frequency resonance. My goal was to cast into spreadsheet form the formulas and equations that determine resonance for simple circuits that one often encounters in crystal radio.

On may ask why create spreadsheets to do what SPICE or Mathematica can easily do already. As I am addressing a crowd who enjoys building their own radios when such can easily and cheaply be had at a local store, I think the answer to my rhetorical question is clear. But more than just "doing it myself", there are good reasons to do so. I have read numerous textbook and online discussions of resonance. Most will feature "resonance curves" either generic cartoons or SPICE plots with no indication of the actual formulas that created the plot. I start to think of SPICE as a kind of black box that magically produces interesting results even to those with little to no understanding of the math inside.

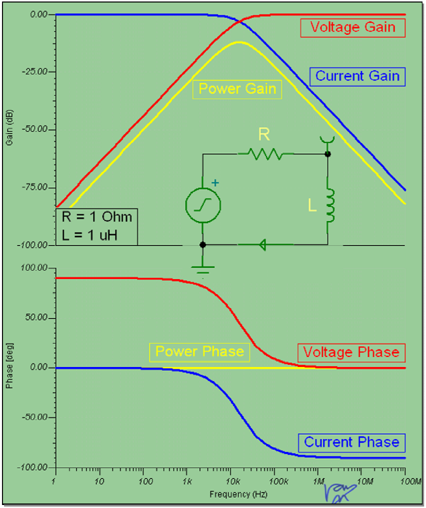
Additionally, those occasional plots with actual scales are for values and magnitudes of R, L, and C that have little to do with medium wave broadcast band work. In order to set or adjust my expectations, I prefer to see things in the scales I typically deal with. Finally, while SPICE and other software may be essential to evaluate complicated circuits, those typically found in crystal radio are really not beyond spreadsheet work.

Something about resonance. An RLC circuit contains both inductive L and capacitive C reactance. Inductive reactance



Circuit 4: One milliHenry Inductor Frequency Response

Next we want to know what happens if the inductance changes, say, to a thousandth of its value. That would be 1 microHenry (uH). Again, TINA computes the AC transfer characteristic, sweeping the frequency from 1 to 100 MegaHertz. This feels more like radio! Out pops our next graph. Decreasing the inductance has shifted all our gain curves to higher frequencies.



Circuit 5: One microHenry Inductor Frequency Response

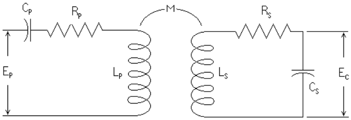
Maximum possible secondary current and maximum possible voltage across C_S, when:

$$\mathbf{E_C / E_P = (1/ 2k_c) * \sqrt{(L_S L_P)} = [\sqrt{(Q_P Q_S)} / 2] * \sqrt{(L_S L_P)}}$$

- goes to zero at unity coupling
- equals 3.01 dB (50 percent loss) at critical coupling
- becomes infinite at zero coupling.

If primary power held constant by adjusting the primary voltage as coupling is varied, then secondary voltage, current, power and power transfer all increase with increasing coupling. There are no maxima at critical coupling -- just the characteristic 3 dB power transfer loss.

Coupled Resonant Circuits, from Terman, p. 154, ff.



The coupling coefficient is:

$$\mathbf{k = M / \sqrt{(L_P L_S)}}$$

Voltage ratio:

$$\mathbf{E_C / E_P = -\sqrt{(L_S L_P)} * k / [k^2 + 1/(Q_P Q_S)]}$$

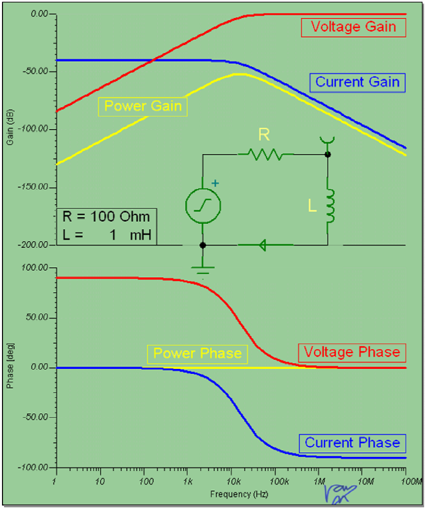
Voltage ratio is maximum when:

$$\mathbf{k = k_c = 1 / \sqrt{(Q_P Q_S)}}, \quad \text{and}$$

$$\boldsymbol{\omega} \mathbf{M = \sqrt{(R_P R_S)}}$$

Now we can run different cases for hours, and trust me, I have. The trick is to focus on essential relationships. What happens if we change the resistor value but not the inductor?

Let's return the inductor to 1 milliHenry and change the resistance from 1 to 100 Ohms. What happens? How does increased input resistance affect frequency response?



Circuit 6: Inductive Frequency Response – Increased Series Resistance

If we compare Circuit 4 and Circuit 6, there is a loss in current gain as a direct consequence of the resistor. That makes sense. So to first order, we observe that with respect to voltage we have a high pass filter – so named because high frequencies are

---

Resistance and reactance components of the coupled impedance (see 1.) are:

Resistance component: $$\frac{\mathbf{(\omega M)^2}}{\mathbf{R_S^2 + X_S^2}} * \mathbf{R_S}$$

Reactance component: $$\frac{\mathbf{-j\ (\omega M)^2}}{\mathbf{R_S^2 + X_S^2}} * \mathbf{X_S}$$

R_S and X_S are resistance and reactance components of Z_S.

The effect of the secondary on the primary is exactly as if these components had been inserted, in series, into the primary circuit. The energy and volt-amperes consumed by the primary current flowing through this hypothetical resistance and reactance represent the energy and reactive volt-amperes that are transferred to the secondary circuit. (Alternatively, $\mathbf{Z_P + (\omega M)^2 / Z_S}$ can be calculated directly using standard complex algebra.)

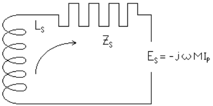
When primary and secondary are both resonant at the same frequency, X_S equals zero, the reactance component equals zero, and coupled impedance equals the resistance component, $\mathbf{(\omega M)^2 / R_S}$.

If, further, the coupling is critical, the coupled impedance is simply R_P.

If input voltage is held constant and coupling is varied, then primary and secondary currents and powers and secondary voltage all change with coupling.
Secondary voltage, current and power all reach maximum values when coupling is critical. Power transfer loss (from primary to secondary):

Z_S = series impedance of secondary when considered by itself

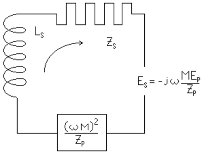
2. The voltage induced into the secondary by primary current, I_P, has a magnitude, ω M I_P, and lags the current that produces it by 90 degrees. The equivalent secondary circuit is:



(I_P is the primary current after the coupled impedance from the secondary has been factored in.)

3. The secondary current is exactly the same current that would flow if the induced voltage, E_S, were applied in series with the secondary and with the primary absent.

An alternate form of the equivalent secondary circuit is:



(Z_P is the primary series impedance before the coupled impedance from the secondary is factored in.)

---

passed and low frequencies are blocked. With respect to current, we have a low¬¬-¬¬¬¬pass filter, and with respect to power, we have a band-pass filter. Interesting, no?

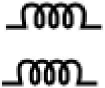
Inductor Calculations

Inductors are like resistors when it comes to equivalent circuits.

Adding two inductors in series gives the equivalent inductance of the pair:

$$\boxed{L_{series} = L_1 + L_2}$$

Formula: Series Equivalent Inductance



Use the product over sum for inductors in parallel:

$$\boxed{L_{parallel} = \frac{L_1 L_2}{L_1 + L_2}}$$

Formula: Parallel Equivalent Inductance

Transformers are inductors that are magnetically coupled by their proximity to each other. We will discuss them in more detail later.

Inductors have a kind of imaginary AC resistance called inductive reactance that has units of Ohms.

$$\boxed{X_L = 2\pi f L}$$

Formula: Inductive Reactance

Inductive circuits have a time constant that we alluded to above. This is the time it takes for the current to build up to 63.2% of its steady state value. The units are seconds.

$$\boxed{t_L = \frac{L}{R}}$$

Formula: Inductive Time Constant

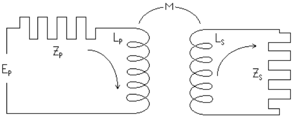
By choosing the right value of inductors, we can tailor the frequencies we block or pass using "analog filtering". More on that and its upscale digital cousin in a moment. Take a break. Don't become incapacitated!

Capacitors (Farads)

Chapter 2-3 Coupled Circuits

Inductively Coupled Circuits -- from Terman, p. 149, ff. See also Landee, Davis and Albrecht, Section 13.

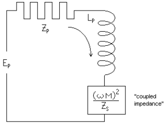
Terman Model:



Pertinent mesh equations:

$$\mathbf{E_P = I_P Z_P + j\omega M I_S}$$
$$\mathbf{E_S = -j\omega M I_P = I_S Z_S}$$ induced voltage in secondary

1. The effect of the presence of the secondary, coupled to the primary, is to add a series impedance, $\mathbf{(\omega M)^2 / Z_S}$, to the primary.



M = mutual inductance
$\omega = 2\pi * \text{frequency}$

- the coupled impedance components are added to the primary circuit impedance components to give the complex impedance of the primary.

- magnitude of the total primary current

- the current flow divides going through "Lp", thus the actual current through the L-R branch (through L) is proportional to the ratio of the L-R branch admittance magnitude to the overall "Lp" admittance magnitude:

L-R branch current = total primary current * | Y (L-R branch) | / | Y (Co branch) + Y (L-R branch) | (Note, the L-R branch current can actually exceed the total primary current due to the "tank" effect of the Co || (L-R) network.)

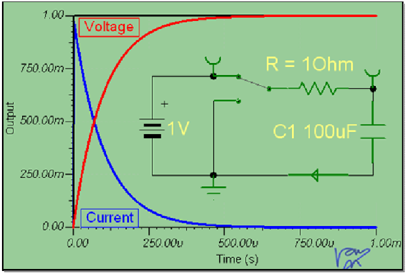
- the voltage induced into the secondary Es is calculated (step 2, above)

The voltage |V2| across load resistor Rload is Es times the ratio Rload / |total sec. impedance|.

---

store energy as an electric field. They consist of plates of foil separated by an insulating or dielectric material. Like their inductive counterparts, capacitors have a direct current (DC) response and an alternating current (AC) response.

When the switch is closed, there is a surge of current until charge accumulates on the plates of the capacitor. After several time constants, the circuit reaches “steady state”. The electric field is established and the current surge disappears. If the switch is opened, nothing happens but the capacitor remains fully charged! A large capacitor can shock you!



Circuit 7: Capacitor Voltage and Current Vs. Time, Transient DC Response

This simulation uses a 1-Farad capacitor, which is physically large, about the size of a large soup can. In radio, we typically work with much smaller values as we shall soon see. The principles and response curves are similar; the time constants are much shorter. Remember these units and abbreviations; you will use them often, especially nano and pico.

Unit	Abbrev.	"Of a Farad"	Multiplier	Comment
Farad	F	1	1	Huge!
milliFarad	mF	1 thousandth	10-3	Big!
microFarad	µF	1 millionth	10-6	Pwr. Sup.
nanoFarad	nF	1 billionth	10-9	Various
picoFarad	pF	1 trillionth	10-12	RF freq.

Table 1: Unit Prefixes, Abbreviations and Multipliers

Consider the same circuit as above, but we replace the DC battery with an AC signal generator like so.

The complex impedance and admittance of primary and secondary coils "Lp" and "Ls" are:

$$\mathbf{Z = R / [(1 - \omega^2 LCo)^2 + \omega^2 Co^2R^2]}$$

$$\mathbf{+\ j * \omega [L(1 - \omega^2 LCo) - CoR^2] / [(1 - \omega^2 LCo)^2 + \omega^2 Co^2 R^2]}$$

$$\mathbf{Y = R / [R^2 + \omega^2 L^2]\ -\ j * \omega[L(1 - \omega^2 LCo) - CoR^2] / [R^2 + \omega^2 L^2]}$$

The **spreadsheet** requires the following **input data**:

L, **Co** and, at each frequency, **R** for coils "Lp" and "Ls." (L's are true inductances.)

Coupling coefficient **k** or mutual inductance M.

Residual circuit resistances (if any) **Rpri** and **Rsec**.

The spreadsheet proceeds by calculating

- the complex impedance and admittance of the primary coil "Lp"

- the admittance calculation is checked by calculating the admittances of the parallel legs in "Lp": the Co leg and the series L-R leg.

- the complex impedance of secondary coil "Ls"

Resistance and reactance components of the **coupled impedance** are:

Resistance component: $$\frac{(\omega M)^2}{R_S^2 + X_S^2} * R_S$$

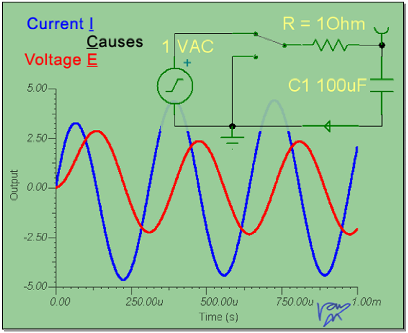
Reactance component: $$\frac{-j\ (\omega M)^2}{R_S^2 + X_S^2} * X_S$$

$\mathbf{R_S}$ and $\mathbf{X_S}$ are the resistance and reactance components of $\mathbf{Z_S}$.

The effect of the secondary on the primary is exactly as if these components had been inserted, in series, into the primary circuit. The energy and volt-amperes consumed by the primary current flowing through this hypothetical resistance and reactance represent the energy and reactive volt-amperes that are transferred to the secondary circuit. (Alternatively, $Z_P + (\omega M)^2 / Z_S$ can be calculated directly using standard complex algebra.)

2. The voltage **Es** induced into the secondary by primary current, $\mathbf{I_P}$, has a magnitude, $\boldsymbol{\omega}$ **M** $\mathbf{I_P}$, and lags the current that produces it by 90 degrees. $\mathbf{I_P}$ is the primary current after the coupled impedance from the secondary has been factored in.

3. The secondary current is exactly the same current that would flow if the induced voltage were applied in series with the secondary and with the primary absent.



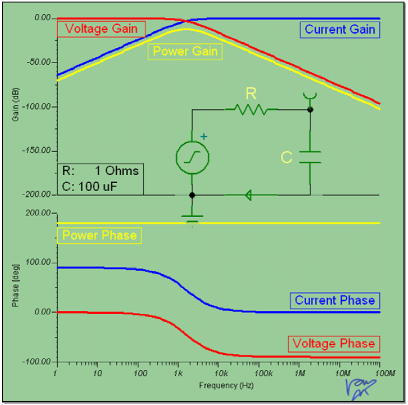
Circuit 8: Capacitive AC Response

The AC signal causes the capacitor’s electric field to repeatedly collapse and expand in alternating directions. Ohm’s law is constantly running, and again there is a phase delay. Current Causes Voltage in a capacitor. The word “Causes” is just a hack so that we remember the C for Capacitor in the famous ELI-the-ICE-man phrase that reminds us that voltage leads current in inductors and current leads voltage in capacitors.

Frequency Response: What Happens When Capacitance and Resistance Change?

Just like before we play with capacitance and resistor values to see what happens in our circuit.

Again, we will measure this by comparing the gain of various configurations. First, we fix the resistor at 1 Ohms and set the capacitor to 100 uF. Then we ask TINA to compute the AC Transfer Characteristic. A graph again provides insight:

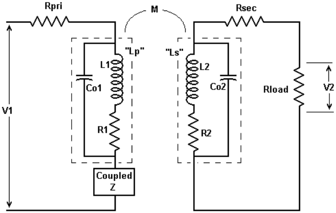


Circuit 9: 100 uF Capacitor Frequency Response

As before we want to know what happens if the capacitance changes, this time to a hundredth of its value. We set the capacitor to 1 uF (1 microFarad). Again, TINA computes the AC transfer

Terman Inductive Coupling Model

Mike Tuggle
(Personal Comm)



While the primary and secondary circuit impedances involve the Co || (L-R) networks "Lp" and "Ls", we assume that the coupling between circuits is a function solely of true inductances L1 and L2 and their mutual inductance M.

The **basis of the calculation** is drawn from F.E.Terman, Radio Engineers' Handbook, 1st ed., 1943, p. 148 ff:

1. The effect of the presence of the secondary, coupled to the primary, is to add a series impedance, **coupled Z =** $(\omega M)^2 / Z_S$, to the primary, where:

M = mutual inductance
$\omega = 2\pi * \text{frequency}$
Z_S = series impedance of secondary when considered by itself

v3 = jω M23 i2

The voltage v1 induced in L1 will be:

v1 = jω M12 i2

Since voltages in series must add up, the voltage across the entire coil v1 will be:

v1 = v2 + v3

Putting these voltages in terms of i2 from the previous relationships, we get

jωM12 i2 = jωL2 i2 + jωM23 i2

Taking out the common factor jωi2, this simplifies to

M12 = L2 + M23

This page last updated: January 3, 2016

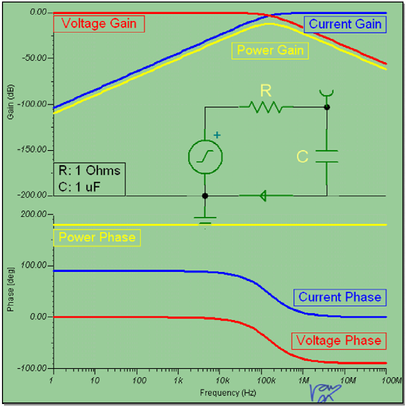
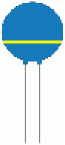
characteristic, sweeping the frequency from 1 to 100 MegaHertz. That radio feeling is coming on strong.

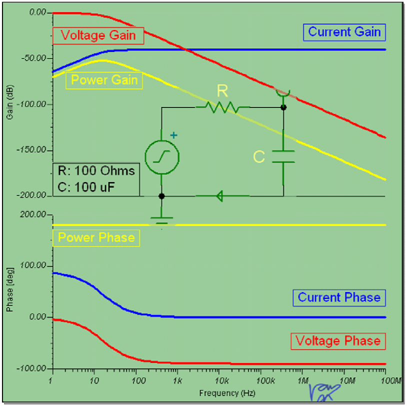


Circuit 10: 1 uF Capacitor Frequency Response



Are you starting to see a pattern? What happens if we change the value of the resistor but not the capacitor? Let’s return the capacitor to 100 uF and change the resistance from 1 to 100 Ohms.

What happens? How does increased series resistance affect circuit frequency response?



Circuit 11: Capacitive Frequency Response – Increased Series Resistance

If we compare Circuit 9 and Circuit 11, there are two effects of keeping the same capacitor and increasing the resistance. Current gain decreases. That makes sense. The second effect is to shift the curves to the left. It looks like we increased the capacitance, but we didn't.

---

components. To develop formulae to find the required component values is beyond the scope of this discussion. In this case we are better off availing ourselves of a spreadsheet using these formulae, and then plugging in various values until we have the desired frequency range. If it turns out that the practical values of inductor and bandspread capacitor we have to work with don't give a narrow enough frequency range, we can of course, reduce the range of the bandspread capacitor as we did in Parts 1 and 2 by adding a padder and/or trimmer.

Acknowledgement

I would like to express my thanks to Mike Tuggle who provided valuable feedback and also performed SPICE simulations verifying the formulae.

Appendix

Derivation of Mutual Inductance Between a Coil and a Section of the Same Coil

Using the same notation as used previously, L1 is the inductance of the entire coil, L2 is the inductance of the bottom section, and L3 is the inductance of the top section.

If an AC voltage source v2 is impressed across L2, the current i2 will be:

$$\mathbf{i2 = v2/(j\omega L2)}$$

and hence

$$\mathbf{v2 = j\omega L2\ i2}$$

The voltage v3 induced in L3 will be:

$$(1-k^2)L_1L_2C_AC_B\omega^4 - L_1C_A\omega^2 - L_2C_B\omega^2 + 1 = 0 \tag{31}$$

where the coupling coefficient k is given by:

$$k = \frac{L_1 + L_2 - L_3}{2\sqrt{L_1L_2}}$$

and then (31) can be solved for frequency using the usual quadratic formula:

$$x = \frac{-b - \sqrt{b^2 - 4ac}}{2a}$$

where:

$x = \omega^2$

$a = (1-k^2)L_1L_2C_AC_B$

$b = -(L_1C_A + L_2C_B)$

$c = 1$

Having calculated x from the above, the resonant frequency F will be

$$F = \frac{\sqrt{x}}{2\pi}$$

where F is in Hz, and the other component values are given in Farads and Henries.

For convenience, the calculation may be done using picofarads and microhenries, but the resulting frequency will then be in Gigahertz, and therefore will need to be multiplied by 1,000,000 to get kHz. Hence:

$$F = \frac{10^6\sqrt{x}}{2\pi}$$

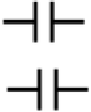
In contrast to Parts 1 and 2, where we selected an arbitrary frequency range and then developed formulae to find the necessary components values, here we have developed a formula to find the resonant frequency from a given set of

---

We observe that our capacitor drains more slowly when the resistance is higher. In an opposite sense to inductors, capacitors are a low-pass filter with respect to voltage and a high-¬¬¬¬pass filter with respect to current. With respect to power, we have a band-pass filter as before.

Capacitor Calculations

Capacitors are the opposite of inductors and resistors when it comes to equivalent circuits.



Because it looks like increasing plate area, adding two capacitor values gives the PARALLEL equivalent capacitance:

$$\boxed{C_{parallel} = C_1 + C_2}$$

Formula: Parallel Equivalent Capacitance

Use the product over sum for capacitors in SERIES:

$$\boxed{C_{series} = \frac{C_1 C_2}{C_1 + C_2}}$$

Formula: Parallel Equivalent Inductance

There isn’t the capacitive equivalent of a transformer.

Capacitive circuits have a time constant. This is the time it takes for the voltage to build up to 63.2% of its steady state value. The units are seconds.

$$\boxed{t_C = RC}$$

Formula: Capacitive Time Constant

Capacitors also have a kind of imaginary AC resistance called capacitive reactance that has units of Ohms.

$$\boxed{X_L = \frac{1}{2\pi f C}}$$

Formula: Capacitive Reactance

That’s it for capacitance right now. Consult the references in the last chapter if you want to delve in deeper than time allows here.

Summary – Capacitance and Inductance:

The figure below summarizes what we have just discovered by direct simulation. Inductors and Capacitors are the inverses of each other. This is an idea as deep as the electron itself.The left

aiding or opposing, and the sign and value of M12 will be self-evident.

If we are dealing with the single tapped winding of the circuit in figure 1, then we can directly measure the values of L1, L2 and L3.

Then the mutual inductance between L2 and L3, is

$$M_{23} = \frac{L_1 - L_2 - L_3}{2}$$

And it can be shown (see Appendix below) that the mutual inductance between L1 and L2 is

$$M_{12} = M_{23} + L_2$$

Hence:

$$M_{12} = \frac{L_1 + L_2 - L_3}{2}$$

Now that we have determined M12 by one of the above methods, the coupling coefficient is then given by:

$$k_{12} = \frac{M_{12}}{\sqrt{L_1 L_2}}$$

or combining these two formula, we get:

$$k_{12} = \frac{L_1 + L_2 - L_3}{2\sqrt{L_1 L_2}}$$

This now gives us all the information required to calculate resonant frequency of the bandspread tank circuit.

Summary

The relationship between component values, and resonant frequency of a tapped coil bandspread circuit has been given by formula (31):

$$x = \omega^2$$
$$a = (1 - k^2) L_1 L_2 C_A C_B$$
$$b = -(L_1 C_A + L_2 C_B)$$
$$c = 1$$

Note, that a quadratic equation will generally have two solutions because the square root portion can be either positive or negative. For normal situations, the form given above will provide the correct frequency. The other result is equally valid mathematically, and will give a much higher resonant frequency which we may interpret as a parasitic. Therefore, it may be prudent to ensure that related circuit components are selected to prevent operation at undesired frequencies.

Now, we can plug the component values into the above formula and solve for ω2, and consequently solve for ω and frequency.

The only value that will not be readily known is the coupling coefficient. However it can be calculated from the other coil parameters.

If we are dealing with the isolated windings of the circuit in figure 2, then we can measure the inductance of the two windings separately, and then connect them in series, and measure them again. Using the following formula, the mutual inductance can be calculated:

$$L_{SERIES} = L_1 + L_2 \pm 2M_{12}$$

Hence:

$$M_{12} = \pm \frac{L_{SERIES} - L_1 - L_2}{2}$$

The contribution due to M12 will be positive or negative depending on whether the polarity of the series connections are

---

column shows a capacitive circuit and the right column shows its inductive counterpart. The component values are summarized in the lower left corner of each diagram. As before voltage gain is red, current gain is blue, and power gain is yellow.

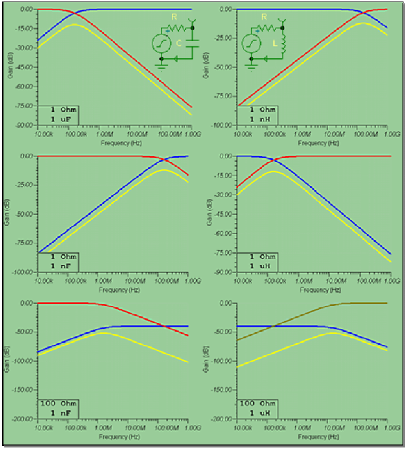


Figure 8: Side-By-Side Comparison - Capacitance and Inductance

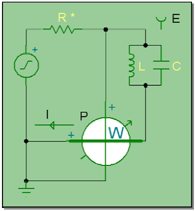
RLC Behavior – Parallel Case

Consider an RLC circuit where the inductor and capacitor are in parallel. The following figures catalog voltage, current and power gain as we vary component values. You can reproduce these results in Tidy TINA and see which values result in which curves, a worthwhile bit of fun. The flat line in each image is the gain for the source, set to 1 milliVolt to simulate a strong radio station.



Circuit 12: RLC Circuit – Parallel LC

$$Z_N = Z_{CA} \,||\, \frac{(k^2-1)\omega^2 L_1 L_2 + j\omega L_1 Z_{CB}}{j\omega L_2 + Z_{CB}} \tag{26}$$

Next, we invert the formula so that we can combine the parallel impedances:

$$\frac{1}{Z_N} = \frac{1}{Z_{CA}} + \frac{j\omega L_2 + Z_{CB}}{(k^2-1)\omega^2 L_1 L_2 + j\omega L_1 Z_{CB}} \tag{27}$$

Also note that the reciprocal of the impedance is the admittance, and at parallel resonance the admittance 1/ZN (neglecting any resistive components) will be zero. Hence:

$$\frac{1}{Z_{CA}} + \frac{j\omega L_2 + Z_{CB}}{(k^2-1)\omega^2 L_1 L_2 + j\omega L_1 Z_{CB}} = 0 \tag{28}$$

Capacitive reactance is given by:

ZC = – j/(ωC) = 1/(jωC)

Substituting this for the ZCx terms in the formula:

$$j\omega C_A + \frac{j\omega L_2 + \frac{1}{j\omega C_B}}{(k^2-1)\omega^2 L_1 L_2 + \frac{L_1}{C_B}} = 0 \tag{29}$$

Multiplying everything by the denominator of the fraction:

$$j\omega C_A((k^2-1)\omega^2 L_1 L_2 + \frac{L_1}{C_B}) + j\omega L_2 + \frac{1}{j\omega C_B} = 0 \tag{30}$$

and then multiplying by jωCB we get a relatively simple formula:

$$(1-k^2)L_1 L_2 C_A C_B \omega^4 - L_1 C_A \omega^2 - L_2 C_B \omega^2 + 1 = 0 \tag{31}$$

Since there are no ω or ω3 terms we can solve this as yet another quadratic equation:

$$x = \frac{-b - \sqrt{b^2 - 4ac}}{2a}$$

where

Note that when we convert from impedance to capacitance, 1/n2 becomes n2. Also, since n=N2/N1, and we assume that because N2 represents the tapped part of the coil in the original circuit, it is smaller than N1. Hence, n will be less than 1. Therefore, when CB is transferred to the primary side, its effective value becomes smaller.

We have demonstrated that if the coupling coefficient is 1, then the equivalent circuit is reduced to the secondary impedance multiplied by the turns ratio and transferred to the primary in parallel with the primary inductance and capacitance, which agrees with traditional transformer theory. The capacitor CB on the secondary side can be scaled by multiplying by n2 and placed in parallel with CA on the primary side. However, it's worth noting one important fact. In traditional transformer theory, the self inductance of the primary is generally considered much higher than the transferred impedance from the secondary side, and is often neglected. However, we can't neglect it in our case, since it forms the inductive part of the resonant circuit.

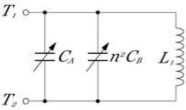


Figure 5

Since we have carried the effect of the coupling coefficient k through to formula (21), we can go back a few steps and see the effect of a coupling coefficient less than 1.

Starting with (21) again:

$$Z_N = Z_{CA} \,||\, \frac{-\omega^2 L_1 L_2 + j\omega L_1 Z_{CB} + \omega^2 k^2 L_1 L_2}{j\omega L_2 + Z_{CB}} \qquad (21)$$

First we combine the common ω2L1L2 terms

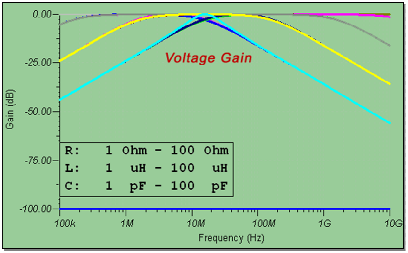

Figure 9: RLC Circuit – Parallel LC – Voltage Gain

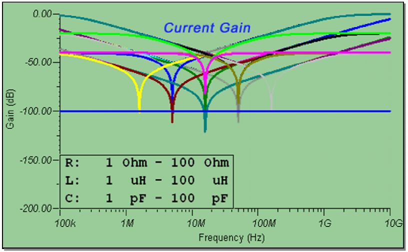

Figure 10: RLC Circuit – Parallel LC – Current Gain

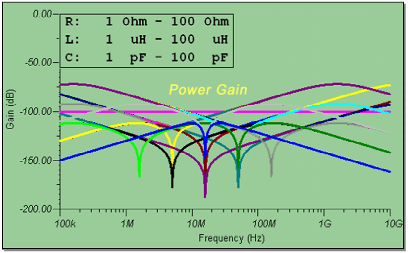

Figure 11: RLC Circuit – Parallel LC – Power Gain

RLC Behavior – Series Case

Consider an RLC circuit where the inductor and capacitor are in series. Note the difference in the response curves in series versus parallel components. You can right click a specific curve in Tidy TINA to discover the RLC values that gave rise to it. One thing you will notice is that while the parallel case is a band-stop filter for RF power, the series case is a band-pass in most cases. The peakiness of the filter is the Q or Quality Factor of the resonant circuit. More on that later. Notice that series resistance hurts performance of the band-pass filter, turning it into a band-stop filter! Not good for tuning in your favorite crystal radio station. Again, we set the source to 1 mV to simulate a strong station. We will make those conditions more severe later.

Taking everything on the right to a common denominator:

$$Z_N = Z_{CA} \,||\, \left(\frac{j\omega L_1(j\omega L_2+Z_{CB})}{j\omega L_2+Z_{CB}} + \frac{\omega^2 k^2 L_1 L_2}{j\omega L_2+Z_{CB}}\right)$$

$$Z_N = Z_{CA} \,||\, \left(\frac{j\omega L_1(j\omega L_2+Z_{CB})+\omega^2 k^2 L_1 L_2}{j\omega L_2+Z_{CB}}\right) \quad (20)$$

Remembering that **j2=-1**:

$$Z_N = Z_{CA} \,||\, \frac{-\omega^2 L_1 L_2 + j\omega L_1 Z_{CB} + \omega^2 k^2 L_1 L_2}{j\omega L_2+Z_{CB}} \quad (21)$$

Notice that in the numerator, the first and last terms will cancel each other out when k=1. Let's assume for the moment that this is the case. Then we are left with:

$$Z_N = Z_{CA} \,||\, \frac{j\omega L_1 Z_{CB}}{j\omega L_2+Z_{CB}} \quad (22)$$

Also when k=1, the n2 relationship exists between inductance values as previously mentioned:

L2/L1 =(N2/N1)2=n2

where we define n as the turns ratio. Substituting L2/n2 for L1

$$Z_N = Z_{CA} \,||\, \frac{1}{n^2}\frac{j\omega L_2 Z_{CB}}{j\omega L_2+Z_{CB}} \quad (23)$$

Notice that we now have a fraction in the form of AB/(A+B) which is the formula used when combining parallel impedances. Therefore, this is equivalent to having A and B in parallel. Hence:

$$Z_N = Z_{CA} \,||\, \frac{1}{n^2} Z_{CB} \,||\, \frac{1}{n^2} j\omega L_2 \quad (24)$$

or

$$Z_N = Z_{CA} \,||\, \frac{1}{n^2} Z_{CB} \,||\, j\omega L_1 \quad (25)$$

So, for the case of k=1 (which would generally apply in the situation of a coil on a ferromagnetic core), we can redraw our circuit as shown in figure 5.

From this we can define Z', the coupled impedance as:

$$Z' = \frac{(\omega M)^2}{Z_2+Z_{CB}} \qquad (16)$$

Using equation (16) we can simplify the circuit of figure 3 into a single loop as shown in figure 4.

In summary then, the effect that the current flowing in the secondary circuit has on the primary circuit can be treated as another voltage drop VZ' due to an impedance Z' applied to the primary circuit as shown in figure 4. Here, Z' is placed in series with the other primary circuit components, and completely accounts for the effect due to the secondary circuit. We have now reduced the original two loop circuit to a single loop circuit.

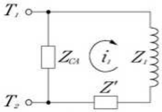

Figure 4

The net impedance ZN of the primary circuit is:

$$Z_N = Z_{CA} \mid\mid (Z_1 + \frac{(\omega M)^2}{Z_2+Z_{CB}}) \qquad (17)$$

where || indicates components combined in parallel.

Substituting (11) into (17) we put M in terms of L1 L2 and k.

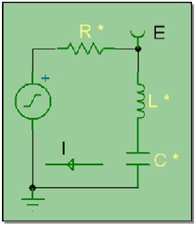
$$Z_N = Z_{CA} \mid\mid (Z_1 + \frac{\omega^2 k^2 L_1 L_2}{Z_2+Z_{CB}}) \qquad (18)$$

If we neglect any resistance in the circuit, then the impedances are purely reactive. The impedance of an inductor is given as:

$$Z=j\omega L$$

Hence:

$$Z_N = Z_{CA} \mid\mid (j\omega L_1 + \frac{\omega^2 k^2 L_1 L_2}{j\omega L_2+Z_{CB}}) \qquad (19)$$



Circuit 13: RLC Circuit – Series LC

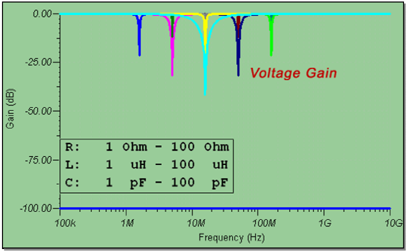


Figure 12: RLC Circuit – Series LC – Voltage Gain

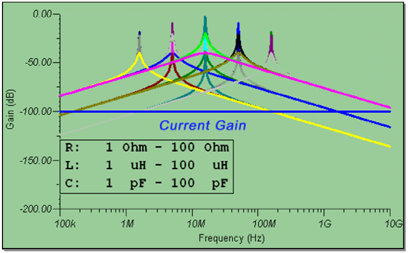

Figure 13: RLC Circuit – Series LC – Current Gain

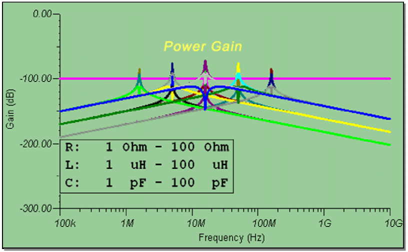

Figure 14: RLC Circuit – Series LC – Power Gain

Now, let us assume that a sinusoidal alternating voltage VT is applied across terminals T1 and T2. This causes an alternating current i1 to flow in the primary circuit. This is illustrated in figure 3, which shows the circuit components as impedances.

From the previous definition of mutual inductance, then this alternating current induces a voltage VZ2 in the secondary circuit across Z2, which in turn causes a current i2 to flow in the secondary circuit.

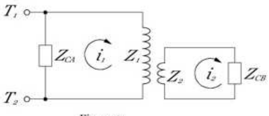

Figure 3

Now, current i2 in the secondary also induces a voltage VZ1 back in the primary across Z1.

The voltage and current relationships are given by the following formulae:

$$V_T = i_1 Z_1 + j\omega M i_2 \tag{12}$$

$$i_2 = \frac{V_{Z2}}{Z_2+Z_{CB}} \tag{13}$$

$$V_{L2} = -j\omega M i_1 \tag{14}$$

The second term in equation (12) shows that the effect of the secondary circuit corresponds to a voltage drop. We can substitute in equations (13) and (14) to get this voltage drop in terms of i1.

$$V_T = i_1 Z_1 + \frac{(j\omega M)(-j\omega M) i_1}{Z_2+Z_{CB}}$$

or

$$V_T = i_1 Z_1 + \frac{(\omega M)^2}{Z_2+Z_{CB}} i_1 \tag{15}$$

L2/L1 =(N2/(N2 +N3))2=(N2/N1)2

etc.

However, except as specifically noted below we will not make any assumptions about the value of the coupling coefficient.

Note that L1 is not equal to L2+L3 (except when k=0). The inductance of the entire coil is, in fact, given by:

L1=L2+L3+2M23

We will leave the circuit of Figure 1 for the time being, and deal with an equivalent coupled circuit consisting of completely separate windings as shown in Figure 2.

In this circuit, we will still assume that even though the coils are separate, they are still inductively coupled. Notice also, we keep the same terminology between figures 1 and 2 such that CA is still connected across L1 and CB is still connected across L2. We will also assume that L1 has the same number of turns in both figures and L2 has the same number of turns in both figures. Consequently, for the purpose of this analysis, both circuits will behave essentially the same. The reason for separating the bandspread section of the circuit into an electrically isolated winding is to make the circuit analysis a bit simpler to follow.

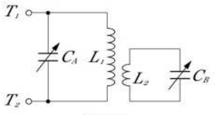

Figure 2

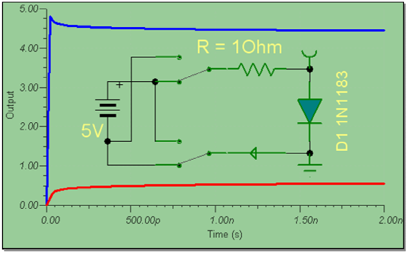
Diodes
do not store energy like capacitors and inductors. They are one-way valves for the flow of current. They are arguably the most important single component in radio because of the multiple purposes they serve. Diodes are semiconductors consisting of a P-N junction doped to attain desireable characteristics. Like their siblings, diodes have a direct current (DC) response and an alternating current (AC) response. These responses can be steady state or transient. Let’s throw the switch!

Notice that the circuit below uses two single pole double throw switches connected so that we can switch the polarity on the diode. We retain the series resistor as a current-limiting resistor, although in a real circuit, say with a light-emitting diode, the value would be considerably higher, between 500 and 2000 Ohms to prevent the diode from burning out.

In this simulation we assume the diode can take whatever the flow of current is and we observe the transient DC response for two cases. The first case when both switches are down, corresponds to the normal polarity of DC voltage seen in previous examples. The diode is positioned so that this is a forward voltage corresponding to the direction in which the diode allows current to flow. The current curve is blue and the forward voltage curve is red. Notice that the diode takes only a few picoseconds for the diode to switch on. The time it takes a diode to turn on is an imporant parameter of the diode, especially for radio work.



Circuit 14: Diode Transient DC Response – Forward Current

Now let's reverse the position of both switches to simulate flipping a double pole double throw (DPDT) switch. This reverses the polarity of the battery. What do think the curves will look like?

$$V_2 = \omega M i_1 \qquad (10)$$

and conversely

$$V_1 = \omega M i_2$$

where the subscripts 1 and 2 designate the parameters of the first and second coil respectively. M is the mutual inductance between the two coils, and the voltages and currents are sinusoidal at an angular frequency ω=2πf. (ω is the lowercase Greek letter omega.) If the two coils are perfectly coupled, then

$$M = \sqrt{L_1 L_2}$$

If they are not perfectly coupled then we introduce a coupling coefficient into the relationship thus:

$$M = k\sqrt{L_1 L_2} \qquad (11)$$

where k ranges between zero (no coupling at all) and one (perfect coupling).

From Figure 1:

L3 is the inductance of the upper section of the coil, and has N3 turns

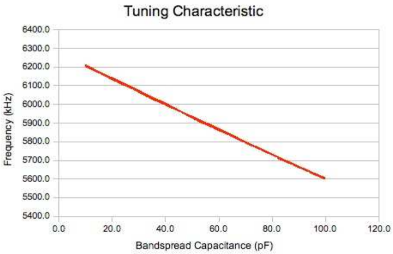
L2 is the inductance of the bottom section of the coil, and has N2 turns

L1 is the total inductance of the whole coil and has N1=N2+N3 turns

If the coupling coefficient is one, then there is a direct relationship between number of turns and inductance, and the following relationships apply:

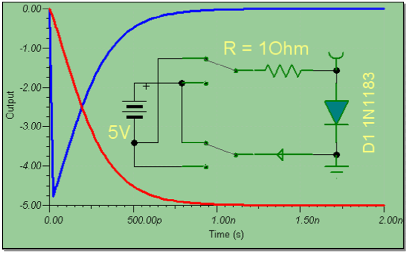
L3/L2=(N3/N2)2

linear relationship between frequency and tuning capacitance, as the following graph illustrates:



In this analysis we will treat the coil as an autotransformer keeping in mind that traditional transformer theory diverges somewhat from loosely coupled coil theory. With transformer theory, the coupling coefficient between windings is nearly unity, which allows for a few simplifications. Therefore, in this analysis, we will need to adjust the model to account for the fact that the sections of the coil are loosely coupled. (This work is based largely on the information provided in the classic texts: 'Radio Engineering' and 'Radio Engineer's Handbook,' both by Frederick E. Terman.)

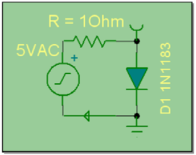
When two coils are inductively coupled, then a current in one coil will induce a magnetic flux in the other coil and vice versa. When the current in one coil changes, the flux changes, and the changing flux will induce a voltage in the other coil according to this relationship:



Circuit 14: Diode Transient DC Response – Reverse Current

This case shows the diode in the direction it does not want to conduct. There is a momentary surge of current until the diode turns off. Note that it takes this diode longer to turn off than it does to turn on – in the simulation at least. About a nanosecond. Do these curves remind you of anything familiar?

Now let's replace the DC battery with an AC signal generator and simplify the circuit to. We don't need the DPDT switch, because the AC signal generator is doing that for us. The simplified circuit looks like this:



Circuit 15: Diode AC Circuit

Let’s run the signal generator at a low frequency, say 60 Hz. This is the frequently encountered in power supplies running from wall current in the US after a step-down transformer. We obtain the expected and classic waveform for half-wave rectification of an AC signal.

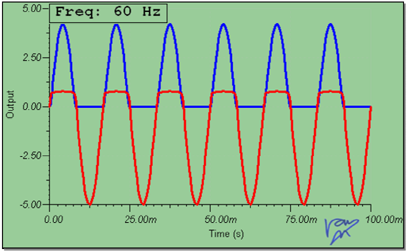


Figure 15: Diode 60 Hz Frequency Response

Now let’s run the frequency up to the high end of the audio sampling spectrum, say 44 kHz. Notice that we start

---

Using a Bandspread Capacitor

Robert Weaver

http://electronbunker.ca/eb/Bandspreading_3.html

Connected to a Tap on the Tank Coil

Here in Part 3, we take off in another direction. We are going to analyze a method of bandspreading where the bandspread capacitor is connected to a tap on the tank inductor, and a bandset capacitor is connected across the entire coil. This configuration is shown in Figure 1.

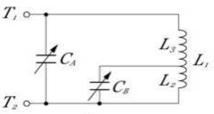

Figure 1

This is a system that has been used on both commercial and homebrew shortwave receivers dating back to the 1930’s. The circuit is as shown in figure 1. In this circuit, the main “Bandset” variable capacitor is CA, and may be either fixed or variable, while the “Bandspread” capacitor CB is variable.

In essence, the goal is to find a relationship between circuit impedance across terminals T1 & T2 and frequency for given values of capacitance and inductance.

Before we go any further, we may ask ourselves why we want to do something that looks quite a bit more complicated than the bandspread arrangements we have already looked at. The answer, as we will discover, is that this gives a remarkably is no longer maximum at resonance. As we have already noted, at a frequency slightly below resonance the coupled impedance is *inductive*, whereas the impedance of the series tuned primary is *capacitive*. Therefore there are two frequencies, one slightly above the resonant frequency and one slightly below where the coupled reactance tunes the primary reactance to give minimum total primary impedance and therefore maximum primary current. This double hump in the primary current tends to flatten the peak of the secondary current response curve since the emf induced into the secondary at the resonant frequency is not quite as great as at the two hump frequencies either side of resonance.

If the tuned circuits are overcoupled, the increase in coupled impedance moves the primary current humps further apart. This in turn causes such a decrease in primary current at resonance that the secondary current also starts to show a double humped curve as shown in Fig. 19.15. In practice a coefficient of coupling of 1.5 times the critical coefficient of coupling produces such a slight dip in the secondary current at resonance that the resulting secondary current resonance curve has a very desirable flat top with steep skirts.

---

encountering some switching noise as we approach the switching speed of the diode.

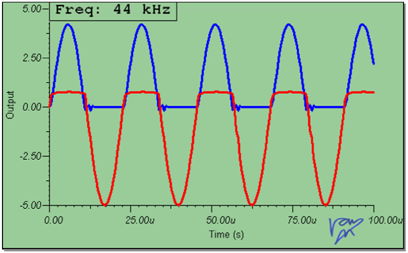

Figure 16: Diode 44 kHz Frequency Response

Finally let’s run the diode at a frequency we might encounter in our crystal radio, say the middle of the AM band:

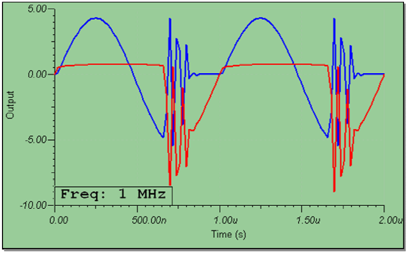

Figure 17: 1N1183 Diode 1 MHz Frequency Response

Now our signal is dominated by switching noise. This particular diode, can't switch fast enough to rectify the signal. Notice the ringing. The only way to see it is to integrate using the Gear method with a 6th order integration. Changing the diode to a faster 1N4150 largely eliminates the ringing.

---

a **critical coupling** for a given pair of tuned circuits at which maximum energy transfer from primary to secondary takes place.

At resonance, $Z_p = R_p$

and the coupled $Z = \dfrac{(\omega M)^2}{R_s}$

Therefore for critical coupling,

$$M^2 = R_pR_s/\omega^2$$

But $M^2 = K^2L_pL_s$ (19.32)

Therefore $K^2 = \dfrac{R_p}{\omega L_p} \times \dfrac{R_s}{\omega L_s}$

from which $K_c = \dfrac{1}{\sqrt{Q_pQ_s}}$ (19.40)

With critical coupling, the secondary current attains its greatest value. But with the coupled impedance rising at resonance, the primary current

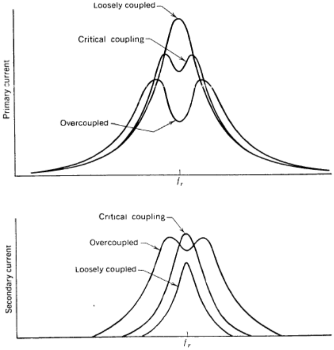

Fig. 19.15. Effect of coefficient of coupling on the resonance curves of a tuned transformer.

Considering now the effect of tuning the secondary circuit, the total secondary circuit impedance [$\mathbf{Z}_s + \mathbf{Z}_L$ in Equation (19.39)] will be minimum and equal to R_s at resonance. Therefore the secondary circuit behaves like a series resonant circuit. Since $(\omega M)^2$ is essentially constant over the small range of frequencies near resonance, when $\mathbf{Z}_s + \mathbf{Z}_L$ becomes a *minimum*, the coupled impedance becomes a *maximum* as shown in Fig. 19.14. And when the source frequency is slightly lower than the resonant frequency, X_C, is greater than X_L, and the secondary impedance becomes capacitive. But dividing a *capacitive* impedance into $(\omega M)^2$ with its 0° angle results in an *inductive* coupled impedance. Therefore, as far as the signal source is concerned, the secondary behaves as if it were a *parallel* resonant circuit in *series* with the primary winding.

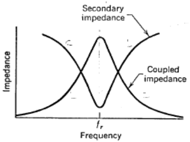

Fig. 19.14. Effect of a tuned secondary circuit.

The primary impedance by itself in the circuit of Fig. 19.13 is attempting to become a minimum at resonance in order to allow maximum primary current to flow. But the coupled impedance is attempting to raise the primary impedance at resonance, thus limiting the maximum primary current. The extent to which the coupled secondary tuned circuit affects the primary resonance curve depends on the degree of coupling between the coils. When the coupling is very loose, the mutual inductance is very small and even at resonance the coupled impedance is *smaller* than the resistance of the primary circuit. Under these circumstances, the only effect that the coupled secondary has on the shape of the primary current resonance curve is to limit its peak value slightly. The secondary current tends to have the usual series resonance curve. But with loose coupling, since the primary current rises to a maximum at resonance and since the secondary induced emf depends on the primary current, the secondary resonance curve is much sharper than that of a single tuned circuit having the same Q.*

We will recall from earlier studies that maximum transfer of energy occurs when the load resistance is equal to the resistance of the source. Applying this to magnetically coupled tuned circuits, maximum energy transfer will take place when the coupled resistance is equal to the primary circuit resistance. Since the coupled resistance depends on the mutual inductance, which in turn depends on the coefficient of coupling, there is

---

* The bandwidth is approximately $\Delta f \approx Kf_r$.

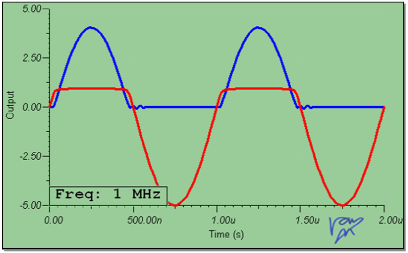

Figure 18: 1N4150 Diode 1 MHz Frequency Response

Diode Calculations

For low frequency applications diodes can be stacked in series.

Connecting two diodes in series doubles the peak reverse voltage (PRV) rating:

$$\boxed{PRV_{series} = PRV_1 + PRV_2}$$

Formula: Series Equivalent Inductance

Connecting two diodes in parallel doubles the current rating:

$$\boxed{I_{parallel} = I_1 + I_2}$$

Formula: Series Equivalent Inductance

It the first case it is necessary connect a high value resistor across eacg diode to minimize transients and equalize slight differences in the characteristics of the diode. One rule of thumb is to multiply the PRV of the diode by 400. In the second a low-value resistor, usually less than an ohm, is connected in series with the pair of diodes.

Summary

This concludes chapter one. We have seen a simple radio, a crystal radio, and how each of the parts work. Now we will look in detail at fundamentals of software defined radio, including software and hardware.

---

the vector division, dividing an impedance with a + angle into $(\omega M)^2$ with its 0° angle results in a *capacitive* coupled impedance. Since $\boldsymbol{Z}_p$ is largely *inductive*, the *capacitive* impedance coupled into the primary circuit via the mutual inductance adds the coupled resistance component in series with the primary resistance component but *reduces* the total primary reactance. As a result, the total impedance becomes smaller as the secondary is loaded with a resistance, thus allowing more primary current to flow in order to transfer energy to the secondary circuit. This then checks with our first approach to transformer action in which we discovered that primary current must increase when a transformer is loaded in order to keep the amplitude of the mutual flux sine wave constant.

Example 8: If the resistance of the windings can be neglected, determine the total input impedance to the transformer of Examples 6 and 7, (a) with the secondary open circuit, and (b) with a 50 ohm resistance connected to the secondary.

Solution:

(a) $$\boldsymbol{Z}_{in} = \boldsymbol{Z}_p = \omega L_p = 377 \times 5 = +j1885 \text{ ohms}$$

(b) $$\text{Coupled } \boldsymbol{Z} = \frac{(\omega M)^2}{\boldsymbol{Z}_s + \boldsymbol{Z}_L} = \frac{(377 \times 1.67)^2}{+j(377 \times 0.8) + 50}$$

$$= \frac{396000\angle 0^\circ}{304\angle 80.5^\circ} = 1300\angle -80.5^\circ = 213 - j1284 \text{ ohms}$$

$$\therefore \quad \boldsymbol{Z}_{in} = (+j1885) + (213 - j1284) = 213 + j601$$
$$= \mathbf{636 \text{ ohms}\angle +70.5^\circ}$$

7. Tuned Transformers

The most important application of loose coupling is the use of tuned transformers in radio circuitry. If we consider the source of emf to be a constant voltage source as in Fig. 19.13, the primary winding is designed to form a series resonant circuit with the capacitive reactance of C_p equal to the inductive reactance of the primary winding at the desired resonant frequency. This will result in maximum current in the primary winding at resonance (neglecting for the moment any coupled impedance due to secondary current).*

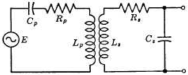

Fig. 19.13. A tuned transformer.

---

* If a vacuum-tube amplifier is used to feed the primary of a tuned transformer, the vacuum tube represents a constant *current* source providing a signal current equal to the mutual conductance of the tube times the signal input voltage to its grid. Hence C_p must then be connected in *parallel* with the primary winding to obtain maximum primary current (resonant rise of current) at resonance.

form of equivalent circuit for this transformer, representing the self-induced emf by an inductance symbol and the mutually induced emf by a generator symbol. To satisfy Lenz's law, the polarity of the generator must be such that it opposes changes in $\mathbf{I}_1$ due to the applied emf $\mathbf{E}_1$. Hence, changing the polarity of the generator symbol in the secondary circuit will *not* change the polarity of the voltage $\mathbf{I}_s(+j\omega M)$ in the primary circuit. Consequently, Kirchhoff's voltage law equation for the primary loop becomes

$$\mathbf{E}_p = \mathbf{I}_p(R_p + j\omega L_p) + \mathbf{I}_s(+j\omega M)$$

or

$$\mathbf{E}_p = \mathbf{I}_p\mathbf{Z}_p + \mathbf{I}_s(+j\omega M) \tag{19.34}$$

where $\mathbf{Z}_p$ is the open-circuit impedance of the primary circuit by itself, and ωM is the mutual reactance of the two windings. Note that Lenz's law gives us the same direction for $\mathbf{I}_2$ that we chose for our generalized coupling network. [Compare Equation (19.34) with Equation (19.5).] Hence, we write the loop equation for the secondary circuit of Fig. 19.12(c) as

$$0 = \mathbf{I}_s(\mathbf{Z}_L + R_s + j\omega L_s) + \mathbf{I}_p(+j\omega M)$$

or

$$0 = \mathbf{I}_s(\mathbf{Z}_L + \mathbf{Z}_s) + \mathbf{I}_p(+j\omega M) \tag{19.35}$$

where $\mathbf{Z}_s$ is the open-circuit impedance of the secondary winding by itself. [Compare Equations (19.35) and (19.14).] From Equation (19.35)

$$\mathbf{I}_s = \frac{-\mathbf{I}_p(+j\omega M)}{\mathbf{Z}_s + \mathbf{Z}_L} \tag{19.36}$$

Substituting in Equation (19.34),

$$\mathbf{E}_p = \mathbf{I}_p\mathbf{Z}_p - \mathbf{I}_p\frac{(+j\omega M)^2}{\mathbf{Z}_s + \mathbf{Z}_L} \tag{19.37}$$

Equation (19.37) is the equivalent of Equation (19.16). In this case we can go one step further by substituting -1 for j^2. Thus

$$\mathbf{E}_p = \mathbf{I}_p\mathbf{Z}_p + \mathbf{I}_p\frac{(\omega M)^2}{\mathbf{Z}_s + \mathbf{Z}_L} \tag{19.38}$$

and dividing through by $\mathbf{I}_p$,

$$\mathbf{Z}_{in} = \mathbf{Z}_p + \frac{(\omega M)^2}{\mathbf{Z}_s + \mathbf{Z}_L} \tag{19.39}$$

where $(\omega M)^2/(\mathbf{Z}_s + \mathbf{Z}_L)$ is the **coupled impedance** *for transformer coupling.* Note that when we substitute -1 for j^2, $(\omega M)^2$ has now become an impedance with a 0° angle.

We can check Equation (19.39) by considering the effect of loading the secondary winding of a pair of magnetically coupled coils. If the secondary is left open-circuit, $\mathbf{Z}_L$ is infinitely large and, therefore, the coupled impedance in Equation (19.39) becomes zero. Therefore, the total impedance is simply the primary impedance alone as we would expect. If we connect a resistance across the secondary winding, $\mathbf{Z}_L$ will have a 0° angle. Since $\mathbf{Z}_s$ is largely the inductive reactance of the secondary winding, the total secondary circuit impedance is inductive. Therefore, when we carry out

---

Resonant Circuits
Mouloud Rahmani
http://mouloudrahmani.com/Electrical/RFMicrowave/ResonantCircuits.html

The resonant circuit is used in electronics systems to selectively pass a certain frequency or group of frequencies from a source to a load while attenuating all other frequencies outside of this passband.

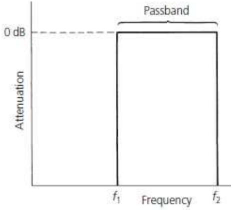

FIG. 2-1. The perfect filter response.

Bandwidth

The bandwidth of any resonant circuit is most commonly defined as being the difference between the upper and lower frequency (f2 −f1) of the circuit at which its amplitude response is 3 dB below the passband response. It is often called the half-power bandwidth.

Q

The ratio of the center frequency of the resonant circuit to its bandwidth is defined as the circuit Q.

Q = fe/(f2 − f1)

Shape Factor

The shape factor of a resonant circuit is typically defined as being the ratio of the 60-dB bandwidth to the 3-dB bandwidth of the resonant circuit. Shape factor is simply a degree of measure of the steepness of the skirts. The smaller the number, the steeper are the response skirts.

Insertion Loss

Whenever a component or group of components is inserted between a generator and its load, some of the signal from the generator is absorbed in those components due to their inherent resistive losses. Thus, not as much of the transmitted signal is transferred to the load as when the load is connected directly to the generator. (No impedance matching function is being performed.) The attenuation that results is called insertion loss and it is usually expressed in decibels (dB).

The voltage division rule (illustrated in Fig. 2-4) states that whenever a shunt element of impedance Zp is placed across the output of a generator with an internal resistance Rs, the maximum output voltage available from this circuit is:

Vout =(Vin) Zp/(Rs + Zp)

of $\boldsymbol{E}_1$ in Fig. 19.12, we can reverse the phase of the output voltage by reversing the direction of one of the windings, or simply by reversing the leads to one of the windings. Where it is necessary to keep track of this phase relationship in a circuit diagram, we mark one end of each winding with a dot as shown in Fig. 19.12(a) and (b). If, at a certain moment, changing mutual flux induces an instantaneous emf into the primary winding with a polarity such that the dotted end of the winding is positive with respect to the undotted end, then the same mutual flux change must induce an instantaneous emf into the secondary winding with a polarity such that the dotted end of the secondary winding is positive with respect to the undotted end.

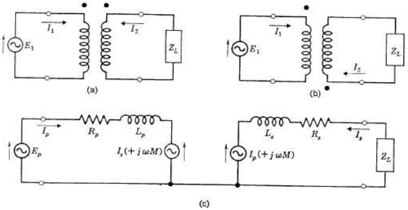

Fig. 19.12. An equivalent circuit of an air-core transformer.

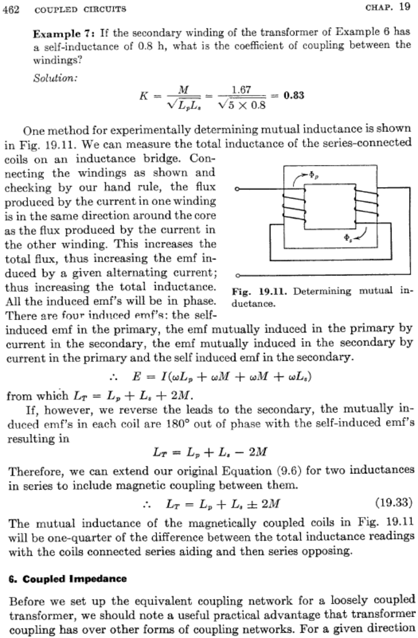
Although reversing the secondary polarity will reverse the current through the external circuit, note that $\boldsymbol{I}_2$ in Fig. 19.12(b) still must flow into the dot end of the secondary winding just as it does in Fig. 19.12(a). Hence, the primary circuit is not affected by any phase reversal we obtain by reversing the secondary leads. In selecting the direction for these current arrows, we must remember that the *same* mutual flux (which is produced by these currents) induces emf's into both primary and secondary windings. So if we draw $\boldsymbol{I}_1$ pointing into the dot end of the primary winding, we must also draw $\boldsymbol{I}_2$ pointing into the dot end of the secondary winding.

When we write the Kirchhoff's voltage law (loop) equation for the primary loop, there are three voltages which add up (vectorially) to equal $\boldsymbol{E}_1$: an IR drop across the resistance of the primary circuit, a *self*-induced emf due to $\boldsymbol{I}_1$ flowing through the primary winding, and a *mutually* induced emf due to $\boldsymbol{I}_2$ flowing in the secondary circuit. Figure 19.12(c) shows one



Example 7: If the secondary winding of the transformer of Example 6 has a self-inductance of 0.8 h, what is the coefficient of coupling between the windings?

Solution:

$$K = \frac{M}{\sqrt{L_pL_s}} = \frac{1.67}{\sqrt{5 \times 0.8}} = \mathbf{0.83}$$

One method for experimentally determining mutual inductance is shown in Fig. 19.11. We can measure the total inductance of the series-connected coils on an inductance bridge. Connecting the windings as shown and checking by our hand rule, the flux produced by the current in one winding is in the same direction around the core as the flux produced by the current in the other winding. This increases the total flux, thus increasing the emf induced by a given alternating current; thus increasing the total inductance. All the induced emf's will be in phase. There are four induced emf's: the self-induced emf in the primary, the emf mutually induced in the primary by current in the secondary, the emf mutually induced in the secondary by current in the primary and the self induced emf in the secondary.

Fig. 19.11. Determining mutual inductance.

$$\therefore \quad E = I(\omega L_p + \omega M + \omega M + \omega L_s)$$

from which $L_T = L_p + L_s + 2M$.

If, however, we reverse the leads to the secondary, the mutually induced emf's in each coil are 180° out of phase with the self-induced emf's resulting in

$$L_T = L_p + L_s - 2M$$

Therefore, we can extend our original Equation (9.6) for two inductances in series to include magnetic coupling between them.

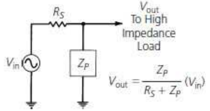
$$\therefore \quad L_T = L_p + L_s \pm 2M \tag{19.33}$$

The mutual inductance of the magnetically coupled coils in Fig. 19.11 will be one-quarter of the difference between the total inductance readings with the coils connected series aiding and then series opposing.

6. Coupled Impedance

Before we set up the equivalent coupling network for a loosely coupled transformer, we should note a useful practical advantage that transformer coupling has over other forms of coupling networks. For a given direction

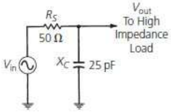
---



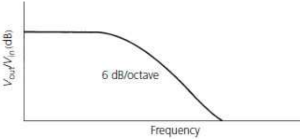
$$V_{out} = \frac{Z_P}{R_S + Z_P}(V_{in})$$

FIG. 2-4. Voltage division rule.

If Zp is a frequencydependent impedance, such as a capacitive or inductive reactance, then Vout will also be frequency dependent and the ratio of Vout to Vin, which is the gain (or, in this case, loss) of the circuit, will also be frequency dependent.



(A) *Simple circuit*



(B) *Response curve*

FIG. 2-5. Frequency response of a simple RC (resistor-capacitor) low-pass filter.

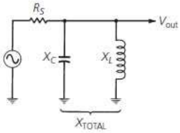


FIG. 2-7. Resonant circuit with two reactive components.

And $$M = L_p \frac{E_s}{E_p} = 5 \times \frac{40}{120} = \mathbf{1.67\ h}$$

Writing Equation (19.28) in terms of the instantaneous emf induced into the secondary,

$$e_s = M \frac{di_p}{dt} \qquad (19.28)$$

And since we are concerned only with sine-wave primary currents,

$$i_p = I_m \sin \omega t \quad \text{and} \quad \frac{di_p}{dt} = \omega I_m \cos \omega t$$

Hence, $$e_s = \omega M I_m \cos \omega t \qquad (19.31)$$

Since the instantaneous emf in Equation (19.31) will be at its peak value when $\cos \omega t = 1$,

$$E_m = 2\pi f M I_m$$

from which $$X_m = \frac{E_{m(\text{sec})}}{I_{m(\text{pri})}} = 2\pi f M \qquad (19.30)$$

Combining Equations (18.1) and (19.28),

$$\frac{N\Phi_m}{t} = \frac{MI_{p_m}}{t}$$

But from Equation (19.27), $\Phi_m = K\Phi_p$

$$\therefore \quad MI_{p_m} = N_s K \Phi_p \qquad (1)$$

If we now reverse the windings and use the original secondary winding as the primary and vice versa, it follows that

$$MI_{s_m} = N_p K \Phi_s \qquad (2)$$

Multiplying Equations (1) and (2),

$$M^2 = K^2 \left(\frac{N_p \Phi_p}{I_{p_m}}\right) \left(\frac{N_s \Phi_s}{I_{s_m}}\right) \qquad (3)$$

But from the definition of self-inductance,

$$E_{av} = \frac{LI_m}{t}$$

and from the definition of the weber,

$$E_{av} = \frac{N\Phi}{t}$$

$$\therefore \quad L = \frac{N\Phi}{I_m}$$

Substituting in Equation (3) gives

$$M = K\sqrt{L_p L_s} \qquad (19.32)$$

5. Mutual Inductance

To develop an equivalent coupling network for an air-core transformer, we require one parameter which is common to both primary and secondary circuits. This parameter is the **mutual inductance** of the pair of coils. In Chapter 9, we found that a coil has a *self*-inductance of one henry when current in that coil *changing* at the rate of one ampere per second induces a cemf of one volt in the coil. Applying the same line of thought to the process of mutual induction, we can say that

> **A pair of magnetically-coupled coils has a mutual inductance of one henry when current changing at the rate of one ampere per second in one coil induces an average emf of one volt in the other coil.**
>
> **The letter symbol for mutual inductance is M.**

Therefore, by definition, $$E_{s_{av}} = \frac{MI_{p_m}}{t} \qquad (19.28)$$

Since the instantaneous current must rise from zero to maximum in one quarter of a cycle of a sine wave,

$$E_{s_{av}} = \frac{MI_{p_m}}{1/4f} = 4fMI_{p_m}$$

But $$E_{av} = \frac{2}{\pi}E_m \qquad (11.15)$$

Therefore $$\frac{2}{\pi}E_{s_m} = 4fMI_{p_m}$$

from which $$E_s = 2\pi fMI_p \qquad (19.29)$$

Rearranging Equation (19.29) gives

$$\frac{E_s}{I_p} = 2\pi fM = X_M \qquad (19.30)$$

where X_M is called the **mutual reactance** *of the magnetically coupled windings.*

> **Example 6:** 120 v, 60 c is applied to the primary of a transformer whose primary inductance is 5 h. The open-circuit secondary voltage is 40 v. Neglecting losses, what is the mutual inductance between the two windings?
>
> *Solution:*
>
> $$E_s = \omega MI_p$$
>
> But $$I_p = \frac{E_p}{\omega L_p}$$
>
> $$\therefore \quad E_s = \frac{M}{L_p}E_p$$

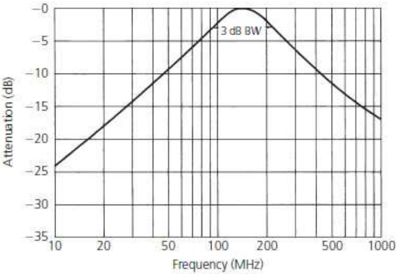

FIG. 2-8. Frequency response of an LC (inductor–capacitor) resonant circuit.

Notice, in Fig. 2-8, that as we near the resonant frequency of the tuned circuit, the slope of the resonance curve increases to 12 dB/octave. This is due to the fact that we now have two significant reactances present and each one is changing at the rate of 6 dB/octave and sloping in opposite directions.

As we move away from resonance in either direction, however, the curve again settles to a 6-dB/octave slope because, again, only one reactance becomes significant.

Loaded Q

The Q of a resonant circuit was defined earlier to be equal to the ratio of the center frequency of the circuit to its 3-dB bandwidth. This “circuit Q,” , is often given the label loaded Q because it describes the passband characteristics of the resonant circuit under actual in-circuit or loaded conditions. The loaded Q of a resonant circuit is dependent upon three main factors.

1 The source resistance (Rs).

2 The load resistance (RL).

3 The component Q.

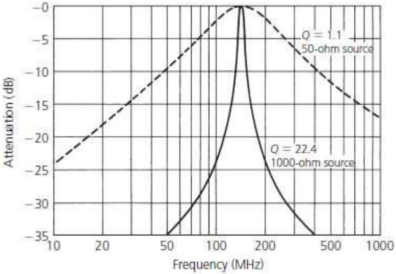

FIG. 2-10. The effect of R_s and R_L on loaded Q.

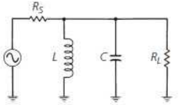
Raising the source impedance will increase the Q of our resonant circuit.

Mutual Inductance
From an unknown text
Pdf downloaded from BGU Lab 7 web page

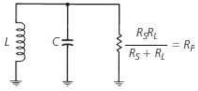
http://www.ee.bgu.ac.il/~intrlab/lab_number_7/

http://www.ee.bgu.ac.il/~intrlab/lab_number_7/Mutual%20Inductance%20and%20coupled%20RLC%20circuits.pdf

If an external load were attached to the resonant circuit, the effect would be to broaden or “de-Q” the response curve to a degree that depends on the value of the load resistance.



(A) *Resonant circuit with an external load*

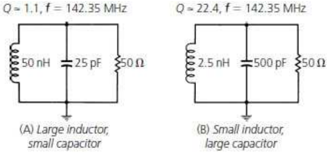


(B) *Equivalent circuit for Q calculations*

FIG. 2-11. The equivalent parallel impedance across a resonant circuit.

The resonant circuit sees an equivalent resistance of Rs in parallel with RL, as its true load. This total external resistance is, by definition, smaller in value than either Rs or RL, and the loaded Q must decrease. If we put this observation in equation form, it becomes (assuming lossless components):
Q = Rp/Xp

This illustrates that a decrease in Rp will decrease the Q of the resonant circuit and an increase in Rp will increase the circuit Q, and it also illustrates another very important point. The same effect can be obtained by keeping Rp constant and varying Xp.



(A) Large inductor, small capacitor

(B) Small inductor, large capacitor

FIG. 2-12. Effect of Q vs. X_p at 142.35 MHz.

In most cases, we only need to involve the Q of the inductor in loaded-Q calculations. The Q of most capacitors is quite high over their useful frequency range, and the equivalent shunt resistance they present to the circuit is also quite high and can usually be neglected. Care must be taken, however, to ensure that this is indeed the case.

Impedance Transformation

Low values of source and load impedance tend to load a given resonant circuit down and, thus, tend to decrease its loaded Q and increase its bandwidth. This makes it very difficult to design a simple LC high-Q resonant circuit for use between two very low values of source and load resistance.

One method of getting around this potential design problem is to make use of one of the impedance transforming circuits shown in Fig. 2-18.

---

dip much between the peaks and the response is close to what is ideally required. The bandwidth can be estimated as BW = kfo, where k is the coefficient of coupling and fo is the resonant frequency of each circuit.

Figure 3 shows an example of secondary circuit response Vc(f) (voltage measured on capacitor) for different coupling coefficients.

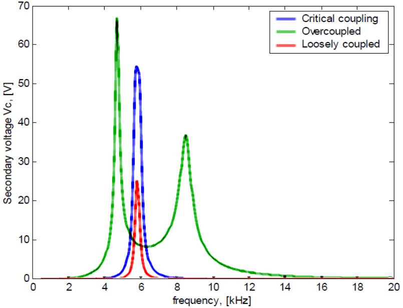


Fig 3

(R = 250 Ohm, C = 5 nF, L = 0.15 H, Vin =5V) inductance (Ze ≈ Z1 + ω2M2·jωC), and an inductance as a capacitance (Ze ≈ Z1 + ω2M2/ jωL).

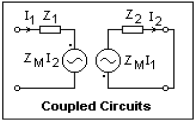

Fig 2

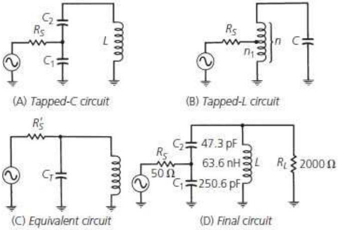
At resonance, the reflected impedance is resistive, and acts to lower the Q of the primary, and thereby to reduce the output. This is counteracted by the increased coupling, which increases the output. The lower Q gives a wider passband. At frequencies lower than exact resonance, the reflected impedance is inductive, which adds to the inductance of the primary and resonates at a lower frequency, producing a peak in the output. At frequencies higher than exact resonance, the reflected impedance is capacitive, which cancels part of the inductance and causes the circuit to resonate at a higher frequency, producing the other peak.

As the coupling is reduced, the response becomes single-peaked at critical coupling, and then decreases as the coupling is made even looser.

The critical coupling coefficient is given by $k_c = \frac{1}{\sqrt{Q_1 \cdot Q_2}}$.

in terms of the Q's of the individual tuned circuits.

Frequently it is assumed that optimum coupling occurs for k ≈ 1.5kc. In this case, the response is double-peaked, but does not



(A) Tapped-C circuit (B) Tapped-L circuit

(C) Equivalent circuit (D) Final circuit

FIG. 2-18. Two methods used to perform an impedance transformation.

For the tapped- C transformer (Fig. 2-18A), we use the formula:

R's = R's (1 + C1/ C2)^2

The equivalent capacitance (CT) that will resonate with the inductor is equal to C1 in series with C2, or:

CT = C1C2/(C1 + C2)

For the tapped-L network of Fig. 2-18B, we use the following formula:

R's = R's (1 + n/ n1)^2

Coupling of Resonant Circuits

In many applications where steep passband skirts and small shape factors are needed, a single resonant circuit might not be sufficient. In situations such as this, individual resonant circuits are often coupled together to produce more attenuation at certain frequencies than would normally be available with a single resonator.

The coupling mechanism that is used is generally chosen specifically for each application, as each type of coupling has its own peculiar characteristics that must be dealt with. The most common forms of coupling are: capacitive, inductive, transformer (mutual), and active (transistor).

Capacitive Coupling

If capacitor C12 of Fig. 2-19 is too large, too much coupling occurs and the frequency response broadens drastically with two response peaks in the filter's passband. If capacitor C12 is too small, not enough signal energy is passed from one resonant circuit to the other and the insertion loss can increase to an unacceptable level. The compromise solution to these two extremes is the point of critical coupling, where we obtain a reasonable bandwidth and the lowest possible insertion loss and, consequently, a maximum transfer of signal power.

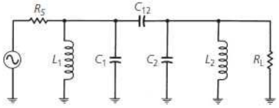


FIG. 2-19. Capacitive coupling.

Thus, the solution from which the frequency response can be obtained is:

$$I_1 = \frac{aV_0}{a^2 - b^2} \text{ and } I_2 = -\frac{bV_0}{a^2 - b^2} \qquad (4)$$

Resonance occurs at the 2 frequencies given by the following equations:

$$\omega_1^2 = \frac{1}{LC \cdot \left[1 - \frac{M}{L}\right]} \text{ and } \omega_2^2 = \frac{1}{LC \cdot \left[1 + \frac{M}{L}\right]}$$

Here, the coupling coefficient k = M/L (for L1=L2).

The behavior of the circuit can be understood qualitatively on the basis of the reflected impedance (or coupled impedance).

A transformer (or inductively coupled circuit) is said to "reflect" impedance in the secondary into the primary circuit. Consider the coupled circuits shown in Fig 2. The positive direction of the currents is chosen into the polarity mark on the generator representing the induced voltages, so that Kirchhoff's equations are

$$\mathbf{Z}_1\mathbf{I}_1 + \mathbf{Z}_M\mathbf{I}_2 = \mathbf{V}_1, \text{ and } \mathbf{Z}_M\mathbf{I}_1 + \mathbf{Z}_2\mathbf{I}_2 = 0. \text{ (see Eq.2)}$$

ZM is the mutual impedance jωM, Z1 includes the source impedance, and Z2 the secondary load. These equations may be solved for the equivalent primary impedance

$$\mathbf{Z}_e = \mathbf{V}_1/\mathbf{I}_1 = \mathbf{Z}_1 - \mathbf{Z}_M^2/\mathbf{Z}_2. \text{ (from eqs. (2) and (4))}$$

The reflected impedance is then ω2M2/Z2. Note that a resistance is reflected as a resistance, a capacitance as an

The coupling constant is independent of the number of turns in a coil. The number of turns in a coil determines the magnetic field, which will be produced for a given current. The coupling constant is concerned with how the lines of magnetic force produced by one coil interact with another coil, and hence the coupling constant between two air spaced coils depends only on their physical size and disposition in space. Hence to obtain the best coupling between primary and secondary in an air-cored transformer we can only change the size and spatial relationships of the coils.

Kirchhoff's voltage law equations for the primary and secondary loops are given by

$$\left[R + j\omega L + \frac{1}{j\omega C}\right] \cdot I_1 + j\omega M \cdot I_2 = V_0 \qquad (2)$$

$$j\omega M \cdot I_1 + \left[R + j\omega L + \frac{1}{j\omega C}\right] \cdot I_2 = 0$$

(it is assumed that R1+RL1 = R2+RL2 =R and L1 = L2).
We can write these eqs. in the matrix form as follows

$$\begin{bmatrix} a & b \\ b & a \end{bmatrix} \cdot \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} V_0 \\ 0 \end{bmatrix} \qquad (3)$$

where, $a = \left[R + j\omega L + \frac{1}{j\omega C}\right]$ and $b = j\omega M$.

Following Cramer's rule $I_1 = \frac{\Delta_1}{\Delta}$ and $I_2 = \frac{\Delta_2}{\Delta}$,

where $\Delta_1 = \begin{vmatrix} V_0 & b \\ 0 & a \end{vmatrix}$, $\Delta_2 = \begin{vmatrix} a & V_0 \\ b & 0 \end{vmatrix}$, and $\Delta = a^2 - b^2$.

There are instances in which overcoupling or undercoupling might serve a useful purpose in a design, such as in tailoring a specific frequency response that a critically coupled filter cannot provide.

In this section, we will only concern ourselves with critical coupling as it pertains to resonant circuit design.

The loaded Q of a critically coupled two-resonator circuit is approximately equal to 0.707 times the loaded Q of one of its resonators. Therefore, the 3-dB bandwidth of a two-resonator circuit is actually wider than that of one of its resonators. Thus, the main purpose of the two-resonator passively coupled filter is not to provide a narrower 3-dB bandwidth, but to increase the steepness of the stopband skirts and, thus, to reach an ultimate attenuation much faster than a single resonator could.

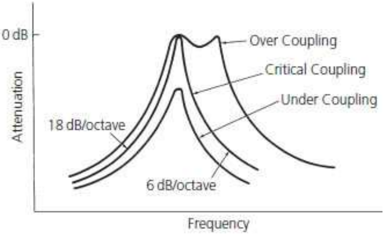

FIG. 2-20. The effects of various values of capacitive coupling on passband response.

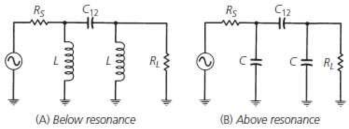
Notice that even for the critically coupled case, the response curve is not symmetric around the center frequency but is skewed somewhat. The lower frequency portion of the response plummets down at the rate of 18-dB/octave while the upper slope decreases at only 6-dB/octave.

Below resonance, we have the circuit of Fig. 2-22A. The reactance of the two resonant-circuit capacitors (Fig. 2-19) has increased, and the reactance of the two inductors has decreased to the point that only the inductor is seen as a shunt element and the capacitors can be ignored. This leaves three reactive components and each contributes 6-dB/octave to the response.



(A) Below resonance (B) Above resonance

FIG. 2-22. Equivalent circuit of capacitively coupled resonant circuits.

Above resonance, the equivalent circuit approaches the configuration of Fig. 2-22B. Here the inductive reactance has increased above the capacitive reactance to the point where the inductive reactance can be ignored as a shunt element. We now have an arrangement of three capacitors that effectively look like a single shunt capacitor and yields a slope of 6-dB/octave.

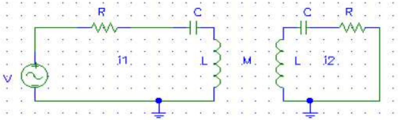
Inductive Coupling

Two inductively coupled RLC circuits

Ben-Gurion University

http://www.ee.bgu.ac.il/~intrlab/lab_number_7/Two%20inductively%20coupled%20RLC%20circuits.pdf

Two inductively coupled RLC circuits are shown in Figure 1. Having 2 circuits gives 2 resonant frequencies whose separation depends on the value of the mutual inductance M (the ratio of the voltage in the secondary to the rate of change of primary current with time, and the unit is the henry. This has a reactance at the operating frequency Xm = ωM).



The mutual inductance coupling between primary and secondary can be related to their self-inductance by means of the coupling constant k:

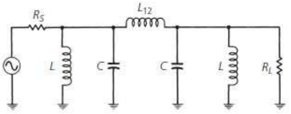
$$k = \frac{M}{\sqrt{L_1 \cdot L_2}}$$

Notice, that since k is defining the relationship between magnetic flux linkages in the circuit, it can never be greater than 1. A value of 1 means that all the flux produced by the primary is linked with the secondary and vice versa. A value of k greater than 1 would mean that more than all of the flux produced by the primary is linked with the secondary.

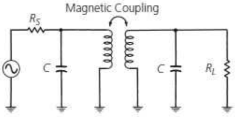
control and high Q are essential to good response and selectivity.

If the primary circuit is made to resonate at a different frequency from the secondary, audio response is much worse, and considerable distortion is likely. Moreover, the response at mean frequency is less than it would be if the circuits were properly tuned. Air-core transformers are usually made adjustable for tuning and coupling.

Two types of inductively coupled resonant circuits are shown in Fig. 2-23. One type (Fig. 2-23A) uses a series inductor or coil to transfer energy from the first resonator to the next, and the other type (Fig. 2-23B) uses transformer coupling for the same purpose.

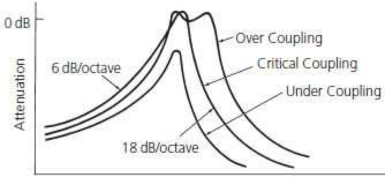


(A) *Series inductor*

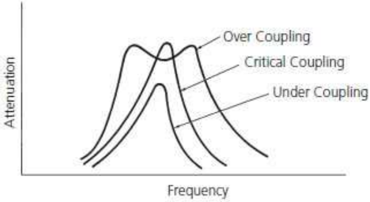


(B) *Transformer*

FIG. 2-23. Inductive coupling.



(A) *Inductive coupling*



(B) *Transformer coupling*

FIG. 2-24. The effects of various values of inductive coupling on passband response.

different values of coupling. If the value of coupling is such that

$$X_M = \sqrt{R_1 R_2}$$

we obtain a condition similar to that of equation 103, in which the maximum power or current is produced in the secondary circuit. Maximum current through condenser C2 gives maximum voltage E2. This value of coupling is known as the critical value. Smaller coefficient of coupling gives a smaller maximum value of E2. Greater coefficient of coupling results in a "double hump" as shown in Fig. 173.

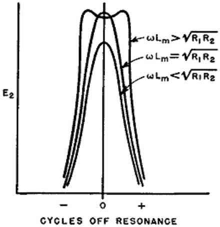


Fig. 173. Response curves for circuit of Fig. 172.

The heights of resonant peaks and frequency distance between peaks depend upon circuit Q and coefficient of coupling k. The double hump curve of Fig. 173 is desirable because, with modulated waves, frequencies in adjacent channels are rejected; yet very little attenuation is offered to audio frequencies which effectively add or subtract from the carrier frequency normally corresponding to resonance. Close tuning

$$k = \frac{L_m}{\sqrt{L_1 L_2}} = \frac{L_m}{\sqrt{\left(L_m + \frac{L_s}{2}\right)^2}}$$ [104a]

$$= \frac{1}{1 + (L_s/2L_m)}$$

If Lm >> Ls

$$k \approx 1 - \frac{L_s}{2L_m}$$ [104b]

Equations 104 (a) and (b) are useful in estimating approximate transformer band width.

A tuned air-core transformer often used in receivers is shown in Fig. 172.

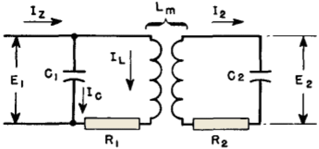

Fig. 172. Tuned air-core transformer.

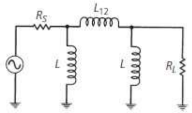
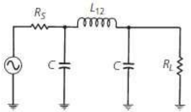
Here a sinusoidal voltage E1 may be impressed on the primary circuit by a vacuum tube amplifier. Resistances R1 and R2 are usually the inevitable resistance of coils, but occasionally resistance is added to change the circuit response. The value of voltage E2 obtained from this circuit depends on the impressed frequency; in Fig. 173 it is shown for resonance at three

---



(A) *Below resonance*



(B) *Above resonance*

FIG. 2-25. Equivalent circuit of inductively coupled resonant circuits.

states that the mutual reactance XM is the geometric mean between the two values of resistance.

The ratio of mutual inductance to the geometric mean of the primary and secondary self-inductances is the coupling coefficient:

$$k = L_m/\sqrt{(L_1 L_2)} \qquad [104]$$

The value of k is never greater than unity, even when coils are interleaved to the maximum possible extent. Values of k down to 0.01 or lower are common at high frequencies.

Coupling coefficient is related to untuned transformer open- and short-circuit reactance by means of the transformer equivalent circuit shown in Fig. 107(a), p. 147. Assume that the transformer has a 1:1 ratio, and leakage inductance is equally divided between primary and secondary windings. Then if L1 and L2 are the self-inductances of primary and secondary, respectively, Ls is the total leakage inductance (measured in the primary with secondary short-circuited), and Lm the mutual inductance,

$$L_1 = \frac{X_P + X_N}{2\pi f} = \frac{L_s}{2} + L_m$$
$$L_2 = \frac{X_S + X_N}{2\pi f} = \frac{L_s}{2} + L_m$$

From equation 104,

$$0 = Z_2 I_2 + j\omega L_m I_1 \qquad [101]$$

where ω = 2π times operating frequency, and Lm is the mutual inductance between the primary and secondary coils.

From equation 101 we see that the voltage in the secondary coil is numerically equal to ωLmI1, the product of primary current and mutual reactance at the frequency of applied voltage E1. The equivalent impedance of the circuit of Fig. 171 when referred to the primary side is given by

$$Z' = Z_1 + (X_M{}^2/Z_2) \qquad [102]$$

where $X_M = j\omega L_m$.

In the above formulas, the impedances Z1, Z2, and Z' are complex quantities whose real and imaginary terms depend upon the values of resistance, inductance, and capacitance in the circuit. One common practical case arises when the primary resistance is zero, or virtually zero, and the secondary coil is tuned to resonance so that Z2 is a pure resistance R2. Under these conditions, equation 102 reduces to

$$R' = X_M{}^2/R_2 \qquad [103]$$

where R' is the equivalent resistance in the primary.

Equation 103 gives the value of mutual inductance required for coupling a resistance R2 so that it will appear like resistance R' with a maximum power transfer between the two coils, and

RESONANCE

Tony R. Kuphaldt

http://www.allaboutcircuits.com/vol_2/chpt_6/1.html

6.1 An electric pendulum

Capacitors store energy in the form of an electric field, and electrically manifest that stored energy as a potential: static voltage. Inductors store energy in the form of a magnetic field, and electrically manifest that stored energy as a kinetic motion of electrons: current. Capacitors and inductors are flip-sides of the same reactive coin, storing and releasing energy in complementary modes. When these two types of reactive components are directly connected together, their complementary tendencies to store energy will produce an unusual result.

If either the capacitor or inductor starts out in a charged state, the two components will exchange energy between them, back and forth, creating their own AC voltage and current cycles. If we assume that both components are subjected to a sudden application of voltage (say, from a momentarily connected battery), the capacitor will very quickly charge and the inductor will oppose change in current, leaving the capacitor in the charged state and the inductor in the discharged state: (Figure 6.1)

The capacitor will begin to discharge, its voltage decreasing. Meanwhile, the inductor will begin to build up a “charge” in the form of a magnetic field as current increases in the circuit: (Figure 6.2)

Air-Core Transformers

Reuben Lee

http://www.vias.org/eltransformers/lee_electronic_transformers_07b_22.html

Air-Core Transformers

Transformers considered hitherto have had iron or ferrite cores. A class of transformers is widely used in radio-frequency circuits without cores or with small slugs of powdered iron. In a transformer with an iron core, the exciting current required for inducing the secondary voltage is a small percentage of the load component of current. In an air-core transformer all the current is exciting current and induces a secondary voltage proportional to the mutual inductance.

Figure 6.3: Capacitor fully discharged: zero voltage, inductor fully charged: maximum current. The inductor will maintain current flow even with no voltage applied. In fact, it will generate a voltage (like a battery) in order to keep current in the same direction. The capacitor, being the recipient of this current, will begin to accumulate a charge in the opposite polarity as before: (Figure 6.4)

When the inductor is finally depleted of its energy reserve and the electrons come to a halt, the capacitor will have reached full (voltage) charge in the opposite polarity as when it started: (Figure 6.5) Now we’re at a condition very similar to where we started: the capacitor at full charge and zero current in the circuit. The capacitor, as before, will begin to discharge through the inductor, causing an increase in current (in the opposite direction as before) and a decrease in voltage as it depletes its own energy reserve: (Figure 6.6)

Eventually the capacitor will discharge to zero volts, leaving the inductor fully charged with

Mutual Inductance, M : 703 µH
Min Inductance Value, Lm : 1333 µH
Max Inductance Value, LM : 4144 µH

When the coils can not rotate but only move along their axis (coaxial coils), assuming a distance D between the two coils centres, we have:

Mutual Inductance, Md : 10.4 µH
Total Inductance, Ld : 2759 µH

The total inductance value for this case is computed assuming a positive mutual inductance (coils not rotated 180°).

[2] F.E. Terman, "Radio Engineers' Handbook," London, McGraw-Hill, 1st ed., Sep. 1950.

rotating a coil 180° gives a variation of the total inductance of 4Lm.

Two coaxial coils If the two coaxial coils are moved along their axis instead (D<>0), the mutual inductance decreaes, eventually reaching zero at infinity, but does not change sign. This means that there is less variation in the total inductance just moving the coils with respect to rotating them.

The form below computes the main parameters for the two types of variometer described above. The self-inductances are calculated using the formulas in [1], while the mutual inductances use the formulas from [2], with some minor corrections.

These formulas agree very well with the results of some electromagnetic simulations I have done, see the page for details.

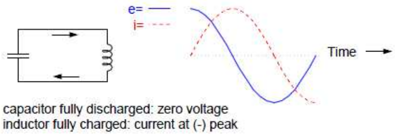
CALCULATED VALUES

Outer Coil Inductance, L1 : 1842 µH
Inner Coil Inductance, L2 : 896 µH

In a typical variometer the two coils are concentric (i.e. D=0) and the overall inductance is varied rotating the inner coil; in this case we have:

Figure 6.6: Capacitor discharging: voltage decreasing, inductor charging: current increasing. full current through it:

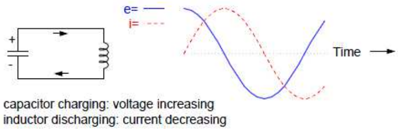
(Figure 6.7)



e=
i=
Time
capacitor fully discharged: zero voltage
inductor fully charged: current at (-) peak

Figure 6.7: Capacitor fully discharged: zero voltage, inductor fully charged: current at (-) peak.

The inductor, desiring tomaintain current in the same direction, will act like a source again, generating a voltage like a battery to continue the flow. In doing so, the capacitor will begin to charge up and the current will decrease in magnitude: (Figure 6.8)



e=
i=
+
-
Time
capacitor charging: voltage increasing
inductor discharging: current decreasing

Figure 6.8: Capacitor charging: voltage increasing, inductor discharging: current decreasing.

Eventually the capacitor will become fully charged again as the inductor expends all of its energy reserves trying to maintain current. The voltage will once again be at its positive peak and the current at zero. This completes one full cycle of the energy exchange between the capacitor and inductor: (Figure 6.9)

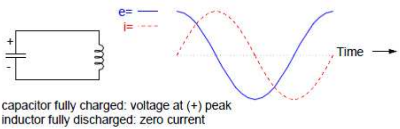


Figure 6.9: Capacitor fully charged: voltage at (+) peak, inductor fully discharged: zero current.

This oscillation will continue with steadily decreasing amplitude due to power losses from stray resistances in the circuit, until the process stops altogether. Overall, this behavior is akin to that of a pendulum: as the pendulum mass swings back and forth, there is a transformation of energy taking place from kinetic (motion) to potential (height), in a similar fashion to the way energy is transferred in the capacitor/inductor circuit back and forth in the alternating forms of current (kinetic motion of electrons) and voltage (potential electric energy).

At the peak height of each swing of a pendulum, the mass briefly stops and switches directions. It is at this point that potential energy (height) is at a maximum and kinetic energy (motion) is at zero. As the mass swings back the other way, it passes quickly through a point where the string is pointed

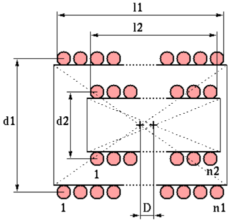
Variometer Design

Claudio Girardi
http://www.qsl.net/in3otd/variodes.html

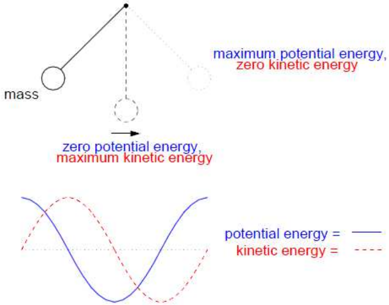
Variometer Design

A variometer consists usually of two coaxial coils, connected in series, where the coils relative position can be varied in some way. If L1 and L2 are the self-inductances of the first and second coil and Lm is the mutual inductance between the two, the total inductance can be written as Ltot=L1+L2±2Lm. The mutual inductance is defined as the flux linked by the turns of an inductance when the other carries a unit current; this of course depends not only on the coil length and diameter but also on their relative position.
For two coaxial coils, like the ones in the picture, the mutual inductance is at maximum when they are also concentrical, i.e. D=0.

If the two concentrical coils are rotated, so that their axes are not parallel any more, the mutual inductance decreases, reaching zero (almost) when the angle is 90°. Continuing the rotation beyond 90° the mutual inductance increases again, but this time with the opposite sign. So, according to the above formula,



straight down. At this point, potential energy (height) is at zero and kinetic energy (motion) is at maximum. Like the circuit, a pendulum's back-and-forth oscillation will continue with a steadily dampened amplitude, the result of air friction (resistance) dissipating energy. Also like the circuit, the pendulum's position and velocity measurements trace two sine waves (90 degrees out of phase) over time: (Figure 6.10)



maximum potential energy,
zero kinetic energy
mass
zero potential energy,
maximum kinetic energy
potential energy = ——
kinetic energy = - - - -

Figure 6.10: Pendelum transfers energy between kinetic and potential energy as it swings low to high.

In physics, this kind of natural sine-wave oscillation for a mechanical system is called Simple Harmonic Motion (often abbreviated as "SHM"). The same underlying principles govern both the oscillation of a capacitor/inductor circuit and the action of a pendulum, hence the similarity in effect. It is an interesting property of any pendulum that its periodic time is governed by the length of the string holding the mass, and not the weight of the mass itself. That is why a pendulum will keep swinging at the same frequency as the oscillations decrease in amplitude. The oscillation rate is independent of the amount of energy stored in it.

The same is true for the capacitor/inductor circuit. The rate of oscillation is strictly dependent on the sizes of the capacitor and inductor, not on the amount of voltage (or current) at each respective peak in the waves. The ability for such a circuit to store energy in the form of oscillating voltage and current has earned it the name tank circuit. Its property of maintaining a single, natural frequency regardless of how much or little energy is actually being stored in it gives it special significance in electric circuit design.

However, this tendency to oscillate, or resonate, at a particular frequency is not limited to circuits exclusively designed for that purpose. In fact, nearly any AC circuit with a combination of capacitance and inductance (commonly called an “LC circuit”) will tend to manifest unusual effects when the AC power source frequency approaches that natural frequency. This is true regardless of the circuit’s intended purpose.

If the power supply frequency for a circuit exactly matches the natural frequency of the circuit’s LC combination, the circuit is said to be in a state of resonance. The unusual effects will reach maximum in this condition of resonance. For this reason, we need to be able to predict what the resonant frequency will be for various combinations of L and C, and be aware of what the effects of resonance are.

$$\Phi = \mu_0 \frac{NI}{l}A. \;\; L = \frac{N\Phi}{I} = \frac{N}{\cancel{I}}\mu_0 \frac{N\cancel{I}}{l}A$$

$$L = \mu_0 \frac{N^2}{l}A \;\text{ or }\; \boxed{L = \mu_0 n^2 A l} \;\text{ where } n = \frac{N}{l}.$$

(Note how L is independent of the current I.)

be turned into an equation by introducing a constant. Call this constant L, the ***self-inductance*** (or simply ***inductance***) of the coil:

$$N\Phi = LI \quad \text{or} \quad L = \frac{N\Phi}{I}$$

As with mutual inductance, the unit of self-inductance is the henry.

The self-induced emf can now be calculated using Faraday’s law:

$$\mathcal{E} = -N\frac{\Delta\Phi}{\Delta t} = -\frac{\Delta(N\Phi)}{\Delta t} = -\frac{\Delta(LI)}{\Delta t} = -L\frac{\Delta I}{\Delta t}$$

$$\boxed{\mathcal{E} = -L\frac{\Delta I}{\Delta t}}$$

The above formula is the ***emf due to self-induction***.

Example

Find the formula for the self-inductance of a solenoid of N turns, length l, and cross-sectional area A.

Assume that the solenoid carries a current I. Then the magnetic flux in the solenoid is

---

- REVIEW:

- A capacitor and inductor directly connected together form something called a tank circuit, which oscillates (or resonates) at one particular frequency. At that frequency, energy is alternately shuffled between the capacitor and the inductor in the form of alternating voltage and current 90 degrees out of phase with each other.

- When the power supply frequency for an AC circuit exactly matches that circuit’s natural oscillation frequency as set by the L and C components, a condition of resonance will have been reached.

6.2 Simple parallel (tank circuit) resonance

A condition of resonance will be experienced in a tank circuit (Figure 6.11) when the reactance of the capacitor and inductor are equal to each other. Because inductive reactance increases with increasing frequency and capacitive reactance decreases with increasing frequency, there will only be one frequency where these two reactances will be equal.

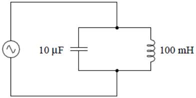


Figure 6.11: Simple parallel resonant circuit (tank circuit).

In the above circuit, we have a 10 µF capacitor and a 100 mH inductor. Since we know the equations for determining the reactance of each at a given frequency, and we're looking for that point where the two reactances are equal to each other, we can set the two reactance formulae equal to each other and solve for frequency algebraically:

$$X_L = 2\pi fL \qquad X_C = \frac{1}{2\pi fC}$$

. . . setting the two equal to each other, representing a condition of equal reactance (resonance) . . .

$$2\pi fL = \frac{1}{2\pi fC}$$

Multiplying both sides by f eliminates the f term in the denominator of the fraction . . .

$$2\pi f^2L = \frac{1}{2\pi C}$$

Dividing both sides by 2pL leaves f2 by itself on the left-hand side of the equation . . .

$$f^2 = \frac{1}{2\pi 2\pi LC}$$

Taking the square root of both sides of the equation leaves f by itself on the left side . . .

$$f = \frac{\sqrt{1}}{\sqrt{2\pi 2\pi LC}}$$

. . . simplifying . . .

The apparatus used in Experiment EM-11B consists of two coaxial solenoids. A solenoid is essentially just a coil of wire. For a long, tightly-wound solenoid of *n* turns per unit length carrying current *I* the magnetic field over its cross-section is nearly constant and given by $B = \mu_0 nI$. Assume that the two solenoids have the same cross-sectional area *A*. Find a formula for the mutual inductance of the solenoids.

The magnetic flux in the primary coil is

$\Phi_1 = \mu_0 \frac{N_1 I_1}{l_1} A$ where l_1 is the length of the primary coil.

$$M = \frac{N_2\Phi_2}{I_1} \text{ But } \Phi_2 = \Phi_1 : \ M = \frac{N_2\Phi_2}{I_1} = \frac{N_2}{\cancel{I_1}}\mu_0 \frac{N_1 \cancel{I_1}}{l_1} A; \quad \boxed{M = \mu_0 \frac{N_1 N_2}{l_1} A}$$

(Note how M is independent of the current I_1.)

Self-Inductance

A current-carrying coil produces a magnetic field that links its own turns. If the current in the coil changes the amount of magnetic flux linking the coil changes and, by Faraday's law, an emf is produced in the coil. This emf is called a *self-induced* emf.

Let the coil have N turns. Assume that the same amount of magnetic flux Φ links each turn of the coil. The net flux linking the coil is then $N\Phi$. This net flux is proportional to the magnetic field, which, in turn, is proportional to the current I in the coil. Thus we can write $N\Phi \propto I$. This proportionality can

Let the primary coil have N_1 turns and the secondary coil have N_2 turns. Assume that the same amount of magnetic flux Φ_2 from the primary coil links each turn of the secondary coil. The net flux linking the secondary coil is then $N_2\Phi_2$. This net flux is proportional to the magnetic field, which, in turn, is proportional to the current I_1 in the primary coil. Thus we can write $N_2\Phi_2 \propto I_1$. This proportionality can be turned into an equation by introducing a constant. Call this constant M, the ***mutual inductance*** of the two coils:

$$N_2\Phi_2 = MI_1 \quad \text{or} \quad M = \frac{N_2\Phi_2}{I_1}$$

the unit of inductance is $\dfrac{\text{wb}}{\text{A}} = henry\ (\text{H})$ named after Joseph Henry.

The emf induced in the secondary coil may now be calculated using Faraday's law:

$$\mathcal{E}_2 = -N_2\frac{\Delta\Phi_2}{\Delta t} = -\frac{\Delta\left(N_2\Phi_2\right)}{\Delta t} = -\frac{\Delta\left(MI_1\right)}{\Delta t} = -M\frac{\Delta I_1}{\Delta t}$$

$$\boxed{\mathcal{E}_2 = -M\frac{\Delta I_1}{\Delta t}}$$

The above formula is the ***emf due to mutual induction***.

Example

$$\boxed{f = \frac{1}{2\pi\sqrt{LC}}}$$

So there we have it: a formula to tell us the resonant frequency of a tank circuit, given the values of inductance (L) in Henrys and capacitance (C) in Farads. Plugging in the values of L and C in our example circuit, we arrive at a resonant frequency of 159.155 Hz.

What happens at resonance is quite interesting. With capacitive and inductive reactances equal to each other, the total impedance increases to infinity, meaning that the tank circuit draws no current from the AC power source! We can calculate the individual impedances of the 10 µF capacitor and the 100mH inductor and work through the parallel impedance formula to demonstrate this mathematically:

$$X_L = 2\pi fL$$

$$X_L = (2)(\pi)(159.155\ \text{Hz})(100\ \text{mH})$$

$$X_L = 100\ \Omega$$

$$X_C = \frac{1}{2\pi fC}$$

$$X_C = \frac{1}{(2)(\pi)(159.155\ \text{Hz})(10\ \mu\text{F})}$$

$$X_C = 100\ \Omega$$

As you might have guessed, I chose these component values to give resonance impedances that were easy to work with (100 even). Now, we use the parallel impedance formula to see what happens to total Z:

$$Z_{\text{parallel}} = \frac{1}{\dfrac{1}{Z_L} + \dfrac{1}{Z_C}}$$

$$Z_{\text{parallel}} = \frac{1}{\dfrac{1}{100\ \Omega \angle 90^\circ} + \dfrac{1}{100\ \Omega \angle -90^\circ}}$$

$$Z_{\text{parallel}} = \frac{1}{0.01 \angle -90^\circ + 0.01 \angle 90^\circ}$$

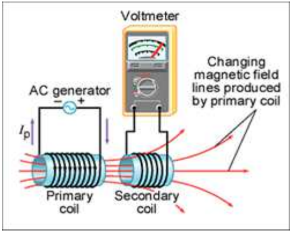
$$Z_{\text{parallel}} = \frac{1}{0} \qquad \textit{Undefined!}$$

We can't divide any number by zero and arrive at a meaningful result, but we can say that the result approaches a value of infinity as the two parallel impedances get closer to each other. What this means in practical terms is that, the total impedance of a tank circuit is infinite (behaving as an open circuit) at resonance. We can plot the consequences of this over a wide power supply frequency range with a short SPICE simulation: (Figure 6.12)

The 1 pico-ohm (1 p) resistor is placed in this SPICE analysis to overcome a limitation of SPICE: namely, that it cannot analyze a circuit containing a direct inductor-voltage source loop. (Figure 6.12) A very low resistance value was chosen so as to have minimal effect on circuit behavior.

Mutual Inductance

Dr. David F. Cattell
faculty.ccp.edu/faculty/dcattell/Sp12/.../Mutual%20Inductance.doc



Suppose we hook up an AC generator to a solenoid so that the wire in the solenoid carries AC. Call this solenoid the primary *coil*. Next place a second solenoid connected to an AC voltmeter near the primary coil so that it is coaxial with the primary coil. Call this second solenoid the *secondary coil*. See the figure at the right.

The alternating current in the primary coil produces an alternating magnetic field whose lines of flux *link* the secondary coil (like thread passing through the eye of a needle). Hence the secondary coil encloses a *changing* magnetic field. By Faraday's law of induction this changing magnetic flux induces an emf in the secondary coil. This effect in which changing current in one circuit induces an emf in another circuit is called ***mutual induction***.

the resulting mutual inductance will be equal to the geometric mean of the two individual inductances of the coils.

Also when the inductances of the two coils are the same and equal, L 1 is equal to L 2, the mutual inductance that exists between the two coils will equal the value of one single coil as the square root of two equal values is the same as one single value as shown.

$$M = \sqrt{L_1 L_2} = L$$

Mutual Inductance Example No1

Two inductors whose self-inductances are given as 75mH and 55mH respectively, are positioned next to each other on a common magnetic core so that 75% of the lines of flux from the first coil are cutting the second coil. Calculate the total mutual inductance that exists between the two coils.

$$M = k\sqrt{L_1 L_2}$$

$$M = 0.75\sqrt{75\text{mH x }55\text{mH}} = 48.2\text{mH}$$

Mutual Inductance Example No2

When two coils having inductances of 5H and 4H respectively were wound uniformly onto a non-magnetic core, it was found that their mutual inductance was 1.5H. Calculate the coupling coefficient that exists between.

$$k = \frac{M}{\sqrt{L_1 L_2}} = \frac{1.5}{\sqrt{5\times 4}} = 0.335 = 33.5\%$$

This SPICE simulation plots circuit current over a frequency range of 100 to 200 Hz in twenty even steps (100 and 200 Hz inclusive). Current magnitude on the graph increases from

left to right, while frequency increases from top to bottom. The current in this circuit takes a sharp dip around the analysis point of 157.9 Hz, which is the closest analysis point to our predicted resonance frequency of 159.155 Hz. It is at this point that total current from the power source falls to zero.

The plot above is produced fromthe above spice circuit file (*.cir), the command (.plot) in the last line producing the text plot on any printer or terminal. A better looking plot is produced by the “nutmeg” graphical post-processor, part of the spice package. The above spice (*.cir) does not require the plot (.plot) command, though it does no harm. The following commands produce the plot below: (Figure 6.13)

```
spice -b -r resonant.raw resonant.cir
(  -b  batch  mode,  -r  raw  file,  input  is
resonant.cir)
nutmeg resonant.raw
```

From the nutmeg prompt:

```
>setplot ac1 (setplot {enter} for list of
plots)
>display (for list of signals)
>plot mag(v1#branch)
```

However, the above equation assumes zero flux leakage and 100% magnetic coupling between the two coils, L 1 and L 2. In reality there will always be some loss due to leakage and position, so the magnetic coupling between the two coils can never reach or exceed 100%, but can become very close to this value in some special inductive coils.

If some of the total magnetic flux links with the two coils, this amount of flux linkage can be defined as a fraction of the total possible flux linkage between the coils. This fractional value is called the coefficient of coupling and is given the letter k.

Coupling Coefficient

Generally, the amount of inductive coupling that exists between the two coils is expressed as a fractional number between 0 and 1 instead of a percentage (%) value, where 0 indicates zero or no inductive coupling, and 1 indicating full or maximum inductive coupling.

In other words, if k = 1 the two coils are perfectly coupled, if k > 0.5 the two coils are said to be tightly coupled and if k < 0.5 the two coils are said to be loosely coupled. Then the equation above which assumes a perfect coupling can be modified to take into account this coefficient of coupling, k and is given as:

Coupling Factor Between Coils

$$k = \frac{M}{\sqrt{L_1 L_2}} \quad \text{or} \quad M = k\sqrt{L_1 L_2}$$

When the coefficient of coupling, k is equal to 1, (unity) such that all the lines of flux of one coil cuts all of the turns of the second coil, that is the two coils are tightly coupled together,

$$M_{12} = \frac{N_2 \Phi_{12}}{I_1}$$

Likewise, the flux linking coil one, L1 when a current flows around coil two, L2 is exactly the same as the flux linking coil two when the same current flows around coil one above, then the mutual inductance of coil one with respect of coil two is defined as M21. This mutual inductance is true irrespective of the size, number of turns, relative position or orientation of the two coils. Because of this, we can write the mutual inductance between the two coils as: M12 = M21 = M.

Then we can see that self inductance characterises an inductor as a single circuit element, while mutual inductance signifies some form of magnetic coupling between two inductors or coils, depending on their distance and arrangement, an hopefully we remember from our tutorials on Electromagnets that the self inductance of each individual coil is given as:

$$L_1 = \frac{\mu_o \mu_r N_1^2 A}{\ell} \text{ and } L_2 = \frac{\mu_o \mu_r N_2^2 A}{\ell}$$

By cross-multiplying the two equations above, the mutual inductance, M that exists between the two coils can be expressed in terms of the self inductance of each coil.

$$M^2 = L_1 L_2$$

giving us a final and more common expression for the mutual inductance between the two coils of:

$$M = \sqrt{L_1 L_2} \ \text{H}$$

Mutual Inductance Between Coils

```
(magnitude of complex current vector
v1#branch)
```

Incidentally, the graph output produced by this SPICE computer analysis is more generally known as a Bode plot. Such graphs plot amplitude or phase shift on one axis and frequency on the other. The steepness of a Bode plot curve characterizes a circuit's "frequency response," or how sensitive it is to changes in frequency.

• REVIEW:

• Resonance occurs when capacitive and inductive reactances are equal to each other.

• For a tank circuit with no resistance (R), resonant frequency can be calculated with the following formula:

$$f_{resonant} = \frac{1}{2\pi \sqrt{LC}}$$

• The total impedance of a parallel LC circuit approaches infinity as the power supply frequency approaches resonance.

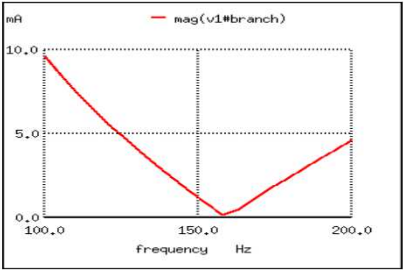

Figure 6.13: Nutmeg produces plot of current I(v1) for parallel resonant circuit.

- A Bode plot is a graph plotting waveform amplitude or phase on one axis and frequency on the other.

6.3 Simple series resonance

A similar effect happens in series inductive/capacitive circuits. (Figure 6.14) When a state of resonance is reached (capacitive and inductive reactances equal), the two impedances cancel each other out and the total impedance drops to zero!

---

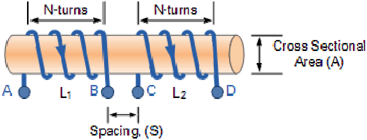
wound one on top of the other over a common soft iron core unity coupling is said to exist between them as any losses due to the leakage of flux will be extremely small. Then assuming a perfect flux linkage between the two coils the mutual inductance that exists between them can be given as.

$$M = \frac{\mu_o \mu_r N_1 N_2 A}{\ell}$$

Where:

- μo is the permeability of free space (4.π.10-7)
- μr is the relative permeability of the soft iron core
- N is in the number of coil turns
- A is in the cross-sectional area in m2
- l is the coils length in meters

Mutual Induction

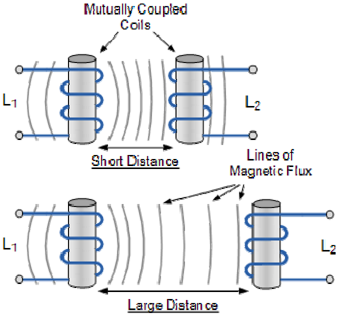


Here the current flowing in coil one, L1 sets up a magnetic field around itself with some of these magnetic field lines passing through coil two, L2 giving us mutual inductance. Coil one has a current of I1 and N1 turns while, coil two has N2 turns. Therefore, the mutual inductance, M12 of coil two that exists with respect to coil one depends on their position with respect to each other and is given as:

coil turns of the second coil inducing a relatively large emf and therefore producing a large mutual inductance value.

Likewise, if the two coils are farther apart from each other or at different angles, the amount of induced magnetic flux from the first coil into the second will be weaker producing a much smaller induced emf and therefore a much smaller mutual inductance value. So the effect of mutual inductance is very much dependant upon the relative positions or spacing, (S) of the two coils and this is demonstrated below.

Mutual Inductance between Coils



The mutual inductance that exists between the two coils can be greatly increased by positioning them on a common soft iron core or by increasing the number of turns of either coil as would be found in a transformer. If the two coils are tightly

---

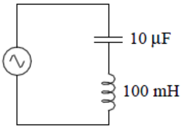


Figure 6.14: Simple series resonant circuit.

At 159.155 Hz:

$Z_L = 0 + j100\ \Omega$ $Z_C = 0 - j100\ \Omega$

$$Z_{series} = Z_L + Z_C$$

$$Z_{series} = (0 + j100\ \Omega) + (0 - j100\ \Omega)$$

$$Z_{series} = 0\ \Omega$$

With the total series impedance equal to 0 at the resonant frequency of 159.155 Hz, the result is a short circuit across the AC power source at resonance. In the circuit drawn above, this would not be good. I'll add a small resistor (Figure 6.15) in series along with the capacitor and the inductor to keep the maximum circuit current somewhat limited, and perform another SPICE analysis over the same range of frequencies: (Figure 6.16)

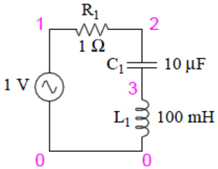

Figure 6.15: Series resonant circuit suitable for SPICE.

```
series lc circuit
v1 1 0 ac 1 sin
r1 1 2 1
c1 2 3 10u
l1 3 0 100m
.ac lin 20 100 200
.plot ac i(v1)
.end
```

As before, circuit current amplitude increases from bottom to top, while frequency increases from left to right. (Figure 6.16) The peak is still seen to be at the plotted frequency point of 157.9 Hz, the closest analyzed point to our predicted resonance point of 159.155 Hz. This would suggest that our resonant frequency formula holds as true for simple series LC circuits as it does for simple parallel LC circuits, which is the case:

Mutual Inductance of Two Coils

Wayne Storr
http://www.electronics-tutorials.ws/inductor/mutual-inductance.html

Mutual Inductance of Two Coils

In the previous tutorial we saw that an inductor generates an induced emf within itself as a result of the changing magnetic field around its own turns, and when this emf is induced in the same circuit in which the current is changing this effect is called Self-induction, (L). However, when the emf is induced into an adjacent coil situated within the same magnetic field, the emf is said to be induced magnetically, inductively or by Mutual induction, symbol (M). Then when two or more coils are magnetically linked together by a common magnetic flux they are said to have the property of Mutual Inductance.

Mutual Inductance is the basic operating principal of transformers, motors, generators and any other electrical component that interacts with another magnetic field. Then we can define mutual induction as the current flowing in one coil induces an emf in an adjacent coil. But mutual inductance can also be a bad thing as "stray" or "leakage" inductance from a coil can interfere with the operation of another adjacent component by means of electromagnetic induction, so some form of electrical screening to a ground potential may be required.

The amount of mutual inductance that links one coil to another depends very much on the relative positioning of the two coils. If one coil is positioned next to the other coil so that their physical distance apart is small, then nearly nearly all of the magnetic flux generated by the first coil will interact with the a frequency point where their two reactive components cancel each other out influencing the characteristics of the circuit. Both circuits have a resonant frequency point.

The difference this time however, is that a parallel resonance circuit is influenced by the currents flowing through each parallel branch within the parallel LC tank circuit. A tank circuit is a parallel combination of L and C that is used in filter networks to either select or reject AC frequencies. Consider the parallel RLC circuit below.

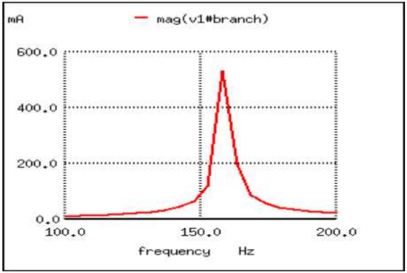

Figure 6.16: Series resonant circuit plot of current I(v1).

$$f_{resonant} = \frac{1}{2\pi \sqrt{LC}}$$

A word of caution is in order with series LC resonant circuits: because of the high currents which may be present in a series LC circuit at resonance, it is possible to produce dangerously high voltage drops across the capacitor and the inductor, as each component possesses significant impedance. We can edit the SPICE netlist in the above example to include a plot of voltage across the capacitor and inductor to demonstrate what happens: (Figure 6.17)

```
series lc circuit
v1 1 0 ac 1 sin
r1 1 2 1
```

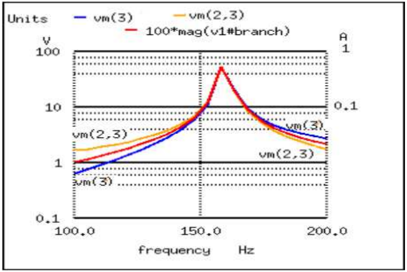
```
c1 2 3 10u
l1 3 0 100m
.ac lin 20 100 200
.plot ac i(v1) v(2,3) v(3)
.end
```

According to SPICE, voltage across the capacitor and inductor reach a peak somewhere around 70 volts! This is quite impressive for a power supply that only generates 1 volt. Needless to say, caution is in order when experimenting with circuits such as this. This SPICE voltage is lower than the expected value due to the small (20) number of steps in the AC analysis statement (.ac lin 20 100 200). What is the expected value?

Given: $f_r = 159.155$ Hz, L = 100mH, R = 1

$X_L = 2\pi fL = 2\pi(159.155)(100mH) = j100\Omega$

$X_C = 1/(2\pi fC) = 1/(2\pi(159.155)(10\mu F)) = -j100\Omega$



G + jB with the duality between the two complex impedances being defined as:

Series Circuit	Parallel Circuit
Voltage, (V)	Current, (I)
Resistance, (R)	Conductance, (G)
Reactance, (X)	Susceptance, (B)
Impedance, (Z)	Admittance, (Y)

As susceptance is the reciprocal of reactance, in an inductive circuit, inductive susceptance, BL will be negative in value and in a capacitive circuit, capacitive susceptance, BC will be positive in value. The exact opposite to XL and XC respectively.

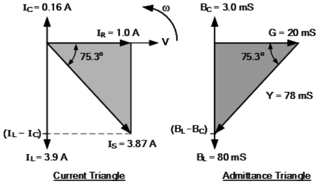
We have seen so far that series and parallel RLC circuits contain both capacitive reactance and inductive reactance within the same circuit. If we vary the frequency across these circuits there must become a point where the capacitive reactance value equals that of the inductive reactance and therefore, XC = XL. The frequency point at which this occurs is called resonance and in the next tutorial we will look at series resonance and how its presence alters the characteristics of the circuit.

Parallel Resonance

The Parallel Resonance Circuit

In many ways a parallel resonance circuit is exactly the same as the series resonance circuit we looked at in the previous tutorial. Both are 3-element networks that contain two reactive components making them a second-order circuit, both are influenced by variations in the supply frequency and both have

Current and Admittance Triangles

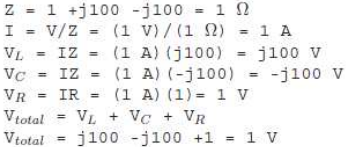


Parallel RLC Circuit Summary

In a parallel RLC circuit containing a resistor, an inductor and a capacitor the circuit current IS is the phasor sum made up of three components, IR, IL and IC with the supply voltage common to all three. Since the supply voltage is common to all three components it is used as the horizontal reference when constructing a current triangle.
Parallel RLC networks can be analysed using vector diagrams just the same as with series RLC circuits. However, the analysis of parallel RLC circuits is a little more mathematically difficult than for series RLC circuits when it contains two or more current branches. So an AC parallel circuit can be easily analysed using the reciprocal of impedance called Admittance.

Admittance is the reciprocal of impedance given the symbol, Y. Like impedance, it is a complex quantity consisting of a real part and an imaginary part. The real part is the reciprocal of resistance and is called Conductance, symbol Y while the imaginary part is the reciprocal of reactance and is called Susceptance, symbol B and expressed in complex form as: Y =

Figure 6.17: Plot of Vc=V(2,3) 70 V peak, VL=v(3) 70 V peak, I=I(V1#branch) 0.532 A peak



$$\begin{aligned}
Z &= 1 + j100 - j100 = 1\ \Omega \\
I &= V/Z = (1\ V)/(1\ \Omega) = 1\ A \\
V_L &= IZ = (1\ A)(j100) = j100\ V \\
V_C &= IZ = (1\ A)(-j100) = -j100\ V \\
V_R &= IR = (1\ A)(1) = 1\ V \\
V_{total} &= V_L + V_C + V_R \\
V_{total} &= j100 - j100 + 1 = 1\ V
\end{aligned}$$

The expected values for capacitor and inductor voltage are 100 V. This voltage will stress these components to that level and they must be rated accordingly. However, these voltages are out of phase and cancel yielding a total voltage across all three components of only 1 V, the applied voltage. The ratio of the capacitor (or inductor) voltage to the applied voltage is the “Q” factor.

$$Q = V_L/V_R = V_C/V_R$$

- REVIEW:

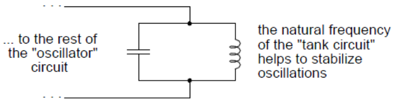
- The total impedance of a series LC circuit approaches zero as the power supply frequency approaches resonance.

- The same formula for determining resonant frequency in a simple tank circuit applies to simple series circuits as well.

- Extremely high voltages can be formed across the individual components of series LC circuits at resonance, due to high current flows and substantial individual component impedances.

6.4 Applications of resonance

So far, the phenomenon of resonance appears to be a useless curiosity, or at most a nuisance to be avoided (especially if series resonance makes for a short-circuit across our AC voltage source!). However, this is not the case. Resonance is a very valuable property of reactive AC circuits, employed in a variety of applications. One use for resonance is to establish a condition of stable frequency in circuits designed to produce AC signals. Usually, a parallel (tank) circuit is used for this purpose, with the capacitor and inductor directly connected together, exchanging energy between each other. Just as a pendulum can be used to stabilize the frequency of a clock mechanism's oscillations, so can a tank circuit be used to stabilize the electrical frequency of an AC oscillator circuit. As was noted before, the frequency set by the tank circuit is solely dependent upon the values of L and C, and not on the magnitudes of voltage or current present in the oscillations: (Figure 6.18)



... to the rest of the "oscillator" circuit
the natural frequency of the "tank circuit" helps to stabilize oscillations

Figure 6.18: Resonant circuit serves as stable frequency source.

Another use for resonance is in applications where the effects of greatly increased or decreased impedance at a particular frequency is desired. A resonant circuit can be used to "block"

7). Total supply current, (IS):

$$I_S = \sqrt{I_R^2 + (I_L - I_C)^2} = \sqrt{1^2 + (3.9 - 0.16)^2} = 3.87\,(A)$$

8). Conductance, (G):

$$G = \frac{1}{R} = \frac{1}{50} = 0.02S \text{ or } 20mS$$

9). Inductive Susceptance, (BL):

$$B_L = \frac{1}{X_L} = \frac{1}{12.6} = 0.08S \text{ or } 80mS$$

10). Capacitive Susceptance, (BC):

$$B_C = \frac{1}{X_C} = \frac{1}{318.3} = 0.003S \text{ or } 3mS$$

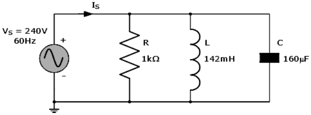
11). Admittance, (Y):

$$Y = \frac{1}{Z} = \frac{1}{12.7} = 0.078S \text{ or } 78mS$$

12). Phase Angle, (φ) between the resultant current and the supply voltage:

$$\cos\phi = \frac{G}{Y} = \frac{20mS}{78mS} = 0.256$$

$$\phi = \cos^{-1}0.256 = 75.3^{o} \;\; (\text{lag})$$



Is
Vs = 240V

+
-
R
1kΩ
L
142mH
C
160µF

1). Inductive Reactance, (XL):

$$X_L = \omega L = 2\pi f L = 2\pi.100.0.02 = 12.6\Omega$$

2). Capacitive Reactance, (XC):

$$X_C = \frac{1}{\omega C} = \frac{1}{2\pi f C} = \frac{1}{2\pi.100.5\times 10^{-6}} = 318.3\Omega$$

3). Impedance, (Z):

$$Z = \frac{1}{\sqrt{\left(\frac{1}{R}\right)^2 + \left(\frac{1}{X_C} - \frac{1}{X_L}\right)^2}} = \frac{1}{\sqrt{\left(\frac{1}{50}\right)^2 + \left(\frac{1}{318.3} - \frac{1}{12.6}\right)^2}}$$

$$Z = \frac{1}{\sqrt{0.0004 + 0.0058}} = \frac{1}{0.0788} = 12.7\Omega$$

4). Current through resistance, R (IR):

$$I_R = \frac{V}{R} = \frac{50}{50} = 1.0\,(A)$$

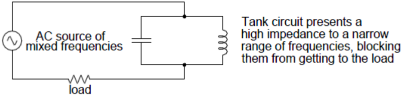
5). Current through inductor, L (IL):

$$I_L = \frac{V}{X_L} = \frac{50}{12.6} = 3.9\,(A)$$

6). Current through capacitor, C (IC):

$$I_C = \frac{V}{X_C} = \frac{50}{318.3} = 0.16\,(A)$$

(present high impedance toward) a frequency or range of frequencies, thus acting as a sort of frequency "filter" to strain certain frequencies out of a mix of others. In fact, these particular circuits are called filters, and their design constitutes a discipline of study all by itself: (Figure 6.19)



AC source of
mixed frequencies
Tank circuit presents a
high impedance to a narrow
range of frequencies, blocking
them from getting to the load
load

Figure 6.19: Resonant circuit serves as filter.

In essence, this is how analog radio receiver tuner circuits work to filter, or select, one station frequency out of the mix of different radio station frequency signals intercepted by the antenna.

• REVIEW:

• Resonance can be employed to maintain AC circuit oscillations at a constant frequency, just as a pendulum can be used to maintain constant oscillation speed in a timekeeping mechanism.

• Resonance can be exploited for its impedance properties: either dramatically increasing or decreasing impedance for certain frequencies. Circuits designed to screen certain frequencies out of a mix of different frequencies are called filters.

6.5 Resonance in series-parallel circuits

In simple reactive circuits with little or no resistance, the effects of radically altered impedance will manifest at the resonance frequency predicted by the equation given earlier. In a parallel (tank) LC circuit, this means infinite impedance at resonance. In a series LC circuit, it means zero impedance at resonance:

However, as soon as significant levels of resistance are introduced into most LC circuits, this simple calculation for resonance becomes invalid. We'll take a look at several LC circuits with added resistance, using the same values for capacitance and inductance as before: 10 μF and 100 mH, respectively. According to our simple equation, the resonant frequency should be 159.155 Hz. Watch, though, where current reaches maximum or minimum in the following SPICE analyses:

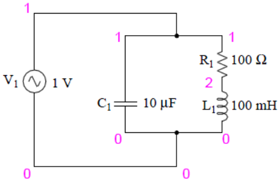


Figure 6.20: Parallel LC circuit with resistance in series with L.

Here, an extra resistor (Rbogus) (Figure 6.22)is necessary to prevent SPICE from encountering trouble in analysis. SPICE

Admittance: $$Y = \sqrt{\left(\frac{1}{R}\right)^2 + \left(\frac{1}{(\omega L)} - (\omega C)\right)^2}$$

Impedance: $$Z = \frac{1}{Y} = \frac{1}{\sqrt{\left(\frac{1}{R}\right)^2 + \left(\frac{1}{(\omega L)} - (\omega C)\right)^2}}$$

Giving us a power factor angle of:

$$\cos\phi = \frac{G}{Y} \qquad \phi = \cos^{-1}\left(\frac{G}{Y}\right)$$

or

$$\tan\phi = \frac{B}{G} \qquad \phi = \tan^{-1}\left(\frac{B}{G}\right)$$

As the admittance, Y of a parallel RLC circuit is a complex quantity, the admittance corresponding to the general form of impedance Z = R + jX for series circuits will be written as Y = G - jB for parallel circuits where the real part G is the conductance and the imaginary part jB is the susceptance. In polar form this will be given as:

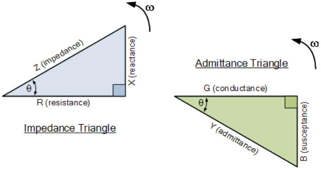
Example No1

A 50Ω resistor, a 20mH coil and a 5uF capacitor are all connected in parallel across a 50V, 100Hz supply. Calculate the total current drawn from the supply, the current for each branch, the total impedance of the circuit and the phase angle. Also construct the current and admittance triangles representing the circuit.

Parallel RLC Circuit

susceptance, B. This makes it possible to construct an admittance triangle that has a horizontal conductance axis, G and a vertical susceptance axis, jB as shown.

Admittance Triangle for a Parallel RLC Circuit



ω
Z (impedance)
X (reactance)
θ
R (resistance)
Impedance Triangle
ω
Admittance Triangle
G (conductance)
θ
Y (admittance)
B (susceptance)

Now that we have an admittance triangle, we can use Pythagoras to calculate the magnitudes of all three sides as well as the phase angle as shown.

from Pythagoras,

$$Y = \sqrt{G^2 + \left(B_L - B_C\right)^2}$$

where: $Y = \frac{1}{Z}$ $G = \frac{1}{R}$

$$B_L = \frac{1}{\omega L} \qquad B_C = \omega C$$

Then we can define both the admittance of the circuit and the impedance with respect to admittance as:

---

can’t handle an inductor connected directly in parallel with any voltage source or any other inductor, so the addition of a series resistor is necessary to “break

Minimum current at roughly 180 Hz instead of 159.2 Hz!

difference between the voltage and the current. The admittance of a parallel circuit is the ratio of phasor current to phasor voltage with the angle of the admittance being the negative to that of impedance.

Conductance (G) :

Conductance is the reciprocal of resistance, R and is given the symbol G.

$$G = \frac{1}{R}\ [S]$$

Conductance is defined as the ease at which a resistor (or a set of resistors) allows current to flow when a voltage, either AC or DC is applied.

Susceptance (B) :

Susceptance is the reciprocal of reactance, X and is given the symbol B.

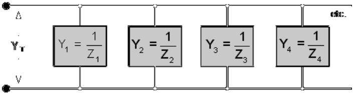
$$B_L = \frac{1}{X_L}\ [S]$$

$$B_C = \frac{1}{X_C}\ [S]$$

In AC circuits susceptance is defined as the ease at which a reactance (or a set of reactances) allows current to flow when a voltage is applied. Susceptance has the opposite sign to reactance so capacitive susceptance BC is positive, +ve in value and inductive susceptance BL is negative, -ve in value.

In AC series circuits the opposition to current flow is impedance, Z which has two components, resistance R and reactance, X and from these two coponents we can construct an impedance triangle. Similarly, in a parallel RLC circuit, admittance, Y also has two components, conductance, G and

$$\frac{1}{Z_T} = Y_T = Y_1 + Y_2 + Y_3 + Y_4 + \ldots\ldots\text{etc}$$



The new unit for admittance is the Siemens, abbreviated as S, (old unit mho's ℧, ohm's in reverse). Admittances are added together in parallel branches, whereas impedances are added together in series branches. But if we can have a reciprocal of impedance, we can also have a reciprocal of resistance and reactance as impedance consists of two components, R and X. Then the reciprocal of resistance is called Conductance and the reciprocal of reactance is called Susceptance.

Conductance, Admittance and Susceptance

The units used for conductance, admittance and susceptance are all the same namely Siemens (S), which can also be thought of as the reciprocal of Ohms or ohm-1, but the symbol used for each element is different and in a pure component this is given as:

Admittance (Y) :

Admittance is the reciprocal of impedance, Z and is given the symbol Y.

$$Y = \frac{1}{Z}\ [S]$$

In AC circuits admittance is defined as the ease at which a circuit composed of resistances and reactances allows current to flow when a voltage is applied taking into account the phase

---

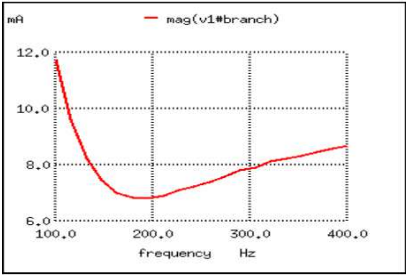


Figure 6.23: Resistance in series with C shifts minimum current from calculated 159.2 Hz to roughly 180 Hz.

Switching our attention to series LC circuits, (Figure 6.24) we experiment with placing significant resistances in parallel with either L or C. In the following series circuit examples, a 1 resistor (R1) is placed in series with the inductor and capacitor to limit total current at resonance. The “extra” resistance inserted to influence resonant frequency effects is the 100 resistor, R2. The results are shown in (Figure 6.25).

And finally, a series LC circuit with the significant resistance in parallel with the capacitor. (Figure 6.26) The shifted resonance is shown in (Figure 6.27)

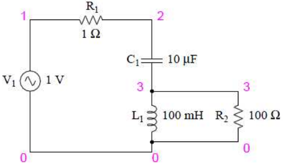

Figure 6.24: Series LC resonant circuit with resistance in parallel with L

```

```

Maximum current at roughly 178.9 Hz instead of 159.2 Hz!

Impedance of a Parallel RLC Circuit

$$R = \frac{V}{I_R} \quad X_L = \frac{V}{I_L} \quad X_C = \frac{V}{I_C}$$

$$Z = \frac{1}{\sqrt{\left(\frac{1}{R}\right)^2 + \left(\frac{1}{X_L} - \frac{1}{X_C}\right)^2}}$$

$$\therefore \frac{1}{Z} = \sqrt{\left(\frac{1}{R}\right)^2 + \left(\frac{1}{X_L} - \frac{1}{X_C}\right)^2}$$

You will notice that the final equation for a parallel RLC circuit produces complex impedances for each parallel branch as each element becomes the reciprocal of impedance, (1/Z) with the reciprocal of impedance being called Admittance. In parallel AC circuits it is more convenient to use admittance, symbol (Y) to solve complex branch impedances especially when two or more parallel branch impedances are involved (helps with the math's). The total admittance of the circuit can simply be found by the addition of the parallel admittances. Then the total impedance, ZT of the circuit will therefore be 1/YT Siemens as shown.

Admittance of a Parallel RLC Circuit

Since the voltage across the circuit is common to all three circuit elements, the current through each branch can be found using Kirchoff's Current Law, (KCL). Kirchoff's current law or junction law states that "the total current entering a junction or node is exactly equal to the current leaving that node", so the currents entering and leaving node "A" above are given as:

$$\text{KCL:}\ I_S - I_R - I_L - I_C = 0$$

$$I_S - \frac{V}{R} - \frac{1}{L}\int v\,dt - C\frac{dv}{dt} = 0$$

Taking the derivative, dividing through the above equation by C and rearranging gives us the following Second-order equation for the circuit current. It becomes a second-order equation because there are two reactive elements in the circuit, the inductor and the capacitor.

$$I_S - \frac{d^2V}{dt^2} - \frac{dV}{RCdt} - \frac{V}{LC} = 0$$

$$\therefore I_{S(t)} = \frac{d^2V}{dt^2} + \frac{dV}{dt}\frac{1}{RC} + \frac{1}{LC}V$$

The opposition to current flow in this type of AC circuit is made up of three components: XL XC and R and the combination of these three gives the circuit impedance, Z. We know from above that the voltage has the same amplitude and phase in all the components of a parallel RLC circuit. Then the impedance across each component can also be described mathematically according to the current flowing through, and the voltage across each element as.

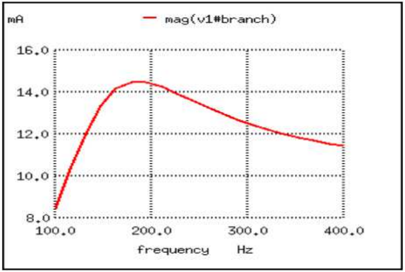

Figure 6.25: Series resonant circuit with resistance in parallel with L shifts maximum currentfrom 159.2 Hz to roughly 180 Hz.

Maximum current at 136.8 Hz instead of 159.2 Hz!

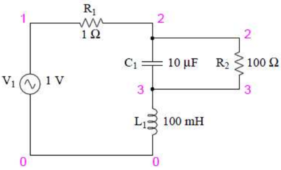

Figure 6.26: Series LC resonant circuit with rsistance in parallel with C.

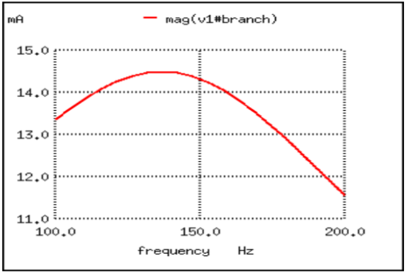

Figure 6.27: Resistance in parallel with C in series resonant circuit shifts curreent maximum from calculated 159.2 Hz to about 136.8 Hz

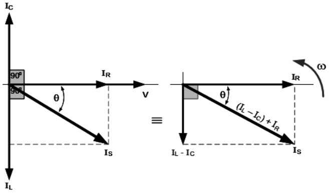
---



We can see from the phasor diagram on the right hand side above that the current vectors produce a rectangular triangle, comprising of hypotenuse IS, horizontal axis IR and vertical axis IL - IC Hopefully you will notice then, that this forms a Current Triangle and we can therefore use Pythagoras's theorem on this current triangle to mathematically obtain the magnitude of the branch currents along the x-axis and y-axis and then determine the total current IS of these components as shown.

Current Triangle for a Parallel RLC Circuit

$$I_S^2 = I_R^2 + \left(I_L - I_C\right)^2$$

$$I_S = \sqrt{I_R^2 + \left(I_L - I_C\right)^2}$$

$$\therefore\ I_S = \sqrt{\left(\frac{V}{R}\right)^2 + \left(\frac{V}{X_L} - \frac{V}{X_C}\right)^2} = \frac{V}{Z}$$

where: $I_R = \frac{V}{R},\quad I_L = \frac{V}{X_L},\quad I_C = \frac{V}{X_C}$

In the above parallel RLC circuit, we can see that the supply voltage, VS is common to all three components whilst the supply current IS consists of three parts. The current flowing through the resistor, IR, the current flowing through the inductor, IL and the current flowing through the capacitor, IC.

But the current flowing through each branch and therefore each component will be different to each other and to the supply current, IS. The total current drawn from the supply will not be the mathematical sum of the three individual branch currents but their vector sum.

Like the series RLC circuit, we can solve this circuit using the phasor or vector method but this time the vector diagram will have the voltage as its reference with the three current vectors plotted with respect to the voltage. The phasor diagram for a parallel RLC circuit is produced by combining together the three individual phasors for each component and adding the currents vectorially.

Since the voltage across the circuit is common to all three circuit elements we can use this as the reference vector with the three current vectors drawn relative to this at their corresponding angles. The resulting vector IS is obtained by adding together two of the vectors, IL and IC and then adding this sum to the remaining vector IR. The resulting angle obtained between V and IS will be the circuits phase angle as shown below.

Phasor Diagram for a Parallel RLC Circuit

The tendency for added resistance to skew the point at which impedance reaches a maximum or minimum in an LC circuit is called antiresonance. The astute observer will notice a pattern between the four SPICE examples given above, in terms of how resistance affects the resonant peak of a circuit:

- Parallel (“tank”) LC circuit:

- R in series with L: resonant frequency shifted down

- R in series with C: resonant frequency shifted up

- Series LC circuit:

- R in parallel with L: resonant frequency shifted up

- R in parallel with C: resonant frequency shifted down

Again, this illustrates the complementary nature of capacitors and inductors: how resistance in series with one creates an antiresonance effect equivalent to resistance in parallel with the other. If you look even closer to the four SPICE examples given, you’ll see that the frequencies are shifted by the same amount, and that the shape of the complementary graphs are mirror-images of each other!

Antiresonance is an effect that resonant circuit designers must be aware of. The equations for determining antiresonance “shift” are complex, and will not be covered in this brief lesson. It should suffice the beginning student of electronics to understand that the effect exists, and what its general tendencies are.

Added resistance in an LC circuit is no academic matter. While it is possible to manufacture capacitors with negligible unwanted resistances, inductors are typically plagued with substantial amounts of resistance due to the long lengths of wire used in their construction. What is more, the resistance of wire tends to increase as frequency goes up, due to a strange phenomenon known as the skin effect where AC current tends to be excluded from travel through the very center of a wire, thereby reducing the wire’s effective cross-sectional area. Thus, inductors not only have resistance, but changing, frequency-dependent resistance at that.

As if the resistance of an inductor’s wire weren’t enough to cause problems, we also have to contend with the “core losses” of iron-core inductors, which manifest themselves as added resistance in the circuit. Since iron is a conductor of electricity as well as a conductor of magnetic flux, changing flux produced by alternating current through the coil will tend to induce electric currents in the core itself (eddy currents). This effect can be thought of as though the iron core of the transformer were a sort of secondary transformer coil powering a resistive load: the less-than-perfect conductivity of the iron metal. This effects can be minimized with laminated cores, good core design and high-grade materials, but never completely eliminated.

One notable exception to the rule of circuit resistance causing a resonant frequency shift is the case of series resistor-inductor-capacitor (“RLC”) circuits. So long as all components are connected in series with each other, the resonant frequency of the circuit will be unaffected by the resistance. (Figure 6.28) The resulting plot is shown in (Figure 6.29).

The Parallel RLC Circuit

http://www.electronics-tutorials.ws/accircuits/parallel-circuit.html

The Parallel Circuit

The Parallel RLC Circuit is the exact opposite to the series circuit we looked at in the previous tutorial although some of the previous concepts and equations still apply. However, the analysis of parallel RLC circuits can a little more mathematically difficult than for series RLC circuits so in this tutorial about parallel RLC circuits only pure components are assumed in this tutorial to keep things simple.

This time instead of the current being common to the circuit components, the applied voltage is now common to all so we need to find the individual branch currents through each element. The total impedance, Z of a parallel RLC circuit is calculated using the current of the circuit similar to that for a DC parallel circuit, the difference this time is that admittance is used instead of impedance. Consider the parallel RLC circuit below.

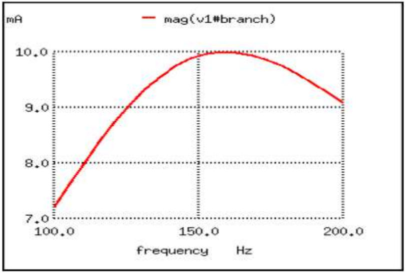

Figure 6.29: Resistance in series resonant circuit leaves current maximum at calculated 159.2 Hz, broadening the curve.

Maximum current at 159.2 Hz once again!

Note that the peak of the current graph (Figure 6.29) has not changed from the earlier series LC circuit (the one with the 1 token resistance in it), even though the resistance is now 100 times greater. The only thing that has changed is the "sharpness" of the curve. Obviously, this circuit does not resonate as strongly as one with less series resistance (it is said to be "less selective"), but at least it has the same natural frequency!

It is noteworthy that antiresonance has the effect of dampening the oscillations of freerunning LC circuits such as tank circuits. In the beginning of this chapter we saw how a capacitor and inductor connected directly together would act something like a pendulum, exchanging voltage and current peaks just like a

$$R_{eq} = \frac{\left(R_L R_C + \frac{L}{C}\right)\left(R_L + R_C\right) + \left(\omega L R_C - \frac{R_L}{\omega C}\right)\left(\omega L - \frac{1}{\omega C}\right)}{\left(R_L + R_C\right)^2 + \left(\omega L - \frac{1}{\omega C}\right)^2}$$

$$X_{eq} = \frac{\left(\omega L R_C - \frac{R_L}{\omega C}\right)\left(R_L + R_C\right) - \left(R_L R_C + \frac{L}{C}\right)\left(\omega L - \frac{1}{\omega C}\right)}{\left(R_L + R_C\right)^2 + \left(\omega L - \frac{1}{\omega C}\right)^2}$$

When the complex impedances of the branches of the parallel RLC circuit are combined, the equivalent impedance is of the form:

$$Z_{equiv} = \frac{Z_L Z_C}{Z_L + Z_C} = \frac{(R_L + j\omega L)\left(R_C - \frac{j}{\omega C}\right)}{(R_L + R_C) + j\left(\omega L - \frac{1}{\omega C}\right)}$$

When this expression is rationalized and put in the standard form:

$$Z_{eq} = R_{eq} + jX_{eq} = |Z|e^{j\phi}$$

then the impedance in ohms and the phase can be determined. By setting the = 0, the resonant frequency can be calculated. The expressions for these calculations are quite lengthy.

RLC Parallel Expressions

The complex impedances of the parallel RLC circuit takes the form:

$$Z_{equiv} = \frac{Z_L Z_C}{Z_L + Z_C} = \frac{(R_L + j\omega L)\left(R_C - \frac{j}{\omega C}\right)}{(R_L + R_C) + j\left(\omega L - \frac{1}{\omega C}\right)}$$

$$Z_{eq} = R_{eq} + jX_{eq} = |Z|e^{j\phi}$$

When rationalized, and the components have the form:

pendulum exchanges kinetic and potential energy. In a perfect tank circuit (no resistance), this oscillation would continue forever, just as a frictionless pendulum would continue to swing at its resonant frequency forever. But frictionless machines are difficult to find in the real world, and so are lossless tank circuits. Energy lost through resistance (or inductor core losses or radiated electromagnetic waves or . . .) in a tank circuit will cause the oscillations to decay in amplitude until they are no more. If enough energy losses are present in a tank circuit, it will fail to resonate at all.

Antiresonance's dampening effect is more than just a curiosity: it can be used quite effectively to eliminate unwanted oscillations in circuits containing stray inductances and/or capacitances, as almost all circuits do. Take note of the following L/R time delay circuit: (Figure 6.30)

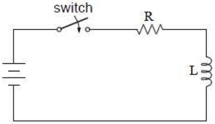

Figure 6.30: L/R time delay circuit

The idea of this circuit is simple: to "charge" the inductor when the switch is closed. The rate of inductor charging will be set by the ratio L/R, which is the time constant of the circuit in seconds. However, if you were to build such a circuit, you might find unexpected oscillations (AC) of voltage across the inductor when the switch is closed. (Figure 6.31)Why is this?

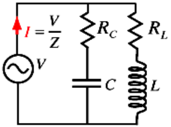
There’s no capacitor in the circuit, so how can we have resonant oscillation with just an inductor, resistor, and battery?

All inductors contain a certain amount of stray capacitance due to turn-to-turn and turn-to-core insulation gaps. Also, the placement of circuit conductors may create stray capacitance. While clean circuit layout is important in eliminating much of this stray capacitance, there will always be some that you cannot eliminate. If this causes resonant problems (unwanted AC oscillations), added resistance may be a way to combat it. If resistor R is large enough, it will cause a condition of antiresonance, dissipating enough energy to prohibit the inductance and stray capacitance from sustaining oscillations for very long.

Interestingly enough, the principle of employing resistance to eliminate unwanted resonance is one frequently used in the design of mechanical systems, where any moving object with mass is a potential resonator. A very common application of this is the use of shock absorbers in automobiles. Without shock absorbers, cars would bounce wildly at their resonant frequency after hitting any bump in the road. The shock absorber’s job is to introduce a strong antiresonant effect by dissipating energy hydraulically (in the same way that a resistor dissipates energy electrically).

RLC Parallel Circuit
HyperPhysics***** Electricity and Magnetism
http://hyperphysics.phy-astr.gsu.edu/hbase/electric/rlcpar.html

RLC Parallel Circuit



Finding the impedance of a parallel RLC circuit is considerably more difficult than finding the series RLC impedance. This is because each branch has a phase angle and they cannot be combined in a simple way. The impedance of the parallel branches combine in the same way that parallel resistors combine:

$$\frac{1}{Z_{equiv}} = \frac{1}{Z_L} + \frac{1}{Z_C} \quad \text{so} \quad Z_{equiv} = \frac{Z_L Z_C}{Z_L + Z_C}$$

But although the branch impedance magnitudes can be calculated from:

$$Z_L = \sqrt{R_L^2 + \omega^2 L^2} \quad \text{and} \quad Z_C = \sqrt{R_C^2 + \frac{1}{\omega^2 C^2}}$$

they cannot be directly combined as suggested by the expression above because they are different in phase - like vectors in different directions cannot be added directly. This dilemma is most easily solved by the complex impedance method.

RLC Parallel: Complex Impedance Method

$$I_{rms} = \frac{V_{rms}}{\sqrt{R^2+(X_L-X_C)^2}},$$

where I_{rms} and V_{rms} are rms current and voltage, respectively. The reactances vary with frequency ν, with X_L large at high frequencies and X_C large at low frequencies given as:

$$X_L = 2\pi\nu L, X_C = \frac{1}{2\pi\nu C}.$$

At some intermediate frequency ν_0, the reactances will be equal and cancel, giving Z=R —this is a minimum value for impedance, and a maximum value for I_{rms} results. We can get an expression for by taking X_L=X_C. Substituting the definitions of X_L and X_C yields:

$$\nu_0 = \frac{1}{2\pi\sqrt{LC}}.$$

ν_0 is the resonant frequency of an RLC series circuit. This is also the natural frequency at which the circuit would oscillate if not driven by the voltage source. At ν_0, the effects of the inductor and capacitor cancel, so that Z=R, and I_{rms} is a maximum. Resonance in AC circuits is analogous to mechanical resonance, where resonance is defined as a forced oscillation (in this case, forced by the voltage source) at the natural frequency of the system.

The receiver in a radio is an RLC circuit that oscillates best at its . A variable capacitor is often used to adjust the resonance frequency to receive a desired frequency and to reject others. is a graph of current as a function of frequency, illustrating a resonant peak in I_{rms} at $\nu_0 = f_0$. The two curves are for two different circuits, which differ only in the amount of resistance in them. The peak is lower and broader for the higher-resistance circuit. Thus higher-resistance circuits do not resonate as strongly, nor would they be as selective in, for example, a radio receiver.

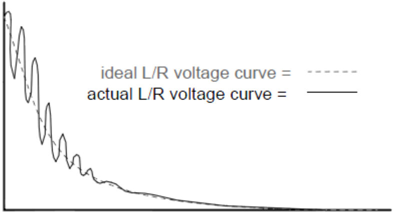


Figure 6.31: Inductor ringing due to resonance with stray capacitance.

- REVIEW:

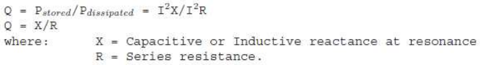
- Added resistance to an LC circuit can cause a condition known as antiresonance, where the peak impedance effects happen at frequencies other than that which gives equal capacitive and inductive reactances.

- Resistance inherent in real-world inductors can contribute greatly to conditions of antiresonance. One source of such resistance is the skin effect, caused by the exclusion of AC current from the center of conductors. Another source is that of core losses in iron-core inductors.

- In a simple series LC circuit containing resistance (an “RLC” circuit), resistance does not produce antiresonance. Resonance still occurs when capacitive and inductive reactances are equal.

6.6 Q and bandwidth of a resonant circuit

The Q, quality factor, of a resonant circuit is a measure of the "goodness" or quality of a resonant circuit. A higher value for this figure of merit correspondes to a more narrow bandwith, which is desirable in many applications. More formally, Q is the ration of power stored to power dissipated in the circuit reactance and resistance, respectively:



$Q = P_{stored}/P_{dissipated} = I^2X/I^2R$

$Q = X/R$

where: X = Capacitive or Inductive reactance at resonance
R = Series resistance.

This formula is applicable to series resonant circuits, and also parallel resonant circuits if the resistance is in series with the inductor. This is the case in practical applications, as we are mostly concerned with the resistance of the inductor limiting the Q. Note: Some text may show X and R interchanged in the "Q" formula for a parallel resonant circuit. This is correct for a large value of R in parallel with C and L. Our formula is correct for a small R in series with L

A practical application of "Q" is that voltage across L or C in a series resonant circuit is Q times total applied voltage. In a parallel resonant circuit, current through L or C is Q times the total applied current.

6.6.1 Series resonant circuits

A series resonant circuit looks like a resistance at the resonant frequency. (Figure 6.32) Since the definition of resonance is XL=XC, the reactive components cancel, leaving only the resistance to contribute to the impedance. The impedance is also at a minimum at resonance. (Figure 6.33) Below the resonant frequency, the series resonant circuit looks capacitive

---

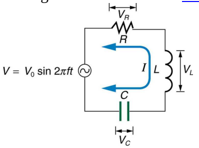
Resonance in RLC Circuits

https://www.boundless.com/physics/textbooks/boundless-physics-textbook/induction-ac-circuits-and-electrical-technologies-22/ac-circuits-162/resonance-in-rlc-circuits-586-3035/

Resonance is the tendency of a system to oscillate with greater amplitude at some frequencies—in an RLC series circuit, it occurs at $\nu_0 = \frac{1}{2\pi\sqrt{LC}}$.

\

Resonance is the tendency of a system to oscillate with greater amplitude at some frequencies than at others. Frequencies at which the response amplitude is a relative maximum are known as the system's resonance frequencies. To study the resonance in an RLC circuit, as illustrated below, we can see how the circuit behaves as a function of the frequency of the driving voltage source.



Combining Ohm's law, $I_{rms}=V_{rms}/Z$, and the expression for impedance Z from

$Z = \sqrt{R^2 + (X_L - X_C)^2}$ gives

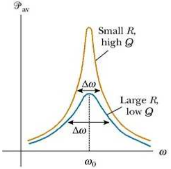


Figure 33.16 Average power versus frequency for a series *RLC* circuit. The width $\Delta\omega$ of each curve is measured between the two points where the power is half its maximum value. The power is a maximum at the resonance frequency ω_0.

The receiving circuit of a radio is an important application of a resonant circuit. One tunes the radio to a particular station (which transmits a specific electromagnetic wave or signal) by varying a capacitor, which changes the resonant frequency of the receiving circuit. When the resonance frequency of the circuit matches that of the incoming electromagnetic wave, the current in the receiving circuit increases. This signal caused by the incoming wave is then amplified and fed to a speaker. Because many signals are often present over a range of frequencies, it is important to design a high-Q circuit to eliminate unwanted signals. In this manner, stations whose frequencies are near but not equal to the resonance frequency give signals at the receiver that are negligibly small relative to the signal that matches the resonance frequency.

---

since the impedance of the capacitor increases to a value greater than the decreasing inducitve reactance, leaving a net capacitive value. Above resonance, the inductive rectance increases, capacitive reactance decreases, leaving a net inductive component.

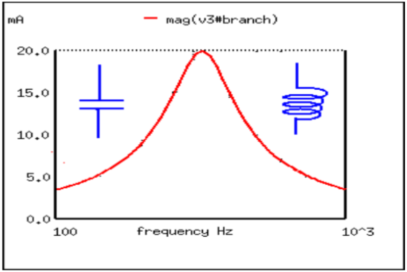

Figure 6.32: At resonance the series resonant circuit appears purely resistive. Below resonance it looks capacitive. Above resonance it appears inductive.

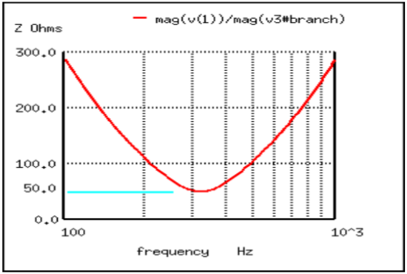

Figure 6.33: Impedance is at a minumum at resonance in a series resonant circuit.

Current is maximum at resonance, impedance at a minumum. Current is set by the value of the resistance. Above or below resonance, impedance increases.

The resonant current peak may be changed by varying the series resistor, which changes the Q. (Figure 6.34) This also affects the broadness of the curve. A low resistance, high Q circuit has a narrow bandwidth, as compared to a high resistance, low Q circuit. Bandwidth in terms of Q and resonant frequency:

Because XL = ωL, XC = 1 /ωC and ω02 = 1/LC, we can express the term (XL - XC)2 as

$$(X_L - X_C)^2 = \left(\omega L - \frac{1}{\omega C}\right)^2 = \frac{L^2}{\omega^2}\,(\omega^2 - {\omega_0}^2)^2 \qquad (33.34)$$

Using this result in Equation 33.34 gives

$$\mathcal{P}_{\mathrm{av}} = \frac{(\Delta V_{\mathrm{rms}})^2\, R\omega^2}{R^2\omega^2 + L^2(\omega^2 - {\omega_0}^2)^2} \qquad (33.35)$$

This expression shows that at resonance, when ω = ω0, the average power is a maximum and has the value (ΔVrms)2/R. Figure 33.15b is a plot of average power versus frequency for two values of R in a series RLC circuit. As the resistance is made smaller, the curve becomes sharper in the vicinity of the resonance frequency. This curve sharpness is usually described by a dimensionless parameter known as the quality factor, denoted by Q:

$$Q = \frac{\omega_0}{\Delta\omega}$$

where Δω is the width of the curve measured between the two values of ω for Pav which has half its maximum value, called the half-power points (see Fig. 33.15b.) It is left as a problem (Problem 70) to show that the width at the half-power points has the value Δω = R/L, so

$$Q = \frac{\omega_0 L}{R}$$

The curves plotted in Figure 33.16 show that a high-Q circuit responds to only a very narrow range of frequencies, whereas a low-Q circuit can detect a much broader range of frequencies. Typical values of Q in electronic circuits range from 10 to 100.

curves correspond to three values of R. Note that in each case the current reaches its maximum value at the resonance frequency ω0 . Furthermore, the curves become narrower and taller as the resistance decreases. By inspecting Equation 33.32, we must conclude that, when R = 0, the current becomes infinite at resonance. Although the equation predicts this, real circuits always have some resistance, which limits the value of the current.

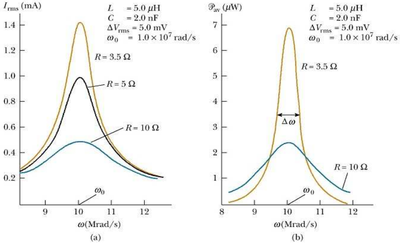

Figure 33.15 (a) The rms current versus frequency for a series RLC circuit, for three values of R. The current reaches its maximum value at the resonance frequency ω0 . (b) Average power versus frequency for the series RLC circuit, for two values of R.

It is also interesting to calculate the average power as a function of frequency for a series RLC circuit. Using Equations 33.30, 33.31, and 33.23, we find that

$$\mathcal{P}_{av} = I_{rms}^2 R = \frac{(\Delta V_{rms})^2}{Z^2} R = \frac{(\Delta V_{rms})^2 R}{R^2 + (X_L - X_C)^2}$$

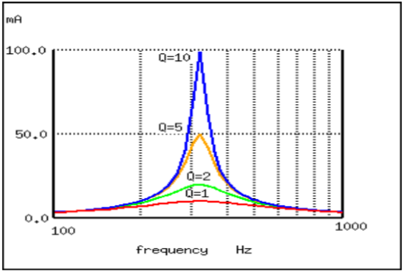

Figure 6.34: A high Q resonant circuit has a narrow bandwidth as compared to a low Q

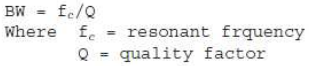

BW = f_c/Q
Where f_c = resonant frquency
Q = quality factor

Bandwidth is measured between the 0.707 current amplitude points. The 0.707 current points correspond to the half power points since P = I2R, (0.707)2 = (0.5). (Figure 6.35)

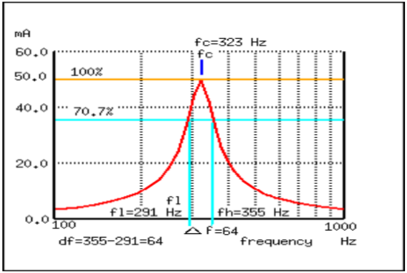

Figure 6.35: Bandwidth, · f ismeasured between the 70.7% amplitude points of series resonant circuit.

BW = Δf = $f_h - f_l$ = f_c/Q

Where f_h = high band edge, f_l = low band edge

f_l = f_c - $\Delta f/2$

f_h = f_c + $\Delta f/2$

Where f_c = center frequency (resonant frequency)

In Figure 6.35, the 100% current point is 50 mA. The 70.7% level is 0707(50 mA)=35.4 mA. The upper and lower band edges read from the curve are 291 Hz for fl and 355 Hz for fh. The bandwidth is 64 Hz, and the half power points are ± 32 Hz of the center resonant frequency:

Resonance in a series RLC circuit

© 2011-2016 Kshitij Education India

http://www.kshitij-iitjee.com/Resonance-in-a-series-RLC-circuit

A series RLC circuit is said to be in resonance when the current has its maximum value. In general, the rms current can be written

$$I_{\text{rms}} = \frac{\Delta V_{\text{rms}}}{Z} \qquad (33.31)$$

where Z is the impedance. Substituting the expression for Z from Equation 33.23 into 33.31 gives

$$I_{\text{rms}} = \frac{\Delta V_{\text{rms}}}{\sqrt{R^2 + (X_L - X_C)^2}} \qquad (33.32)$$

Because the impedance depends on the frequency of the source, the current in the RLC circuit also depends on the frequency. The frequency ω0 at which XL – XC = 0 is called the resonance frequency of the circuit. To find ω0 , we use the condition XL = XC , from which we obtain ω0L = 1/ω0C, or

$$\omega_0 = \frac{1}{\sqrt{LC}} \qquad (33.33)$$

Note that this frequency also corresponds to the natural frequency of oscillation of an LC circuit. Therefore, the current in a series RLC circuit reaches its maximum value when the frequency of the applied voltage matches the natural oscillator frequency—which depends only on L and C. Furthermore, at this frequency the current is in phase with the applied voltage.

A plot of rms current versus frequency for a series RLC circuit is shown in Figure 33.15a. The data assume a constant ΔVrms = 5.0 mV, that L = 5.0 μH, and that C = 2.0 nF. The three

$$BW = \Delta f = f_h - f_l = 355-291 = 64$$

$$f_l = f_c - \Delta f/2 = 323-32 = 291$$

$$f_h = f_c + \Delta f/2 = 323+32 = 355$$

Since BW = fc/Q:

$$Q = f_c/BW = (323\ Hz)/(64\ Hz) = 5$$

6.6.2 Parallel resonant circuits

A parallel resonant circuit is resistive at the resonant frequency. (Figure 6.36) At resonance XL=XC, the reactive components cancel. The impedance is maximum at resonance. (Fig6.6. ure 6.37) Below the resonant frequency, the parallel resonant circuit looks inductive since the impedance of the inductor is lower, drawing the larger proportion of current. Above resonance, the capacitive rectance decreases, drawing the larger current, thus, taking on a capacitive characteristic.

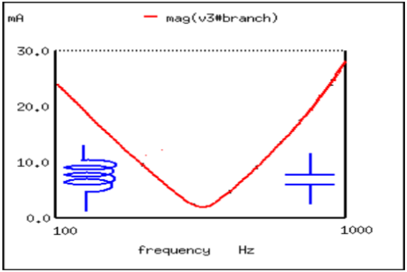

Figure 6.36: A parallel resonant circuit is resistive at resonance, inductive below resonance, capacitive above resonance.

Impedance is maximum at resonance in a parallel resonant circuit, but decreases above or below resonance. Voltage is at a peak at resonance since voltage is proportional to impedance (E=IZ). (Figure 6.37)

A low Q due to a high resistance in series with the inductor produces a low peak on a broad response curve for a parallel resonant circuit. (Figure 6.38) conversely, a high Q is due to a low resistance in series with the inductor. This produces a higher peak in the narrower response curve. The high Q is achieved by winding the inductor with larger diameter (smaller gague), lower resistance wire.

The bandwidth of the parallel resonant response curve is measured between the half power points. This corresponds to the 70.7% voltage points since power is proportional to E2. ((0.707)2=0.50) Since voltage is proportional to impedance, we may use the impedance curve. (Figure 6.39)

In Figure 6.39, the 100% impedance point is 500

. The 70.7% level is 0707(500)=354

. The upper and lower band edges read from the curve are 281 Hz for fl and 343 Hz for fh. The bandwidth is 62 Hz, and the half power points are ± 31 Hz of the center resonant frequency:

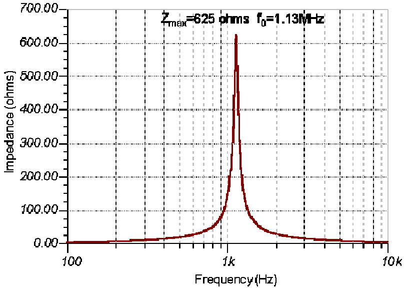
B
x: 1.16k y: 442.82

A - B
x: -63.44 y: -204.89m

The difference of the A-B cursors is 63.44Hz, which is in very good agreement with the theoretical 63.8Hz result even taking the inaccuracy of the graphic procedure into consideration.



Finally let's examine the bandwidth of this circuit.

The calculated value:

$$\Delta f = \frac{f_0}{Q_0} = \frac{1130}{17.7} = 63.8Hz$$

Lets confirm it graphically using the diagram.

Zmax = 625 ohm. The impedance limits that define the cutoff frequencies are:

$$Z_1 = Z_2 = \frac{Z_{max}}{\sqrt{2}} = 442\Omega$$

$BW = \Delta f = f_h - f_l = 343-281 = 62$
$f_l = f_c - \Delta f/2 = 312-31 = 281$
$f_h = f_c + \Delta f/2 = 312+31 = 343$

$Q = f_c/BW = (312\ Hz)/(62\ Hz) = 5$

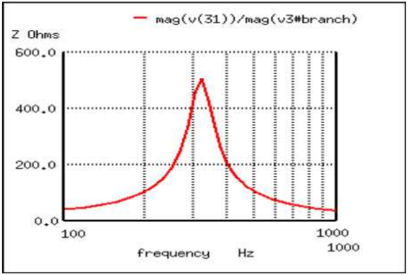


Figure 6.37: Parallel resonant circuit: Impedance peaks at resonance.

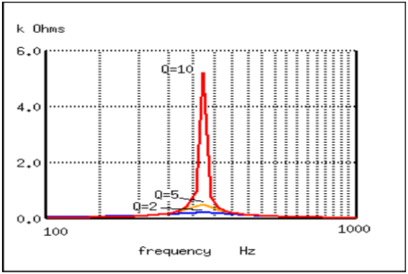

Figure 6.38: Parallel resonant response varies with Q.

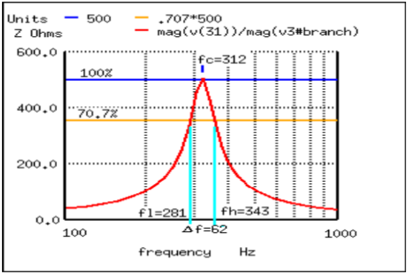
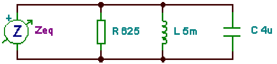
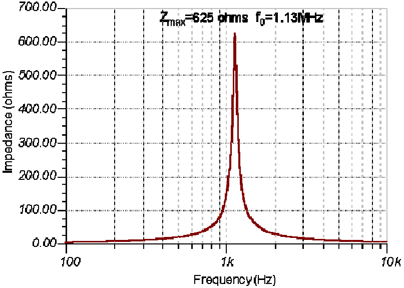


The equivalent parallel resistance: Req = Qo2 RL = 625 ohm

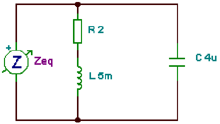
The equivalent parallel circuit:



The impedance diagram:



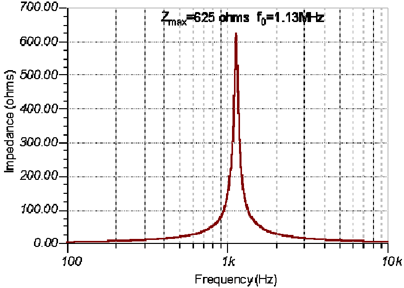
Finally, if we use copy and paste to see both curves on one diagram, we get the following picture where the two curves coincide.



The resonant (Thomson) frequency:

$$\omega_o = \frac{1}{\sqrt{LC}} = \frac{1}{\sqrt{5*4*10^{-9}}} = \frac{10^4}{\sqrt{2}}$$

The impedance diagram is the following:



$$Q_o = \frac{\omega_o L}{R_L} = \frac{10^4}{\sqrt{2}} \frac{5*10^{-3}}{2} = \frac{50}{2*\sqrt{2}} = 12.5*\sqrt{2} = 17.7$$

Figure 6.39: Bandwidth, · f is measured between the 70.7% impedance points of a parallel resonant circuit.

The equivalent impedance:

$$Z_{eq} = \frac{\frac{1}{j\omega C}(R + j\omega L)}{\frac{1}{j\omega C} + (R + j\omega L)} = \frac{R + j \ \omega \ L}{1 - \omega^2 LC + j\omega \ C \ R}$$

Let's examine this impedance at the resonant frequency where 1-w02LC=0

We will also assume that the quality factor Qo = woL/ RL>>1.

$$Z_{eq} = \frac{R_L + j\omega_o L}{j\omega_o CR} = R_L \frac{1 + jQ}{j\omega_o CR} \cong \frac{R\omega_o L}{\omega_o CR}$$

At the resonant frequency

Since at resonant frequencyw0L= 1/w0C

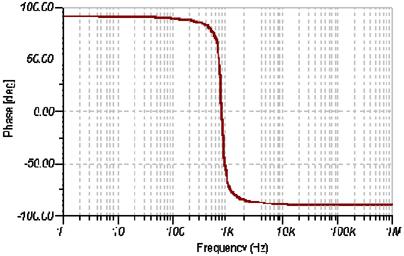
Zeq=Qo2 RL

Since in the pure parallel resonant circuit at the resonant frequency Zeq = R, the real parallel resonant circuit can be replaced by a pure parallel resonant circuit, where:

R = Qo2 RL

Example 3

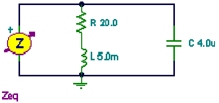
Compare the impedance diagrams of a real parallel and its equivalent pure parallel resonance circuit.



The "pure" parallel circuit above was very easy to examine since all components were in parallel. This is especially important when the circuit is connected to other parts.

However in this circuit, the series loss resistance of the coil was not considered.

Now let's examine the following so called "real parallel resonant circuit," with the series loss resistance of the coil present and learn how we can transform it into a "pure" parallel circuit.



RESONANT CIRCUITS

Copyright © 2012 DesignSoft, Inc.

http://www.tina.com/English/tina/course/28resonant/resonant.htm

Circuits containing R, L, C elements often have special characteristics useful in many applications. Because their frequency characteristics (impedance, voltage, or current vs. frequency) may have a sharp maximum or minimum at certain frequencies these circuits are very important in the operation of television receivers, radio receivers, and transmitters. In this chapter we will present the different types, models and formulas of typical resonant circuits.

SERIES RESONANCE

A typical series resonant circuit is shown in the figure below.

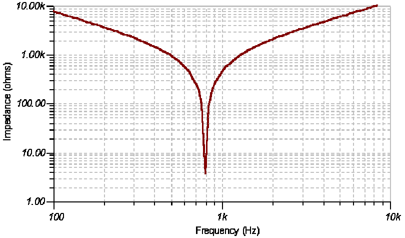
The total impedance:

$$Z = j\omega L + R + \frac{1}{j\omega C} = R + j\left(\omega L - \frac{1}{\omega C}\right)$$

In many cases, R represents the loss resistance of the inductor, which in the case of air core coils simply means the resistance of the winding. The resistances associated with the capacitor are often negligible.

The impedances of the capacitor and inductor are imaginary and have opposite sign. At the frequency w0 L= 1/w0C, the total imaginary part is zero and therefore the total impedance is R, having a minimum at the w0frequency. This frequency is called the series resonant frequency.

The typical impedance characteristic of the circuit is shown in the figure below.



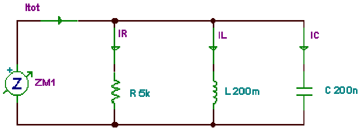
From the w0L= 1/w0Cequation, the angular frequency of the series resonance: or for the frequency in Hz:

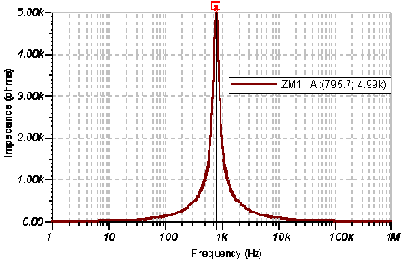
$$T_0 = \frac{2\pi}{\omega_0} = 2\pi\sqrt{LC}.$$

f0 =

This is the so-called Thomson formula.

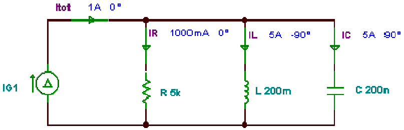
If R is small compared to the XL, XC reactance around the resonant frequency, the impedance changes sharply at the series resonant frequencyIn this case we say that the circuit has good selectivity.





<

Find the resonant frequency and the resonant quality factor of a pure parallel resonance circuit where R = 5 kohm, L = 0.2 H, C = 200 nF.



The resonant frequency:

$$\omega_0 = \sqrt{\frac{1}{LC}} = \sqrt{\frac{1}{0.2*0.2*10^{-6}}} = 5000\, {}^{rad}\!/_{s}$$

$$f_0 = \frac{\omega_0}{2\pi} = 795.8\,Hz$$

and the resonant quality factor:

$$Q = \frac{B_C}{G} = \frac{\omega C}{G} = \omega CR = R\sqrt{\frac{C}{L}} = 5*10^3 * \sqrt{\frac{0.2*10^{-6}}{0.2}} = 5$$

Incidentally, this quality factor is equal to IL /IR at the resonant frequency.

Now let us draw the impedance diagram of the circuit:

The simplest way is to replace the current source by an impedance meter and run an AC Transfer analysis.

The selectivity can be measured by the quality factor Q If the angular frequency in the formula equals the angular frequency of resonance, we get the resonant quality factor There is a more general definition of the quality factor:

$$Q = 2\pi \frac{\text{energy stored in inductor}}{\text{the energy turned to heat during one period}} = \frac{I^2 \omega L}{I^2 R} = \frac{\omega L}{R}$$

The voltage across the inductor or capacitor can be much higher then the voltage of the total circuit. At the resonant frequency the total impedance of the circuit is:

Z=R

Assuming that the current through the circuit is I, total voltage on the circuit is

Vtot=I*R

However the voltage on the inductor and the capacitor

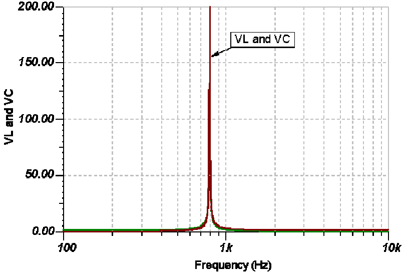
$$V_L = V_C = I\omega_0 L = \frac{I}{\omega_0 C}$$

Therefore

$$\frac{V_L}{V_{tot}} = \frac{V_C}{V_{tot}} = Q_0$$

This means at the resonant frequency the voltages on the inductor and the capacitor are Q0 times greater than the total voltage of the resonant circuit.

The typical run of the VL, VC voltages is shown in the figure below.



Let's demonstrate this via a concrete example.

Example 1

Find the frequency of resonance (f0) and the resonant quality factor (Q0) in the series circuit below, if C=200nF, L=0.2H, R=200 ohms, and R=5 ohms. Draw the phasor diagram and the frequency response of the voltages.

voltage and admittance changes sharply around the resonant frequency. In this case we say the circuit has good selectivity.

Selectivity can be measured by the quality factor Q

$$Q = \frac{B_C}{G} = \frac{\omega C}{G} = \omega CR$$

When the angular frequency equals the angular frequency of resonance, we get the resonant quality factor

$$Q_0 = \frac{B_C}{G} = \frac{\omega_0 C}{G} = \omega_0 CR = R\sqrt{\frac{C}{L}}$$

There is also a more general definition of the quality factor:

$$Q = 2\pi \ \frac{\text{energy stored in capacitance}}{\text{the energy turned to heat during one period}} = \frac{V^2 \omega_0 C}{V^2 G} = \omega_0 C$$

Another important property of the parallel resonant circuit is its bandwidth. The bandwidth is the difference between the two cutoff frequencies, where the impedance drops from its maximum value to $\frac{1}{\sqrt{2}} = 0.707 \quad (-3dB)\ of\ldots$ the maximum.

It can be shown that the Δf bandwidth is determined by the following simple formula:

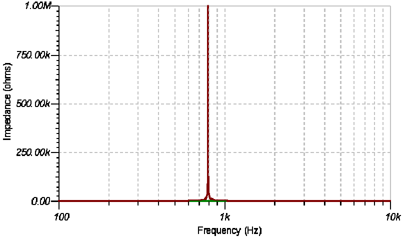
$$\Delta f = \frac{f_0}{Q_0}$$

This formula is also applicable for series resonant circuits.

Let us demonstrate the theory through some examples.

Example 2

linear impedance axis is shown below. Note that viewed with this axis, the impedance appears to be changing even more rapidly near resonance.



The susceptances of the inductance and capacitance are equal but of opposite sign at resonance: BL = BC, 1/w0L = w0C, hence the angular frequency of the parallel resonance:

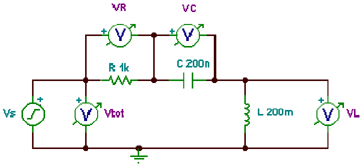
$$\omega_0 = \sqrt{\frac{1}{LC}}$$

determined again by the Thomson formula.

Solving for the resonant frequency in Hz:

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{1}{LC}}$$

At this frequency the admittance Y = 1/R = G and is at its minimum (i.e., the impedance is maximum). The currents through the inductance and capacitance can be much higher then the current of the total circuit. If R is relatively large, the



$$f_0 = \frac{\omega_0}{2\pi} = 795.8Hz$$

For R=200 ohms

This is a quite low value for practical resonant circuits, which normally have quality factors over 100. We have used a low value to more easily demonstrate the operation on a phasor diagram.

The current at the resonance frequency I=Vs/R=5m>

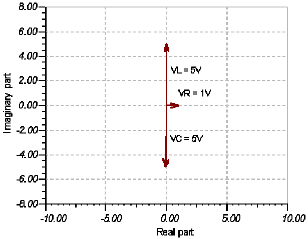
The voltages at current of 5mA: VR = Vs =1 V

meanwhile: VL = VC = I*w0L = 5*10-3 *5000*0.2 = 5V

The ratio between VL, VC,and Vs is equal to the quality factor!

Now let's see the phasor diagram by calling it from the AC Analysis menu of TINA.

We used the Auto Label tool of the diagram window to annotate the picture.



The phasor diagram nicely shows how the voltages of the capacitor and inductor cancel each other at the resonance frequency.

Now let's see VLand VCversus frequency.

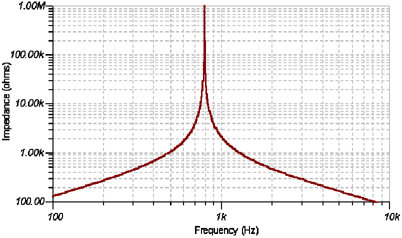
see below the loss resistance of the inductor can be transformed into this resistor.

The total admittance:

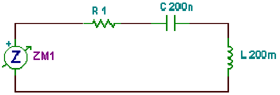
$$Y=\frac{1}{R}+j\omega C+\frac{1}{j\omega L}=R+j(\omega C-\frac{1}{\omega L})$$

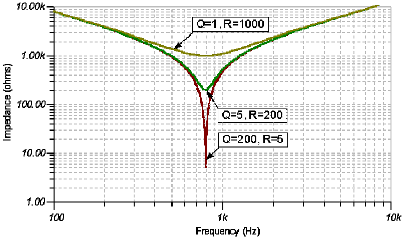
The admittances (called susceptances) of the capacitor and inductor are imaginary and have opposite sign. At the frequency w0C= 1/w0Lthe total imaginary part is zero, so the total admittance is 1/R-its minimum value and the total impedance has its maximum value. This frequency is called the parallel resonant frequency.

The total impedance characteristic of the pure parallel resonant circuit is shown in the figure below:



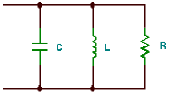
Note that the impedance changes very rapidly around the resonance frequency, even though we used a logarithmic impedance axis for better resolution. The same curve with a



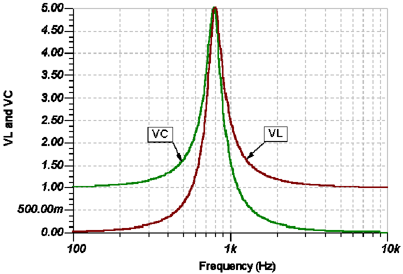


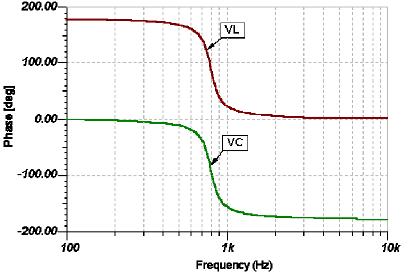
PARALLEL RESONANCE

The pure parallel resonant circuit is shown in the figure below.



If we neglect the loss resistance of the inductor, R represents the leakage resistance of the capacitor. However, as we will





Note that VL starts from zero voltage (because its reactance is zero at zero frequency) while VC starts from 1 V (because its reactance is infinite at zero frequency). Similarly VL tends to 1V and VCto 0V at high frequencies.

Now for R=5 ohms the quality factor is much greater:

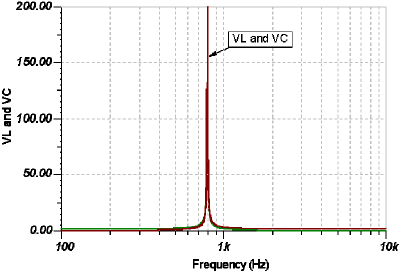
This is a relatively high quality factor, close to the practical achievable values.

The current at the resonance frequency I=Vs/R=0.2A

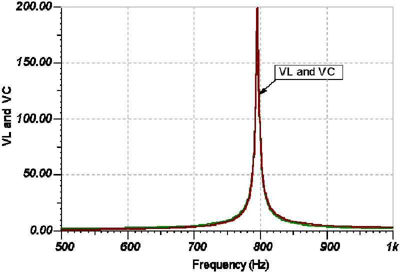
meanwhile: VL = VC = I*w0L = 0.2*5000*0.2 = 200

Again the ratio between the voltages equals the quality factor!

Now let's draw just VL and VC voltages versus frequency. On the phasor diagram, VR would be too small compared to VLand VC



As we can see, the curve is very sharp and we needed to plot 10,000 points to get the maximum value accurately. Using a narrower bandwidth on the linear scale on the frequency axis, we get the more detailed curve below.



Finally let's see the impedance characteristic of the circuit: for different quality factors.

The figure below was created using TINA by replacing the voltage generator by an impedance meter. Also, set up a parameter stepping list for R = 5, 200, and 1000 ohms. To set up parameter stepping, select Control Object from the Analysis menu, move the cursor (which has changed into a resistor symbol) to the resistor on the schematic, and click with the left mouse button. To set a logarithmic scale on the Impedance axis, we have double-clicked on the vertical axis and set Scale to Logarithmic and the limits to 1 and 10k.

KEVIN’S WEBSURFER HANDBOOK VII
FOR CRYSTAL RADIO

DEDICATED ENTIRELY to VACUUM DIODES

Kevin Smith
2012

Printing / Binding Instructions

1. Choose “fit to page” in print menu
2. Print document double sided on letter size paper
3. Cut the entire printed document in half
4. Fold over making sure the page numbering is continuous
5. For the cover: Print just the first page on card stock paper
   Cut the cover in half as well
6. Assemble the covers on the document
7. Punch the left side for a binding, spiral or comb as desired

KJ Smith

NOTES

INTRODUCTION

The contents of this latest handbook, volume 7 already, is concerned exclusively with the subject of vacuum diodes. Crystal radio is already a hobby dominated by an interest in vintage and antiquated technology. Vacuum tubes are yet another aspect of vintage radio technology. Interestingly, the vacuum diode was invented and patented prior to the crystal detector, one year prior it is true, but the priority is there.

As a crystal radio hobbyist, my interest is in diodes and rectification, not amplification so no triode (or higher) type tubes are on the menu. My personal interest in tubes stems from a childhood of listening to classic tube radios. I had one on a small shelf next to my bed and would often lay awake in the dark listening to music (turned down low so my parents would not hear) and look at the red glow from the inside of the set. There was something reassuring about the glow, you knew the radio would work as long as the glow was there. Agreed, having to wait a minute or so while the radio "warmed up" before hearing anything could be at times frustrating. When your friends called and said to "quick, turn on the radio and listen to this...", well, it was probably already too late. I also recall the first transistor radio and how cool it was to have the sound come on instantly. Still, what goes around, comes around. I recently was showing my adult daughter a cool old tube radio I had purchased. I turned it on and, as usual nothing... We talked on a bit about the hobby and stuff when, as if by magic, the sound from the radio behind us came on. She, astonished, exclaimed that’s "So cool!". Novelty is always fun. I note that she didn't go out to buy herself a tube iphone.

As tubes pretty much went the way of the horse and buggy with the introduction of transistors, most, virtually all good technical information on vacuum tubes is vintage in nature. As such, I have conceived this handbook as a historical walk down memory lane as well as technical reference for those, like myself, who wish to add vacuum tubes to their crystal radio projects and need specific technical help. I open with the words of Fleming himself describing the valves' pedigree and his personal involvement as the inventor of the vacuum valve. From there I move quickly to useful references and analysis from the 1940's, the heyday of the vacuum era. For much this I am MOST indebted to Pete Millett's tubebooks.org for scanned reference works on tubes, (http://www.tubebooks.org/). I have only included those portions of documents directly concerned with diode theory and operation. For your interest in triodes and amplification, I encourage you to visit Pete yourself.

I also include a good recent treatise on vacuum tubes by Calvert in 2003, (also included in my Handbook III on Diodes). And finally some of my own measurements, graphs, and notes on a selection of vacuum tubes I have acquired and played with.

While much of the material in this handbook is way out of copyright, some is and I have not sought permission. Therefore this is not presented for publication or copy, and certainly not for profit. It is only my personal resource. I encourage anyone finding this copy to pursue ON THE WEB the web pages identified, especially tubebooks.org. I wish to sincerely thank every author presented for their excellent pages and ask forgiveness for my editing into this handbook.

expressed its real potential. The evidence is given by modern formulation designs wich, often join even in concepts going back to the dawning of electronics (as well as harmonic cancellation, feed-forward, tansformer coupling, choke input filter etc.), can produce sonic results higher than the crowd of Williamson-like amplifiers.

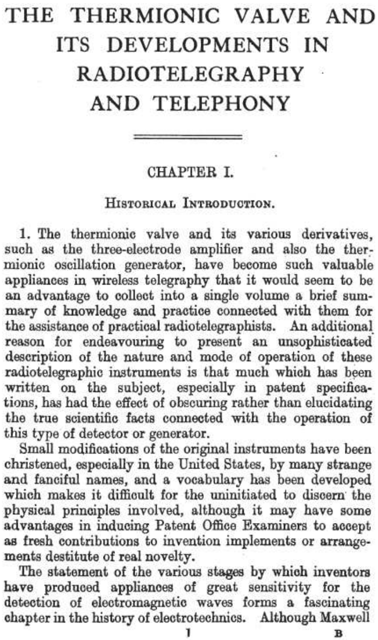
UNIV. OF



THE THERMIONIC VALVE AND ITS DEVELOPMENTS IN RADIOTELEGRAPHY AND TELEPHONY

CHAPTER I.

HISTORICAL INTRODUCTION.

1. The thermionic valve and its various derivatives, such as the three-electrode amplifier and also the thermionic oscillation generator, have become such valuable appliances in wireless telegraphy that it would seem to be an advantage to collect into a single volume a brief summary of knowledge and practice connected with them for the assistance of practical radiotelegraphists. An additional reason for endeavouring to present an unsophisticated description of the nature and mode of operation of these radiotelegraphic instruments is that much which has been written on the subject, especially in patent specifications, has had the effect of obscuring rather than elucidating the true scientific facts connected with the operation of this type of detector or generator.

Small modifications of the original instruments have been christened, especially in the United States, by many strange and fanciful names, and a vocabulary has been developed which makes it difficult for the uninitiated to discern the physical principles involved, although it may have some advantages in inducing Patent Office Examiners to accept as fresh contributions to invention implements or arrangements destitute of real novelty.

The statement of the various stages by which inventors have produced appliances of great sensitivity for the detection of electromagnetic waves forms a fascinating chapter in the history of electrotechnics. Although Maxwell

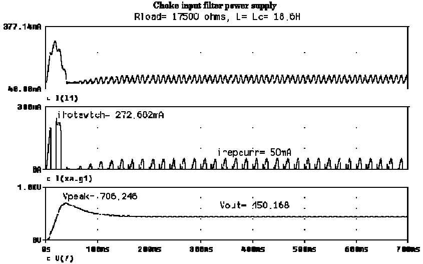


Fig. 11;

As you can observe in Fig. 9 it is rather easy to overcome the limits related to the impulsive currents also with small input condensers therefore their capacitive value has to be valued very attentively. Besides Fig. 11 reveals that the swinging choke calculus is not very accurate.

An actual comparison

In Table 6 I present the results of two simple power supplies with condenser and choke input filter respectively. Schematics are the same of Figs. 9 and 10 but with the following differences:

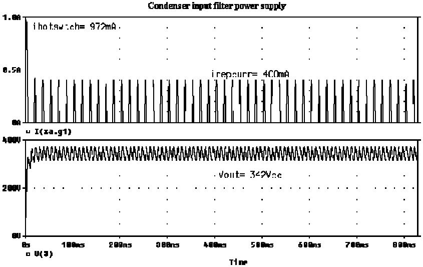

Fig. 9;

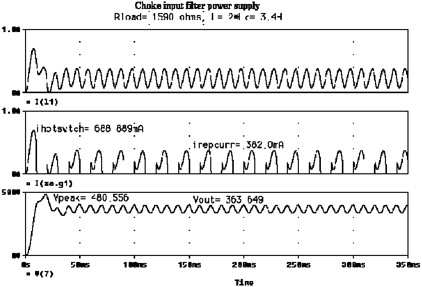

Fig. 10;

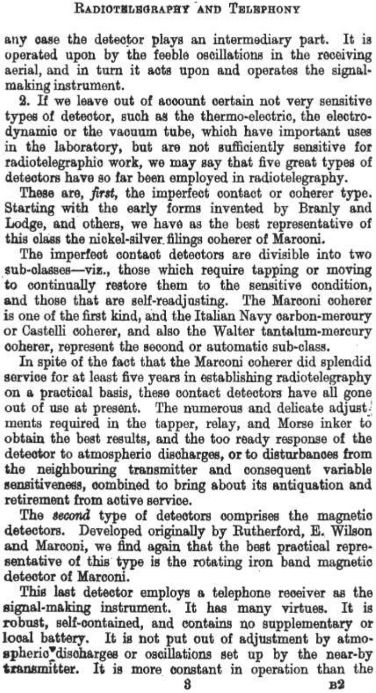
enunciated in 1865 his great epoch-making theory that electromagnetic effects must be propagated through dielectrics as a wave motion, and surmised that such electromagnetic radiation was identical in nature with light, the acceptance of his views was retarded by the want of experimental proof that such waves could be created and detected by purely electromagnetic methods. Hertz's invention of the ring resonator with micro-spark gap supplied the first means of detecting these space waves, which G. F. Fitzgerald had previously suggested might be created by the oscillatory discharge of a Leyden jar. The employment of Maxwell's electromagnetic waves to effect radiotelegraphy, involving the propagation of such waves over distances reckoned in miles, was fundamentally dependent on Marconi's key invention of the aerial wire or antenna, but it necessitated as well the possession of far more sensitive and certain means of detecting these waves than the ring resonator of Hertz.

In radiotelegraphy we make use of electromagnetic waves propagated over the earth's surface to set up in a receiving aerial wire feeble electric oscillations which are a copy on a very reduced scale of the strong oscillations created in the sending aerial wire. In modern radiotelegraphy the oscillations are generated in the aerials either continuously or else in uniformly time-spaced trains, the train or group frequency agreeing with that frequency for which the Bell telephone receiver, acting on the human ear, is most sensitive —viz., about 300-500 per second. These oscillations are then cut up into short and long periods or groups of trains to create the Morse-code signals.

In the ordinary language of wireless telegraphy we call any instrument a *detector* which is employed to detect or make evident by audible or visible means these groups or intermittencies of very feeble electric oscillations in the receiving aerial wire and associated circuits which convey the intelligible signals.

The signal-making instrument may be some form of telegraphic printer, such as the Kelvin syphon recorder or the Morse inker, or the more sensitive Einthoven galvanometer with photographic tape record. On the other hand it may be a Bell telephone receiver, making an audible sound and appealing therefore directly to the ear. In



RADIOTELEGRAPHY AND TELEPHONY

any case the detector plays an intermediary part. It is operated upon by the feeble oscillations in the receiving aerial, and in turn it acts upon and operates the signal-making instrument.

2. If we leave out of account certain not very sensitive types of detector, such as the thermo-electric, the electro-dynamic or the vacuum tube, which have important uses in the laboratory, but are not sufficiently sensitive for radiotelegraphic work, we may say that five great types of detectors have so far been employed in radiotelegraphy.

These are, *first*, the imperfect contact or coherer type. Starting with the early forms invented by Branly and Lodge, and others, we have as the best representative of this class the nickel-silver filings coherer of Marconi.

The imperfect contact detectors are divisible into two sub-classes—viz., those which require tapping or moving to continually restore them to the sensitive condition, and those that are self-readjusting. The Marconi coherer is one of the first kind, and the Italian Navy carbon-mercury or Castelli coherer, and also the Walter tantalum-mercury coherer, represent the second or automatic sub-class.

In spite of the fact that the Marconi coherer did splendid service for at least five years in establishing radiotelegraphy on a practical basis, these contact detectors have all gone out of use at present. The numerous and delicate adjustments required in the tapper, relay, and Morse inker to obtain the best results, and the too ready response of the detector to atmospheric discharges, or to disturbances from the neighbouring transmitter and consequent variable sensitiveness, combined to bring about its antiquation and retirement from active service.

The *second* type of detectors comprises the magnetic detectors. Developed originally by Rutherford, E. Wilson and Marconi, we find again that the best practical representative of this type is the rotating iron band magnetic detector of Marconi.

This last detector employs a telephone receiver as the signal-making instrument. It has many virtues. It is robust, self-contained, and contains no supplementary or local battery. It is not put out of adjustment by atmospheric discharges or oscillations set up by the near-by transmitter. It is more constant in operation than the

Fig. 8;

In Figg. 7 and 8 I have brought two hypotheses of power supply with condenser and choke input filter respectively together with their SPICE codes related to present examples beginning from the pages 1174 and 1183 of the Radiotron Designer's Handbook. The resistances R1 and R2 are the total effective plate supply impedance per plate and they represent the impedances brought to every secondary winding according to the formula:

Rs= Rsec + N2 * Rpri;

where:

N= Voltage ratio of transformer at no load (primary to half secondary in case of full-wave rectification);
Rpri= Resistance of primary winding in ohms;
Rsec= Resistance of secondary windind in ohms (or half secondary in case of full-wave rectification;

---

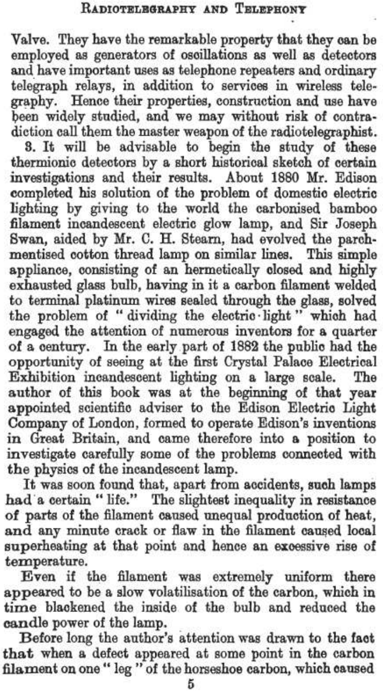
capricious coherer, but it is not one of the most sensitive detectors. Nevertheless, for military or ship work it is still much valued, although not very light in weight.

The *third* class of detector comprises the electrolytic detectors in which the electrical oscillations to be detected are caused to alter the conductivity of an electrolytic cell by varying the ionic films on the electrodes. These detectors have never come into very extensive use in Great Britain.

The *fourth* type of detector, and until lately probably the most extensively used, are the rectifying contact or crystal detectors. Starting with Dunwoody's discovery of the rectifying property of certain crystals of carborundum and with the discoveries of Pickard and G. W. Pierce on the rectifying power of contacts between crystals of zincite and chalcopyrite and molybdenite and copper, there has been an immense amount of research on this type of detector, which depends either upon a true unilateral conductivity in the mass or at the contact or else upon sudden changes in curvature in the volt-ampere or characteristic curve.

The simplest mode of use of such crystal detectors is as rectifiers of the oscillation trains into gushes of electricity in the same direction, thus enabling trains of electrical oscillations to affect a telephone receiver. These detectors are rather easily put out of adjustment by strong atmospheric discharges, or by strong oscillations set up by the proximity of the transmitter. They therefore require somewhat frequent readjustment of contact to obtain the best results. Nevertheless, their sensitiveness, simplicity and cheapness made them very quickly a favourite detector. Their introduction was followed at once by an outburst of irresponsible radiotelegraphy at the hands of innumerable electrical amateurs and students which required the firm intervention of National and International legislation to keep it within bounds of reason and safety.

The *fifth* class of detector comprises those to the consideration of which this book is limited—viz., the thermionic detectors. These depend ultimately upon the emission from incandescent bodies of ions or electrons. They are or can be made highly sensitive and yet are not affected injuriously by atmospherics or by neighbouring electric sparks. They are easy of adjustment and always ready for use. The original of all these detectors is the now well-known Fleming



Valve. They have the remarkable property that they can be employed as generators of oscillations as well as detectors and have important uses as telephone repeaters and ordinary telegraph relays, in addition to services in wireless telegraphy. Hence their properties, construction and use have been widely studied, and we may without risk of contradiction call them the master weapon of the radiotelegraphist.

3. It will be advisable to begin the study of these thermionic detectors by a short historical sketch of certain investigations and their results. About 1880 Mr. Edison completed his solution of the problem of domestic electric lighting by giving to the world the carbonised bamboo filament incandescent electric glow lamp, and Sir Joseph Swan, aided by Mr. C. H. Stearn, had evolved the parchmentised cotton thread lamp on similar lines. This simple appliance, consisting of an hermetically closed and highly exhausted glass bulb, having in it a carbon filament welded to terminal platinum wires sealed through the glass, solved the problem of "dividing the electric light" which had engaged the attention of numerous inventors for a quarter of a century. In the early part of 1882 the public had the opportunity of seeing at the first Crystal Palace Electrical Exhibition incandescent lighting on a large scale. The author of this book was at the beginning of that year appointed scientific adviser to the Edison Electric Light Company of London, formed to operate Edison's inventions in Great Britain, and came therefore into a position to investigate carefully some of the problems connected with the physics of the incandescent lamp.

It was soon found that, apart from accidents, such lamps had a certain "life." The slightest inequality in resistance of parts of the filament caused unequal production of heat, and any minute crack or flaw in the filament caused local superheating at that point and hence an excessive rise of temperature.

Even if the filament was extremely uniform there appeared to be a slow volatilisation of the carbon, which in time blackened the inside of the bulb and reduced the candle power of the lamp.

Before long the author's attention was drawn to the fact that when a defect appeared at some point in the carbon filament on one "leg" of the horseshoe carbon, which caused

calculations and formulae just finalized to the solution of actual situation. Other texts I know lack suitable depth or face the subject in a too academic way not enough finalized to the solution of real problems. On the contrary in the Radiotron's by fast procedures it is possible plan power supplies with both condenser input filter and choke input one. Unfortunately the accuracy, especially in the evaluation of the impulsive currents, is not high but this is due to the use of purposely approximate formulae to have agile calculation that at the time were made by the hand. Besides the book introduces two levels of approximation if you have complete data or not.

Now you can use the data in Table 3 to build the SPICE model of the diode. After the excellent articles by Raynolds [2], Marshall [3] and Koren [4], I don't think you will find any difficulty to understand the code in Table 4. The only required operation is to use the information in Table 3 and complete the code in Table 4 on the grounds of the selected diode.

How use this models

The first reason that can push you to look for an accurate model of vacuum diode is that, you can determine, when the device is used as a rectifier, a series of parameters whose exact evaluation can be either difficult or inaccurate as for istance the repetitive peak current, the hot-switching current, the output impedance etc. Besides the SPICE model you need further informations to place the device in safety areas. These informations are graphically available in Data-Sheets Rating Charts. In my opinion the Radiotron Designer's Handbook magistrally deals with the subject as it faces the whole problem list merely in engineering terms and therefore with

a great rise of temperature at that point, the blackening of the interior of the bulb was less or absent along a certain line in such fashion as to show that the scattered carbon molecules had been shot off in straight lines from the point of excessive heating. Thus was formed what the author termed *a molecular shadow* on the bulb (see Fig. 1). If, for instance, a scent-sprayer is filled with ink and the spray blown on to a sheet of paper the latter will be darkened uniformly by minute drops of ink spray. If, however, a wire or rod is held in the path of the spray the paper will be protected from blackening along a region which corresponds to the shadow of the rod (see Fig. 2). Hence when we find in old carbon filament incandescent lamps a horseshoe filament broken at one spot and the bulb darkened all over the inside with the exception of a white or undarkened line on the bulb corresponding to the shadow of the unbroken part of the filament relatively to the point of rupture or overheating we can conclude that the chief part of the scattering of the carbon particles has taken place in straight lines proceeding from the point in the filament at which it has ultimately burnt through. This phenomenon of "molecular shadows" in incandescent lamps was described by the author in two papers read to the Physical Society of London in 1883 and 1885.[1]

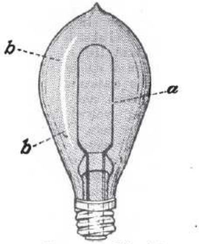

FIG. 1.—Incandescent Electric Lamp, showing the glass bulb blackened by the deposit of carbon or metal due to molecular scattering from point *a* on the filament, a shadow line of no deposit being formed at *b*, due to shielding effect of one leg of the horseshoe filament.

This effect clearly showed that from the incandescent filament there was a projection of matter in straight lines which was deposited on the interior of the bulb, except in those parts shielded by the "shadow" of the rest of the filament, thus leaving a white or unblackened line. This effect is obviously due to the fact that the residual air in the bulb is at such a rarefied condition that the mean free path of a molecule is comparable in length with the diameter of the bulb.

---

[1] See *Proc. Phys. Soc. Lond.*, vol. v., p. 283, 1883, "On a Phenomenon of Molecular Radiation in Incandescent Lamps," by J. A. Fleming; also *Proc. Phys. Soc. Lond.*, vol. vii., p. 178, 1885, "On Molecular Shadows in Incandescent Lamps," by J. A. Fleming.

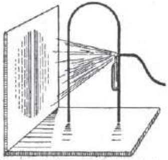

FIG. 2.—A "spray shadow" of a rod thrown on a cardboard screen by ink spray to illustrate the mode of formation of a molecular shadow in a glow lamp.

In air at ordinary temperature and pressure the mean free path of an oxygen or nitrogen molecule is about four one-millionths of an inch, but when the pressure is reduced in a bulb to one-millionth of an atmosphere it becomes increased to about four inches. This means that a molecule of carbon projected in any way from the filament might travel on an average four inches before colliding with other residual air molecules and being deflected from its path.

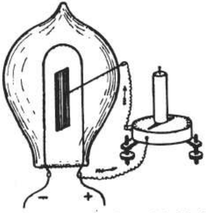

FIG. 3.—Incandescent Lamp with a Metal Plate sealed into the bulb and a galvanometer connected between the terminal of the plate and positive terminal of the filament to show the "Edison effect."

The next important observation on this subject was made by Mr. Edison in 1883.[1] He was apparently examining the phenomena involved when carbon filament lamps are running at a high efficiency, and for that purpose he sealed into the bulb of a glow lamp a metal plate placed between the legs of the horseshoe-shaped carbon filament, the

Tab. 3; Results for $I_p = (K_a + K_b \cdot V_p) \cdot (V_p + EPS)^A$ model

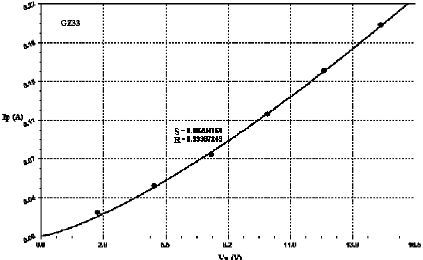

Fig. 6;

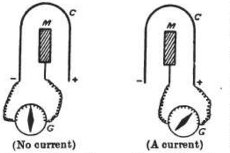
Finally you can get an even better fitting if you use the following equation:

$$Ip= (Ka+Kb*Vp)*(Vp+EPS)A \quad (3).$$

The equation (3) differs from (2) because a linear variation to the perveance has been attributed with respect to Vp. The application of LSM with linear regression leads to the data in Table 3. You can get further short improvement margins using more sophisticated mathematical models although this injuries simplicity and brings larger problems of convergence in simulations.

plate being carried on an insulated wire sealed through the bulb (see Fig. 3). He found that, when the filament was rendered incandescent by a direct current of electricity, a galvanometer connected between the middle plate and the positive terminal of the filament indicated a current of a few milliamperes, but little or no current when connected between the negative terminal and the middle plate (see Fig. 4). He did not furnish any explanation of this effect at that time, but it became known then and after as the "Edison effect" in glow lamps.

Mr. Edison gave to Sir William Preece in October, 1884, certain incandescent lamps made with metal plates sealed into their bulbs or into tubular extensions of them, and in the following year, in March, 1885, Preece described to the Royal Society of London experiments which he had made with these lamps.[1] Preece made quantitative measurements of the current flowing through the galvanometer when connected in between the positive terminal of the carbon filament and the middle plate at various voltages applied to the filament. He found that this current was independent of the nature of the metal of which the middle plate was made, but that it increased very rapidly with increase in the potential difference of the filament terminals. He found that for a given lamp voltage the Edison effect varied with the position of the plate in the bulb, but that it was still sensible when this plate was placed at the closed end of a tube opening out of the bulb, provided this tube was straight, but the current was found to vanish if that side tube was bent up at right angles (see Figs. 5 and 6).



(No current) (A current)

[1] See *Proc. Roy. Soc. Lond.*, vol. xxxviii., p. 219, 1885, "On a Peculiar Behaviour of Glow Lamps when Raised to High Incandescence," by W. H. Preece.

Preece considered that this Edison effect was connected with the discharge or projection of carbon molecules or particles from the filament in straight lines, but he gave

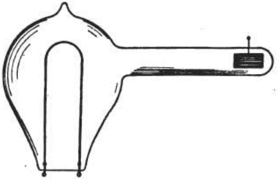

FIG. 5.—Collecting Plate placed at the end of a side tube opening out of the bulb of an incandescent lamp.

no full theory of the phenomenon, nor did he make any application of the facts. A year or two later the author of this book took up the investigation, being convinced that much yet remained to be discovered about it which had not been unravelled by Edison or Preece.

A number of special carbon filament glow lamps with middle plates were made for the author at the Lamp Factory of the Edison and Swan United Electric Light Company and researches were begun with them, and the results communicated to the Royal Society of London in 1889.[1] and in a Friday evening

Tab. 2; Results for the $Ip= K*(Vp+EPS)^A$

to apply LSM to the set of experimental data. The results of this procedure have quoted in Table 2. EPS represents a parameter that can be manually fixed (typical values are 0.1, 0.2) used to guarantee a better convergence of the algorithm. If you compare the Correlation Coefficient of the Table 1 and 2, you can note a real amelioration, underlined subsequently by the new graphic representations of the tubes 12X4, GZ30, GZ33 related in Figg. 4, 5, 6. Futhermore the examination of Table 2 reveals that the real diode is subjugated by the 3/2 power law only in few cases.

discourse on February 14th, 1890, to the Royal Institution.[1]

One of the first new facts the author discovered was that the "Edison effect" was greatly diminished or entirely annulled by surrounding the negative leg of the carbon filament by a glass or metal tube, or by interposing a mica shield between the negative leg of the horseshoe-shaped carbon filament and that side of the middle or insulated plate facing the negative leg (see Figs. 7, 8 and 9). By negative leg is meant that side of the carbon horseshoe loop in connection with the negative pole of the battery which heats the filament. It was not annulled or much diminished when the tube surrounded the positive leg.

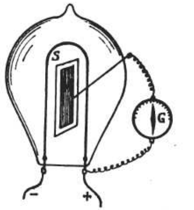

FIG. 7.—Incandescent Lamp having a mica shield placed between the metal plate, *M*, and the negative leg of carbon loop filament, thereby diminishing the "Edison effect."

The author confirmed Preece's observation that the effect

was still visible when the collecting plate was placed at the end of a long straight tube opening into the bulb, but disappeared when the plate was placed at the end of a tube bent at right angles (see Figs. 10 and 11). The next fact discovered by the author was that a charged electric conductor or electric condenser if charged with positive electricity is instantly discharged when connected to the middle plate when the lamp filament is incandescent. If, however, the conductor or condenser is charged with negative electricity, then it is not in the least discharged by so connecting. On the contrary, it will be charged negatively by the incandescent filament.

FIG. 9.—Incandescent Lamp with horseshoe carbon filament and metal cylinder surrounding one leg of filament to show the "Edison effect."

FIG. 10.

This fact may be most clearly proved by the following experiment. Connect a gold-leaf electroscope to the middle plate of the lamp, the filament being cold. Then charge the electroscope with positive electricity by means of a rubbed glass rod. Next, switch on the lamp and incandesce

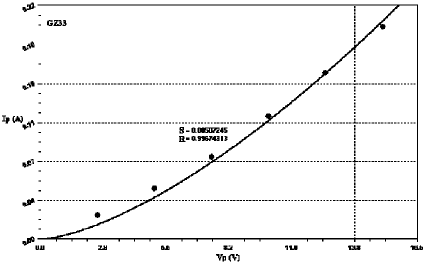

Fig. 3;

Improvement

You can already get a large improvement by varying the exponent of the equation (1). This leads to the following expression:

Ip= K*VpA.

Now use this equation, but modified in the following way:

Ip= K*(Vp+EPS)A (2)

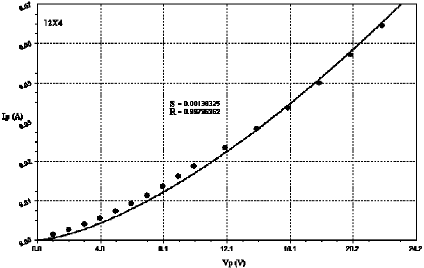

Fig. 1;

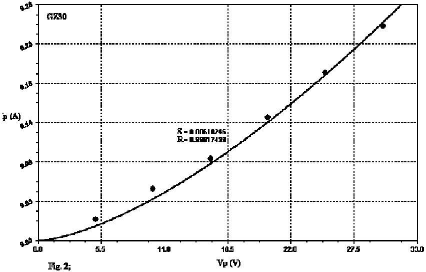

Fig. 2;

the filament. The electroscope instantly loses its positive charge. Then repeat the experiment, charging the gold leaves negatively by means of a rod of sealing wax, and it will be found that switching on the lamp does not discharge the electroscope. These experiments show that the incandescent filament is giving off negative electricity in some manner.

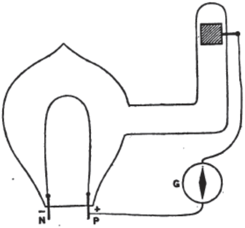

FIG. 11.

The next experiment was arranged to prove that the space between the incandescent filament and the middle plate was conductive for negative electricity from the filament to the plate, but not in the opposite direction. For this purpose a single cell of a battery was joined in series with a galvanometer and one

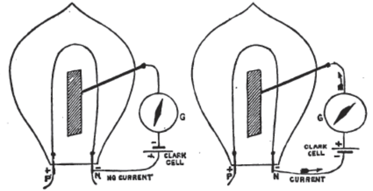

FIG. 12.—Incandescent Lamp with metal plate in the bulb and galvanometer, *G*, connecting plate and negative terminal. Clark cell inserted in plate circuit to show the escape of negative electricity from the incandescent filament.

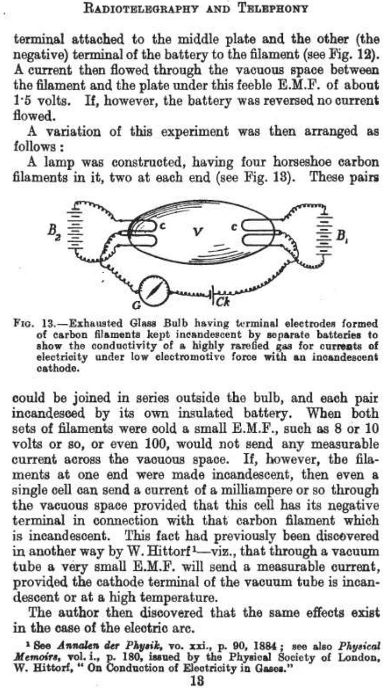

terminal attached to the middle plate and the other (the negative) terminal of the battery to the filament (see Fig. 12). A current then flowed through the vacuous space between the filament and the plate under this feeble E.M.F. of about 1·5 volts. If, however, the battery was reversed no current flowed.

A variation of this experiment was then arranged as follows:

A lamp was constructed, having four horseshoe carbon filaments in it, two at each end (see Fig. 13). These pairs could be joined in series outside the bulb, and each pair incandesced by its own insulated battery. When both sets of filaments were cold a small E.M.F., such as 8 or 10 volts or so, or even 100, would not send any measurable current across the vacuous space. If, however, the filaments at one end were made incandescent, then even a single cell can send a current of a milliampere or so through the vacuous space provided that this cell has its negative terminal in connection with that carbon filament which is incandescent. This fact had previously been discovered in another way by W. Hittorf[1]—viz., that through a vacuum tube a very small E.M.F. will send a measurable current, provided the cathode terminal of the vacuum tube is incandescent or at a high temperature.

FIG. 13.—Exhausted Glass Bulb having terminal electrodes formed of carbon filaments kept incandescent by separate batteries to show the conductivity of a highly rarefied gas for currents of electricity under low electromotive force with an incandescent cathode.

The author then discovered that the same effects exist in the case of the electric arc.

---

[1] See *Annalen der Physik*, vo. xxi., p. 90, 1884; see also *Physical Memoirs*, vol. i., p. 180, issued by the Physical Society of London, W. Hittorf, "On Conduction of Electricity in Gases."

You can see the perveance as the digital imprint or the genetic code of the diode because in (1) it constitues the only parameter able to differentiate the multiplicity of the diodes.

Besides the Child-Langmuir's Law is a phenomenological equation, that is derived on physical considerations grounds.

If we use this equation to apply the Least Square Method (LSM) with linear regression to the set of experimental data extracted by the Data-Sheets it is difficult to get a good fitting, as you can see by examining Table 1. In this table S and R represent the Standard Error and the Correlation Coefficient respectively. A perfect fitting is gotten when R is equal to 1. The good values of the Correlation Coefficient R brought in Table 1 must not deceive you, since R is a paramenter of global evaluation and lower values to 0.998 cannot be thought satisfactory as the graphs of the Figg. 1, 2, 3 related to the diodes 12X4, GZ30, GZ33 show, in wich the model introduces, locally, marked deviations. In this graphs the "small black balls" represent the average data extracted from Data-Sheets. In my opinion this model well represent only tubes like 5U4 and GZ40: you can think of them as perfect diodes (although not ideal !). In all the other cases the results can be improved so to get nearest simulations to the reality. The apparent redundance in Table 1 and those following where is present either 12X4 or EZ90/6X4 will be clarified later.

In the "sacred texts" the equation brought for describing the operation of the diode is the well note Child-Langmuir's Law:

Ip= K*Vp1.5 (1);
where:

Ip is the current that flows in the diode;
Vp is the anode to cathode voltage;
K is a costant said perveance.

Tab. 1; Results for the Ip=k*(Vp)$^{1.5}$ model

If a direct current electric arc of some length is formed between carbon electrodes, and if a third carbon electrode is so placed as just to dip into the flame of the arc, or if the arc is deflected against it by a magnet, it will be found that a galvanometer or ammeter connected between the positive carbon and the third or lateral carbon indicates a current which may even be strong enough to ring an electric bell. If, however, the ammeter or bell is connected between the negative carbon of the arc and the middle carbon, then no current passes (see Fig. 14).

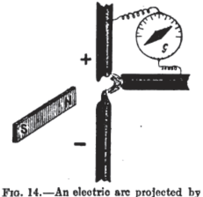

FIG. 14.—An electric arc projected by means of a magnet against a third carbon to show the "Edison effect" in the case of an electric arc.

Also, it can be shown by the same means that the space between the negative carbon of the arc and the middle carbon possesses a unilateral conductivity and will permit negative electricity from a battery to pass from this negative carbon to the middle carbon, but not in the opposite direction (see Fig. 15).

Finally, the author discovered that the same phenomenon can be demonstrated in the air at ordinary pressure. For if a thick carbon filament is rendered incandescent in air by passing a strong current through it, and if an insulated metal plate is held near to it, a galvanometer joined in between this metal

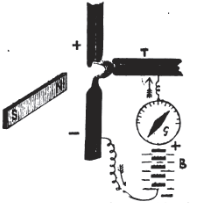

FIG. 15.—An experiment with the electric arc having a third carbon to show that a current of negative electricity can pass under low E.M.F. between the negative terminal of the arc and the third carbon electrode.

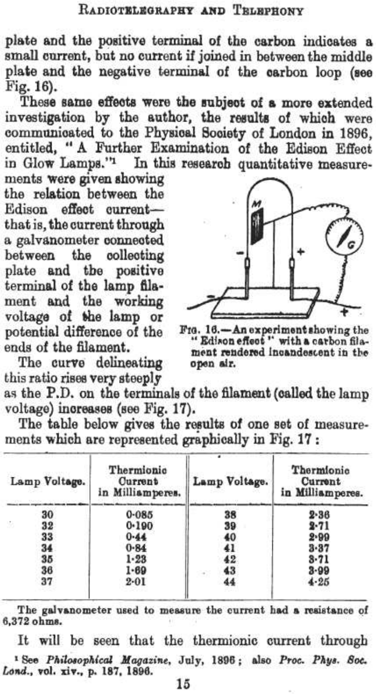

plate and the positive terminal of the carbon indicates a small current, but no current if joined in between the middle plate and the negative terminal of the carbon loop (see Fig. 16).

These same effects were the subject of a more extended investigation by the author, the results of which were communicated to the Physical Society of London in 1896, entitled, "A Further Examination of the Edison Effect in Glow Lamps."[1] In this research quantitative measurements were given showing the relation between the Edison effect current—that is, the current through a galvanometer connected between the collecting plate and the positive terminal of the lamp filament and the working voltage of the lamp or potential difference of the ends of the filament.

FIG. 16.—An experiment showing the "Edison effect" with a carbon filament rendered incandescent in the open air.

The curve delineating this ratio rises very steeply as the P.D. on the terminals of the filament (called the lamp voltage) increases (see Fig. 17).

The table below gives the results of one set of measurements which are represented graphically in Fig. 17:

Lamp Voltage.	Thermionic Current in Milliamperes.	Lamp Voltage.	Thermionic Current in Milliamperes.
30	0·085	38	2·36

Vacuum diode Models & PSpice Simulations

Stefano Perugini
http://digilander.iol.it/paeng/vacuum_diode_models.htm

This article appeared originally in Glass Audio, Vol.10,Nr. 4, 1998.

The renewed interest in the thermionic technology applied to the audio is pushing the most sensitive designers to use, widely, the modern tools of circuit simulation SPICE-oriented, in the convincement that the best sonic results to be gotten with a deep circuit optimization and not simply making use of the most expensive component. An ulterior big advantage is given by the facility wich is possible to experiment unusual and effective solutions saving up time and money contemporarily.

In this article I focus the attention in the creation of a very simple but accurate vacuum diode model in the conviction that the correct realization of an audio amplifier cannot be separated from the correct realization of associate power-supply. Moreover many people are convinced that the best sonic results could be gotten just turning to the vacuum diode as rectifier element. Nevertheless the use of such devices presents some problems; in fact it is necessary to check by calculations often dull and not very careful, several parameters as the repetitive peak current, the hot-switching current, the maximum inverse voltage and so on, otherwise it is possible to lead the device to a premature death. On the contrary if you resort to the circuit simulation, on the condition that you have accurate models, you can overcome the optimization phase in the virtual world, totally, and go out only to effect the inevitable micro-adaptations and therefore build the real object.
At the end of this article I will show the goodness of the mathematical model used by comparing it with a real situation, that is comparing the results gotten by measurements on a simple power supply phisically realized, with the results gotten by the same simulated power supply.

START

the galvanometer, when connected between the collecting plate and the positive terminal of the filament, rises to several milliamperes in value. If the galvanometer is

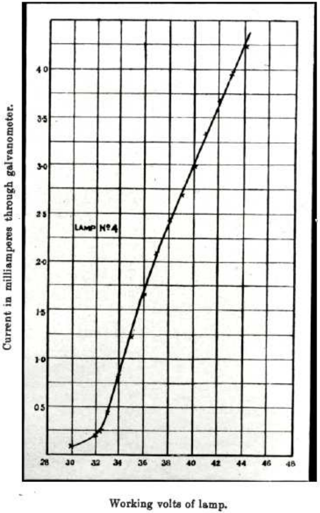

FIG. 17.

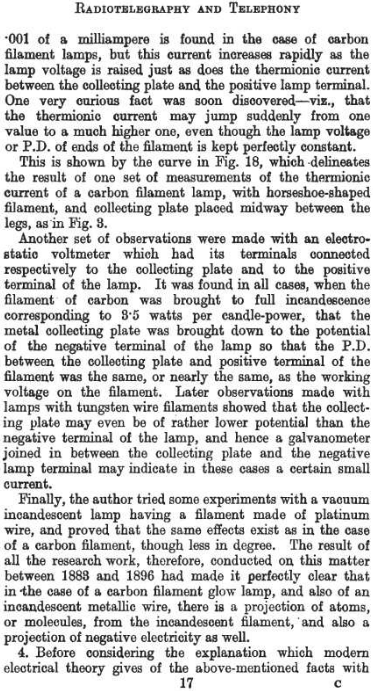
connected between the collecting plate and the negative terminal only a very small current of, perhaps, less than



·001 of a milliampere is found in the case of carbon filament lamps, but this current increases rapidly as the lamp voltage is raised just as does the thermionic current between the collecting plate and the positive lamp terminal. One very curious fact was soon discovered—viz., that the thermionic current may jump suddenly from one value to a much higher one, even though the lamp voltage or P.D. of ends of the filament is kept perfectly constant.

This is shown by the curve in Fig. 18, which delineates the result of one set of measurements of the thermionic current of a carbon filament lamp, with horseshoe-shaped filament, and collecting plate placed midway between the legs, as in Fig. 3.

Another set of observations were made with an electrostatic voltmeter which had its terminals connected respectively to the collecting plate and to the positive terminal of the lamp. It was found in all cases, when the filament of carbon was brought to full incandescence corresponding to 3·5 watts per candle-power, that the metal collecting plate was brought down to the potential of the negative terminal of the lamp so that the P.D. between the collecting plate and positive terminal of the filament was the same, or nearly the same, as the working voltage on the filament. Later observations made with lamps with tungsten wire filaments showed that the collecting plate may even be of rather lower potential than the negative terminal of the lamp, and hence a galvanometer joined in between the collecting plate and the negative lamp terminal may indicate in these cases a certain small current.

Finally, the author tried some experiments with a vacuum incandescent lamp having a filament made of platinum wire, and proved that the same effects exist as in the case of a carbon filament, though less in degree. The result of all the research work, therefore, conducted on this matter between 1883 and 1896 had made it perfectly clear that in the case of a carbon filament glow lamp, and also of an incandescent metallic wire, there is a projection of atoms, or molecules, from the incandescent filament, and also a projection of negative electricity as well.

4. Before considering the explanation which modern electrical theory gives of the above-mentioned facts with

regard to the incandescent lamp, we must briefly review certain earlier researches in connection with the loss of electricity from incandescent bodies.

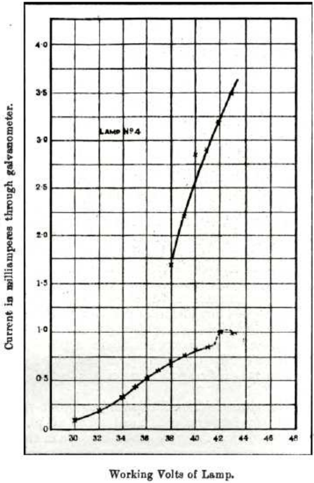

FIG. 18.

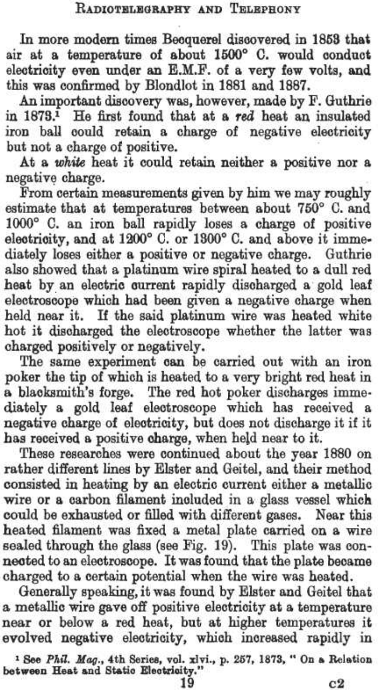
It had become known to the investigators of electrical phenomena in the middle of the eighteenth century that heat and flame cause a leakage of electricity from charged conductors.



In more modern times Becquerel discovered in 1853 that air at a temperature of about 1500° C. would conduct electricity even under an E.M.F. of a very few volts, and this was confirmed by Blondlot in 1881 and 1887.

An important discovery was, however, made by F. Guthrie in 1873.[1] He first found that at a *red* heat an insulated iron ball could retain a charge of negative electricity but not a charge of positive.

At a *white* heat it could retain neither a positive nor a negative charge.

From certain measurements given by him we may roughly estimate that at temperatures between about 750° C. and 1000° C. an iron ball rapidly loses a charge of positive electricity, and at 1200° C. or 1300° C. and above it immediately loses either a positive or negative charge. Guthrie also showed that a platinum wire spiral heated to a dull red heat by an electric current rapidly discharged a gold leaf electroscope which had been given a negative charge when held near it. If the said platinum wire was heated white hot it discharged the electroscope whether the latter was charged positively or negatively.

The same experiment can be carried out with an iron poker the tip of which is heated to a very bright red heat in a blacksmith's forge. The red hot poker discharges immediately a gold leaf electroscope which has received a negative charge of electricity, but does not discharge it if it has received a positive charge, when held near to it.

These researches were continued about the year 1880 on rather different lines by Elster and Geitel, and their method consisted in heating by an electric current either a metallic wire or a carbon filament included in a glass vessel which could be exhausted or filled with different gases. Near this heated filament was fixed a metal plate carried on a wire sealed through the glass (see Fig. 19). This plate was connected to an electroscope. It was found that the plate became charged to a certain potential when the wire was heated.

Generally speaking, it was found by Elster and Geitel that a metallic wire gave off positive electricity at a temperature near or below a red heat, but at higher temperatures it evolved negative electricity, which increased rapidly in

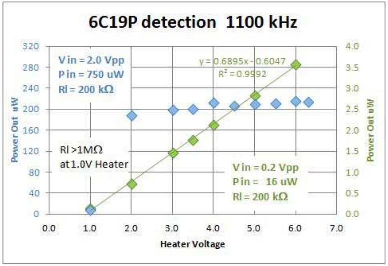
---

[1] See *Phil. Mag.*, 4th Series, vol. xlvi., p. 257, 1873, "On a Relation between Heat and Static Electricity."

at 20mV input (2.0Vpp on signal generator), and a monotonic increase in output power at 6mV input (0.2Vpp on the generator). I was seeking a peak output power at around 4.0V on the heater so this result is disturbing. I can hear it, but cannot measure it.

Biasing the plate positive will have the effect of "pulling" the space charge towards the plate increasing the current while a negative plate bias will have the opposite effect. With 6.0V heater it will take nearly a negative half volt before the current stops. This is death to sensitivity in a crystal set. Operating the heater at 4.0V provides the most efficient rectification.

Note also that high perveance is not merely a matter of placing the plate as close as possible to the cathode. This may cause an excessive zero-bias current to overcome. The surface-area of both cathode and plate are also critical with large areas providing high current transfer. Vacuum tubes such as pentodes with an included diode plate are poor rectifiers having very low perveance. This is due to the small plate stuck in with all the other hardware in the tube. Get a "fit for purpose" diode for best results.



Note that while the above model as well as hearing (a kind of "hearing is beleiving" thing) supports the 4.0V heater voltage as a sweet spot for highest rectification efficiency, I have as yet not been able to measure this. Using my tube-driven Telefunken set (see description on my main radio page) I made a series of output signal power measurements at various tube heater voltages. I we see no relation between matched output power and the tube heater voltage

quantity as the temperature was raised, and therefore gave a negative charge to the insulated plate. Carbon filaments, however, were found to give off negative electricity at all temperatures.

As some references later on will be made to the published papers of Elster and Geitel we give here the titles (in English) and references to the principal papers which concern us in this subject.

(1) "On the Electricity of Flames," *Wiedemann's Annualen*, vol. xvi., p. 193 (1882).

(2) "On the Generation of Electricity by the Contact of Gases and Incandescent Bodies," *Wied. Ann.*, vol. xix., p. 588 (1883).

(3) "On the Unipolar Conductivity of Heated Gases," *Wied. Ann.*, vol. xxvi., p. 1 (1885).

This paper deals with the unsymmetrical conductivity of flames.

(4) "On the Electrification of Rarefied Gases and Electrically Heated Wires," *Wied. Ann.*, vol. xxxi., p. 109 (1887).

In this paper Elster and Geitel describe experiments made with an exhausted glass bulb having stretched across it a platinum wire which could be heated electrically. Above the wire was a metal plate carried on a platinum wire sealed through the glass (see Fig. 19). The bulb could be exhausted or filled with various gases. There is no mention of the use of a carbon filament.

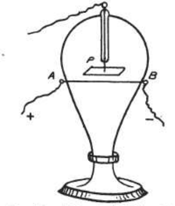


FIG. 19.—Exhausted bulb with incandescent wire, *AB*, in it, and metal plate, *P*, used by Elster and Geitel to show the emission of electricity from incandescent wires.

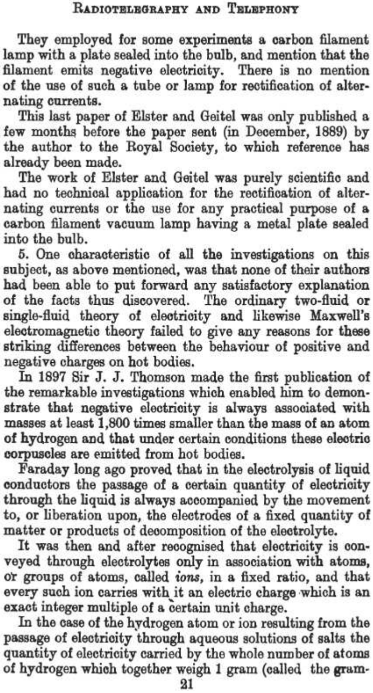
(5) "On the Generation of Electricity by Contact of Rarefied Gas and Electrically Heated Wires," *Wied. Ann.*, vol. xxxvii., p. 319 (1889).

In this paper (dated March, 1889) Elster and Geitel mention the unilateral conductivity for direct currents of rarefied gases in tubes with one hot and one cold electrode.



They employed for some experiments a carbon filament lamp with a plate sealed into the bulb, and mention that the filament emits negative electricity. There is no mention of the use of such a tube or lamp for rectification of alternating currents.

This last paper of Elster and Geitel was only published a few months before the paper sent (in December, 1889) by the author to the Royal Society, to which reference has already been made.

The work of Elster and Geitel was purely scientific and had no technical application for the rectification of alternating currents or the use for any practical purpose of a carbon filament vacuum lamp having a metal plate sealed into the bulb.

5. One characteristic of all the investigations on this subject, as above mentioned, was that none of their authors had been able to put forward any satisfactory explanation of the facts thus discovered. The ordinary two-fluid or single-fluid theory of electricity and likewise Maxwell's electromagnetic theory failed to give any reasons for these striking differences between the behaviour of positive and negative charges on hot bodies.

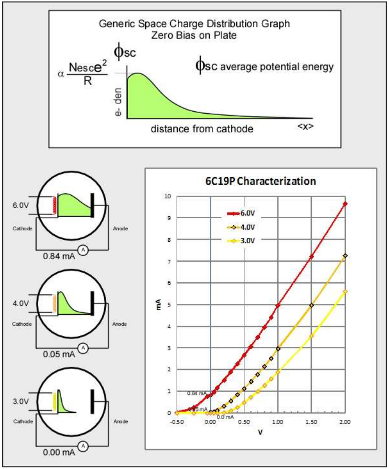
In 1897 Sir J. J. Thomson made the first publication of the remarkable investigations which enabled him to demonstrate that negative electricity is always associated with masses at least 1,800 times smaller than the mass of an atom of hydrogen and that under certain conditions these electric corpuscles are emitted from hot bodies.

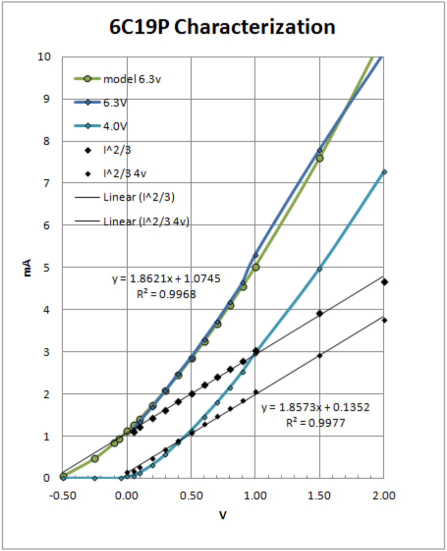
Faraday long ago proved that in the electrolysis of liquid conductors the passage of a certain quantity of electricity through the liquid is always accompanied by the movement to, or liberation upon, the electrodes of a fixed quantity of matter or products of decomposition of the electrolyte.

It was then and after recognised that electricity is conveyed through electrolytes only in association with atoms, or groups of atoms, called *ions*, in a fixed ratio, and that every such ion carries with it an electric charge which is an exact integer multiple of a certain unit charge.

In the case of the hydrogen atom or ion resulting from the passage of electricity through aqueous solutions of salts the quantity of electricity carried by the whole number of atoms of hydrogen which together weigh 1 gram (called the gram-

A conceptual look at the impact of heater temperature on the space charge distribution in the annulus between cathode and anode. I start by drawing a qualitative plot of charge density versus distance from the cathode. This is not how such plots are done in the literature but it is a nice visualization. The distribution of charge is a statistical function of heater temperature and plate bias. For the zero-bias case I show qualitative distributions for three heater voltages, 3.0, 4.0, and 6.0 volts. On my chart of current/voltage I find no current flows with 3.0 volts on the heater. Current just begins to be measurable at 4.0V and at 6.0V I found a significant 0.83mA of current indicating that a good portion of the space charge is not impinging on the plate even with zero bias.





Perveance calculation for the 6C19P diode taken at 6.3 v and 4.0 v heater voltages.

atom of hydrogen) is 96,500 coulombs, or very close to it. Hence, since one coulomb is equal to one-tenth of an electromagnetic unit (E.M.U.) of electrical quantity, we can say that for the hydrogen ion or atom, the weight of which is taken as unity, the ratio of charge (*e*) to mass (*m*) is 9,650.

According to Faraday's Law of Electrolysis the same quantity of electricity passed through various electrolytic cells will liberate on the electrodes masses of ions which are in the ratio of the chemical equivalents of these substances.

Exhaustive experiments have shown that a current of one ampere flowing for one second—that is, one coulomb—deposits in a silver voltameter 0·001118 gram of silver on the cathode. The atomic weight of silver is 108 and its valency is unity. Hence 108 is its chemical equivalent, that of hydrogen being unity. Accordingly a current of one ampere liberates from a water voltameter in one second a mass of hydrogen equal to 0·00001035 gram. In other words, 96,500 coulombs, or 9,650 E.M.U. of electric quantity, liberates one gram of hydrogen and 108 grams of silver at the cathodes of electrolytic cells.

Now 3×10^{10} units of electric quantity in electrostatic measure (E.S.U.) are equivalent to the electromagnetic unit. Accordingly $2895 \times 10^{11} = 3 \times 10^{10} \times 9{,}650$ E.S.U. will liberate at 0° C. and 760 mm. pressure 11,200 cubic centimetres of hydrogen gas which weighs one gram.

Modern researches on the kinetic theory of gases have shown that in one cubic centimetre of any gas at 0° C. and 760 mm. there are most probably $2{\cdot}7 \times 10^{19}$ molecules. As the molecule of hydrogen contains two atoms there are $11{,}200 \times 5{\cdot}4 \times 10^{19}$ atoms of H. liberated by the passage of $2{,}895 \times 10^{11}$ electrostatic units of electricity. Hence each hydrogen ion or atom must be associated with

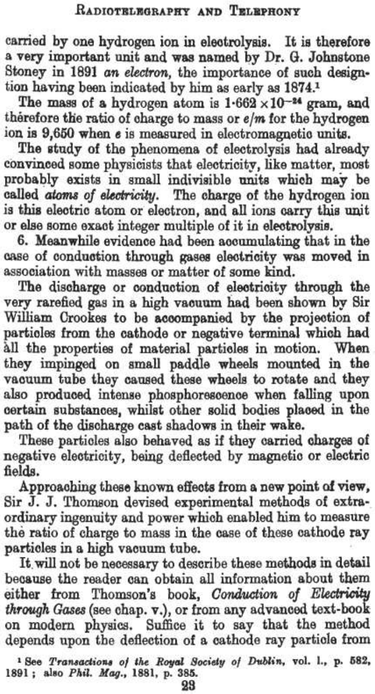
$$\frac{9{,}650 \times 3 \times 10^{10}}{11{,}200 \times 5{\cdot}4 \times 10^{19}} = 4{\cdot}77 \times 10^{-10}$$

electrostatic units (E.S.U.) of electric quantity.

This charge of the hydrogen ion is denoted by *e* and is a negative charge. Hence we have

$$e = 4{\cdot}77 \times 10^{-10} \text{ electrostatic units.}$$
$$= 1{\cdot}59 \times 10^{-20} \text{ electromagnetic units.}$$

This very small quantity of electricity is Nature's unit of electricity and it is the quantity of negative electricity



carried by one hydrogen ion in electrolysis. It is therefore a very important unit and was named by Dr. G. Johnstone Stoney in 1891 *an electron*, the importance of such designation having been indicated by him as early as 1874.[1]

The mass of a hydrogen atom is $1{\cdot}662\times10^{-24}$ gram, and therefore the ratio of charge to mass or *e*/*m* for the hydrogen ion is 9,650 when *e* is measured in electromagnetic units.

The study of the phenomena of electrolysis had already convinced some physicists that electricity, like matter, most probably exists in small indivisible units which may be called *atoms of electricity*. The charge of the hydrogen ion is this electric atom or electron, and all ions carry this unit or else some exact integer multiple of it in electrolysis.

6. Meanwhile evidence had been accumulating that in the case of conduction through gases electricity was moved in association with masses or matter of some kind.

The discharge or conduction of electricity through the very rarefied gas in a high vacuum had been shown by Sir William Crookes to be accompanied by the projection of particles from the cathode or negative terminal which had all the properties of material particles in motion. When they impinged on small paddle wheels mounted in the vacuum tube they caused these wheels to rotate and they also produced intense phosphorescence when falling upon certain substances, whilst other solid bodies placed in the path of the discharge cast shadows in their wake.

These particles also behaved as if they carried charges of negative electricity, being deflected by magnetic or electric fields.

Approaching these known effects from a new point of view, Sir J. J. Thomson devised experimental methods of extraordinary ingenuity and power which enabled him to measure the ratio of charge to mass in the case of these cathode ray particles in a high vacuum tube.

It will not be necessary to describe these methods in detail because the reader can obtain all information about them either from Thomson's book, *Conduction of Electricity through Gases* (see chap. v.), or from any advanced text-book on modern physics. Suffice it to say that the method depends upon the deflection of a cathode ray particle from

its path by the simultaneous action of an electric field and a magnetic field at right angles to each other and to the direction of motion of the particle (see Fig. 20). The charge carried by the cathode particle is denoted by e and its mass by m and the experiments give the ratio e/m where e is measured usually in electromagnetic units. A brief outline of the theory of the action as given by Sir J. J. Thomson is as follows:

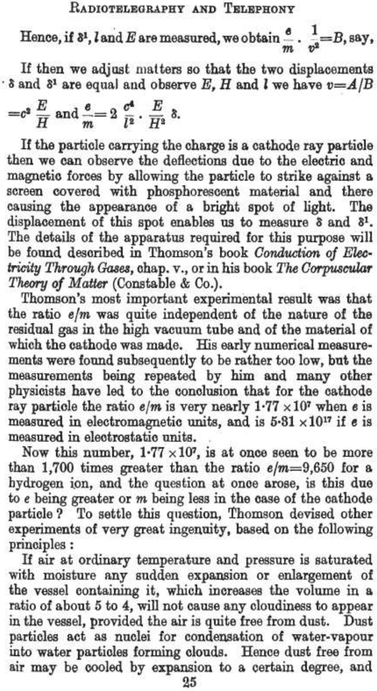
FIG. 20.—Cathode ray tube, having internal deflecting plates, E, and external deflecting magnets, M, and phosphorescent screen, S, to show the deflection of cathode rays by electric or magnetic force.

Let a particle of mass m, carrying a charge of electricity e, be moving in a straight line with velocity v, and let a magnetic force H act on it at right angles to its line of motion. Let e be in electrostatic units and H in electromagnetic units. Then the mechanical force acting on the particle is μHev, where μ is the magnetic permeability of the medium. Hence if we take the dielectric constant K of the medium to be unity, since $\mu K=1/c^2$ where $c=3\times10^{10}$, we have the force f acting on the particle given by Hev/c^2 and the acceleration$=Hev/mc^2$ and the space moved over in a transverse direction in a time t is $\frac{1}{2}\frac{Hev}{mc^2}t^2$.

Let this displacement be called δ. Then during the same time the particle moves a distance l in the original direction, where $l=vt$. Hence $\delta=\frac{1}{2}\frac{Hev}{mc^2}\frac{l^2}{v^2}=\frac{1}{2}\frac{l^2}{c^2}H\frac{e}{m}\frac{1}{v}$. Now δ, l and H are capable of measurement, and hence $\frac{e}{m}\frac{1}{v}=A$, say, becomes known.

Again, suppose we subject the particle to the action in a transverse direction of an electric force E at right angles to its line of motion. The mechanical force exerted on it is Ee and its acceleration is eE/m and its displacement in a time t is

$$\delta^1=\frac{1}{2}\frac{eE}{m}\left(\frac{l}{v}\right)^2=\frac{E}{2}l^2\frac{e}{m}\frac{1}{v^2}.$$



RADIOTELEGRAPHY AND TELEPHONY

Hence, if δ^1, l and E are measured, we obtain $\frac{e}{m} \cdot \frac{1}{v^2} = B$, say,

If then we adjust matters so that the two displacements δ and δ^1 are equal and observe E, H and l we have $v = A/B = c^2 \frac{E}{H}$ and $\frac{e}{m} = 2 \frac{c^4}{l^2} \cdot \frac{E}{H^2} \delta$.

If the particle carrying the charge is a cathode ray particle then we can observe the deflections due to the electric and magnetic forces by allowing the particle to strike against a screen covered with phosphorescent material and there causing the appearance of a bright spot of light. The displacement of this spot enables us to measure δ and δ^1. The details of the apparatus required for this purpose will be found described in Thomson's book *Conduction of Electricity Through Gases*, chap. v., or in his book *The Corpuscular Theory of Matter* (Constable & Co.).

Thomson's most important experimental result was that the ratio e/m was quite independent of the nature of the residual gas in the high vacuum tube and of the material of which the cathode was made. His early numerical measurements were found subsequently to be rather too low, but the measurements being repeated by him and many other physicists have led to the conclusion that for the cathode ray particle the ratio e/m is very nearly $1{\cdot}77 \times 10^7$ when e is measured in electromagnetic units, and is $5{\cdot}31 \times 10^{17}$ if e is measured in electrostatic units.

Now this number, $1{\cdot}77 \times 10^7$, is at once seen to be more than 1,700 times greater than the ratio $e/m = 9{,}650$ for a hydrogen ion, and the question at once arose, is this due to e being greater or m being less in the case of the cathode particle? To settle this question, Thomson devised other experiments of very great ingenuity, based on the following principles:

If air at ordinary temperature and pressure is saturated with moisture any sudden expansion or enlargement of the vessel containing it, which increases the volume in a ratio of about 5 to 4, will not cause any cloudiness to appear in the vessel, provided the air is quite free from dust. Dust particles act as nuclei for condensation of water-vapour into water particles forming clouds. Hence dust free from air may be cooled by expansion to a certain degree, and

25

Here you see the impact of lower operating voltages. With the tube operating between 3 and 4 volts the characteristic curves begin to pass through the origin as in regular solid-state diodes and crystals. It is precisely in this voltage range that I found the radio sensitivity, as measured by loudness to my ear, to be most pronounced. It appears that the diode characteristic needs to pass through the origin of the I-V graph for highest sensitivity. This takes me to the 20D1 tube which operates at 9v but only 200mA. This will still take a power supply to use, but the good thing is that the characteristic curve passes through the origin. Running at its design parameters the tube looks a lot like the 6C19P at 4v.

Note on Perveance

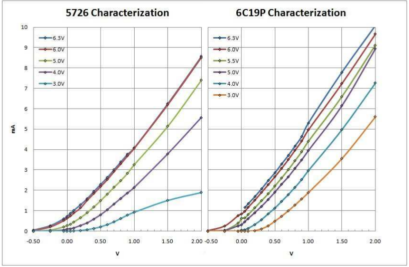
Just a few charts and spreadsheets on my calculations for diode valve perveance. I was very impressed at just how accurately the Langmuir-Child relation was able to predict the modeled results. This enabled me to reduce the observed data to a simple equation that shows the characteristic of the diode over a wide range of voltage values.

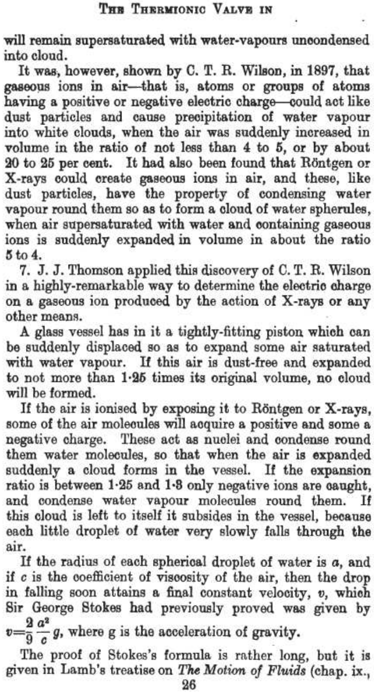
My attempts at calculating the diode resistance proves more troublesome. I can easily calculate the diode DC resistance which is low over the operating ranges. The AC resistance will wait until I know more. Stay tuned!

6AX4GT	1.42
6AV6	0.085
1A3	0.075

The high-perveance diode tube types I tested show an interesting property in that their characteristic curves do not pass through the origin of the graph. These curves are wholly acceptable as crystal radio detectors although they will require power to operate. What I have noticed with such tubes is that when I turn them off after using them with a radio, on cooling they go through a period of much increased sensitivity (very loud) before fading to nothing. It is as though running them at the full 6.3V lowers their full potential as crystal radio rectifiers. The reason is in the high perveance of the tubes, the anode is already proximate to the space charge before any plate voltage is applied. Effectively, while the plate (anode) "Zero" voltage is measured with respect to ground, the plate itself is still positive with respect to the cathodic space charge. Small currents will continue to flow even with a negative bias to the plate, (Contact potential).

In order to explore this idea, I ran a series of tests with the tubes running at lower operating voltages (effectively diminishing the space charge thus lowering the perveance) as shown:





will remain supersaturated with water-vapours uncondensed into cloud.

It was, however, shown by C. T. R. Wilson, in 1897, that gaseous ions in air—that is, atoms or groups of atoms having a positive or negative electric charge—could act like dust particles and cause precipitation of water vapour into white clouds, when the air was suddenly increased in volume in the ratio of not less than 4 to 5, or by about 20 to 25 per cent. It had also been found that Röntgen or X-rays could create gaseous ions in air, and these, like dust particles, have the property of condensing water vapour round them so as to form a cloud of water spherules, when air supersaturated with water and containing gaseous ions is suddenly expanded in volume in about the ratio 5 to 4.

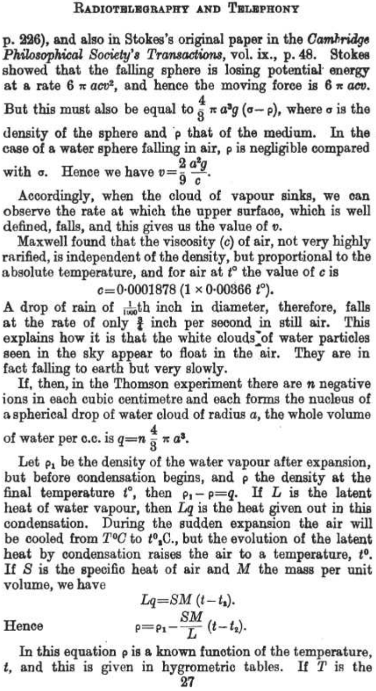
7. J. J. Thomson applied this discovery of C. T. R. Wilson in a highly-remarkable way to determine the electric charge on a gaseous ion produced by the action of X-rays or any other means.

A glass vessel has in it a tightly-fitting piston which can be suddenly displaced so as to expand some air saturated with water vapour. If this air is dust-free and expanded to not more than 1·25 times its original volume, no cloud will be formed.

If the air is ionised by exposing it to Röntgen or X-rays, some of the air molecules will acquire a positive and some a negative charge. These act as nuclei and condense round them water molecules, so that when the air is expanded suddenly a cloud forms in the vessel. If the expansion ratio is between 1·25 and 1·3 only negative ions are caught, and condense water vapour molecules round them. If this cloud is left to itself it subsides in the vessel, because each little droplet of water very slowly falls through the air.

If the radius of each spherical droplet of water is a, and if c is the coefficient of viscosity of the air, then the drop in falling soon attains a final constant velocity, v, which Sir George Stokes had previously proved was given by $v=\frac{2}{9}\frac{a^2}{c}g$, where g is the acceleration of gravity.

The proof of Stokes's formula is rather long, but it is given in Lamb's treatise on *The Motion of Fluids* (chap. ix.,



p. 226), and also in Stokes's original paper in the *Cambridge Philosophical Society's Transactions*, vol. ix., p. 48. Stokes showed that the falling sphere is losing potential energy at a rate $6\pi acv^2$, and hence the moving force is $6\pi acv$. But this must also be equal to $\frac{4}{3}\pi a^3 g(\sigma-\rho)$, where σ is the density of the sphere and ρ that of the medium. In the case of a water sphere falling in air, ρ is negligible compared with σ. Hence we have $v=\frac{2}{9}\frac{a^2 g}{c}$.

Accordingly, when the cloud of vapour sinks, we can observe the rate at which the upper surface, which is well defined, falls, and this gives us the value of v.

Maxwell found that the viscosity (c) of air, not very highly rarified, is independent of the density, but proportional to the absolute temperature, and for air at t° the value of c is

$$c=0{\cdot}0001878\,(1\times 0{\cdot}00366\,t^\circ).$$

A drop of rain of $\frac{1}{1000}$th inch in diameter, therefore, falls at the rate of only $\frac{3}{4}$ inch per second in still air. This explains how it is that the white clouds of water particles seen in the sky appear to float in the air. They are in fact falling to earth but very slowly.

If, then, in the Thomson experiment there are n negative ions in each cubic centimetre and each forms the nucleus of a spherical drop of water cloud of radius a, the whole volume of water per c.c. is $q=n\frac{4}{3}\pi a^3$.

Let ρ_1 be the density of the water vapour after expansion, but before condensation begins, and ρ the density at the final temperature t°, then $\rho_1-\rho=q$. If L is the latent heat of water vapour, then Lq is the heat given out in this condensation. During the sudden expansion the air will be cooled from $T^\circ C$ to $t^\circ{}_2$C., but the evolution of the latent heat by condensation raises the air to a temperature, t°. If S is the specific heat of air and M the mass per unit volume, we have

$$Lq=SM\,(t-t_2).$$

Hence

$$\rho=\rho_1-\frac{SM}{L}\,(t-t_2).$$

In this equation ρ is a known function of the temperature, t, and this is given in hygrometric tables. If T is the

A question remains as to what in fact is different about these tubes to give such different characteristics. While the I/V characteristic of most vacuum diodes pretty much follow the Langmuir-Child Law, the steepness of the I/V characteristic is largely due to the geometry of the tube elements and the volume of electron space-charge between them. JB Calvert's Theory of Vacuum Tubes informs one that this is the property called Perveance in a vacuum diode. Measuring this requires plotting I raised to the 2/3 power against V and taking the slope of the best-fit line through the data. This slope raised to the 3/2 power is the perveance. With my measurements this was practical and quickly done, results as follows:

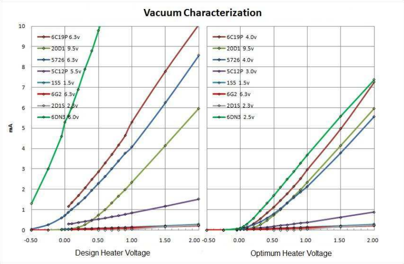
Tube	Perveance	R2	
6C19P	2.54	0.997	
5726	2.19	0.998	
6DN3	5.40	0.997	
20D1	2.02	0.985	(Langmuir-Child?)
5C12P	0.32	0.999	
1S5	0.063	0.999	
2D1S	0.155	0.975	(Langmuir-Child?)
6G2	0.050	0.999	

The perveance numbers above range from 0.02 to over 2 mA/V^3/2 (with >2 being good for small-signal detection) and clearly shows my choice of the 6C19P to be an excellent one. I am surprised to see a huge 5.4 for the 6DN3 diode, a color television damping diode. It takes a Novar 9-pin socket and is a large tube so doing more with this tube may have to wait a bit.

Calvert's 2001 published data

Tube	Perveance
6AL5	2.42
6H6	0.50
7Y4	0.58
2X2A	0.017
6V3-A	2.3

comparison. I was hoping to find a good candidate with sensitive characteristics and low energy consumption. As you will find, such a beast did not exist. Following this research began a period of purchase and testing.



I have finally found, purchased and tested eight different tube types (plot above) including 6.3V rectifier diodes that take a lot of power to run and are not really suitable for battery use, a 9v dual diode tube (20D1), a pentode/diode tube (1S5) that is designed to run on a battery at 1.5V and 50mA, and a couple miscellaneous but cute tubes. In testing the 1S5, I found the filament never glowed incandescent at 1.5V and, on measuring, was barely sensitive to anything. I cannot imagine this tube would make much of a diode for crystal radio use. I tested different manufacture 1S5 tubes from two different suppliers. No dice. Finally, I tried to push the tube to operate at higher-than-specified voltages. At 4.3V the I-V curve was still very flat, but shifted slightly higher, crossing the Amp axis at about 0.4 mA, (see graph). At 5.5V one of my tubes gave up the ghost and I didnt do more. I pretty much rule the 1S5 out for my crystal radio work. Looks like i'll be needing the power supply when I get around to building/operating that Fleming Radio.

temperature at the beginning of the experiment, and P the pressure of the gas in millimetres of mercury, then since 1 c.c. of air at 0^0C and 760 m.m. weighs 0·00129 gram, we have

$$M=\frac{\cdot00129}{x}\cdot\frac{273}{273+T}\cdot\frac{P}{760},$$

where x is the ratio of final to the initial volume of the gas.

Also, $$\rho_1=\frac{\rho^1}{x}$$

where ρ^1 is the density of water vapour at T^0C before expansion. This can be obtained from the hygrometric tables.

Now, in adiabatic or sudden expansion of air the relation between volume v and pressure p is given by the equation $pv^{1\cdot41}=a$ *constant*; whilst for slow expansion we have $pv=R\theta$, where R is the so-called gas constant, and θ is the absolute temperature. Therefore, for adiabatic expansion,

$$v^{0\cdot41}\times\theta=a\ \textit{constant}$$

or $$\log_e\frac{\theta_1}{\theta_2}=0\cdot41\log\frac{v_1}{v_2}$$

or $$\log_e\frac{273+T}{273+t_2}=0\cdot41\log x.$$

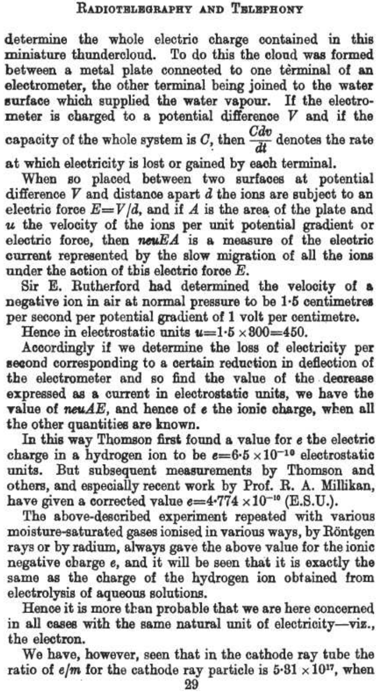
From this equation we can find t_2, when x and T are given. Then we have:

$$\rho=\frac{\rho^1}{x}-\frac{SM}{L}(t-t_2)$$

and we can substitute the value of t_2 and x from the previous equation. This last equation can be solved by substituting various values for t, and finding the corresponding value of ρ, until we reach values of t and ρ, which agree with the corresponding values in the hygrometric tables.

Having then found ρ and ρ_1 we know q, and also having found a from Stokes formula we find $n=3q/4\pi a^3$, which gives us the number of drops and therefore of negative ions in the cloud.

By this very ingenious method Thomson weighed the cloud of water spherules and counted the drops of water forming the cloud and therefore determined the number of ions round which the drops were formed. He had then to



determine the whole electric charge contained in this miniature thundercloud. To do this the cloud was formed between a metal plate connected to one terminal of an electrometer, the other terminal being joined to the water surface which supplied the water vapour. If the electrometer is charged to a potential difference V and if the capacity of the whole system is C, then $\frac{Cdv}{dt}$ denotes the rate at which electricity is lost or gained by each terminal.

When so placed between two surfaces at potential difference V and distance apart d the ions are subject to an electric force $E=V/d$, and if A is the area of the plate and u the velocity of the ions per unit potential gradient or electric force, then $neuEA$ is a measure of the electric current represented by the slow migration of all the ions under the action of this electric force E.

Sir E. Rutherford had determined the velocity of a negative ion in air at normal pressure to be 1·5 centimetres per second per potential gradient of 1 volt per centimetre.

Hence in electrostatic units $u=1{\cdot}5\times 300=450$.

Accordingly if we determine the loss of electricity per second corresponding to a certain reduction in deflection of the electrometer and so find the value of the decrease expressed as a current in electrostatic units, we have the value of $neuAE$, and hence of e the ionic charge, when all the other quantities are known.

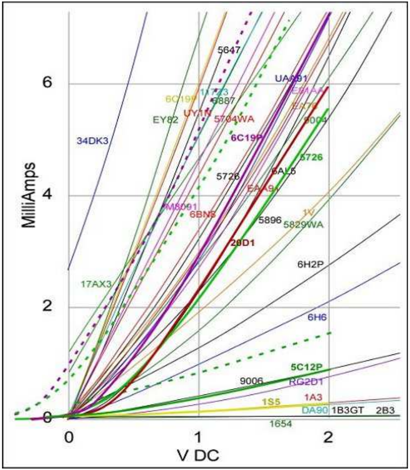
In this way Thomson first found a value for e the electric charge in a hydrogen ion to be $e=6{\cdot}5\times 10^{-10}$ electrostatic units. But subsequent measurements by Thomson and others, and especially recent work by Prof. R. A. Millikan, have given a corrected value $e=4{\cdot}774\times 10^{-10}$ (E.S.U.).

The above-described experiment repeated with various moisture-saturated gases ionised in various ways, by Röntgen rays or by radium, always gave the above value for the ionic negative charge e, and it will be seen that it is exactly the same as the charge of the hydrogen ion obtained from electrolysis of aqueous solutions.

Hence it is more than probable that we are here concerned in all cases with the same natural unit of electricity—viz., the electron.

We have, however, seen that in the cathode ray tube the ratio of e/m for the cathode ray particle is $5{\cdot}31\times 10^{17}$, when

Vacuum Diodes



When I decided early on to construct a radio based on the vacuum diode (see my Fleming Radio section), I had to find a suitable tube for the project. That began with an extensive search through the datasheets checking vacuum diode properties and reviewing the characteristic curves for a large number of diode tubes. Datasheet characteristic curves, if they exist at all, are notoriously difficult to make comparisons between. In the above figure I plot as best I can the V/I characteristics at low signal levels on a common plot for units with the same features. Still, the supply regulator was never designed to adjust the output to precise small values making it somewhat difficult/tedious to adjust. Adding a small rheostat to the test jig may aid for making fine adjustments on the voltage. Another piece of equipment you will need for this test is an amp meter. I use a nice small digital meter I found new on ebay for $15 shipping included. It reads amps to a lowest range of 200uA, more than enough precision for the task. For that price get two. The DVM is, of course, my trusty Keithley workhorse. Easy protocol as follows:

1) Set up the test with the diode and meters clipped to the jig.

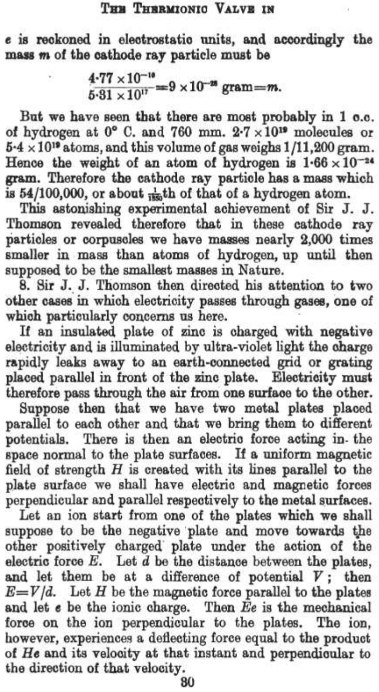
2) Adjust the power supply until the reading on the DVM meter is where you plan to measure. Adjust the voltage (DVM readout) in steps from 0 to 1.0 Volt in 0.1 V increments and record the current (Amps) in a spreadsheet.

3) Repeat at each tenth volt recording while the spreadsheet makes a sweet graph.

Test Results

First, I offer a quick look at my diode modeling setup. I am currently upping the ante on resolution in order to determine diode parameters Is and n, hoping for success soon! Setup and protocol..

Over a period of a few weeks I ran I-V characterization tests on a good number and variety of diodes, crystals and my two tubes to see how very thing stacks up. The following presents the resulting curves, diode photos, and some puzzling questions/conclusions I churned up in the process. I start off with the realization that when one orders diodes, it is by no means certain what one will get. This seems especially true for the supposedly ubiquitous 1N34A. Unless you see the part number actually on the diode, you probably need to test it to know what it really is. So, lets take a look!



e is reckoned in electrostatic units, and accordingly the mass *m* of the cathode ray particle must be

$$\frac{4\cdot77\times10^{-10}}{5\cdot31\times10^{17}}=9\times10^{-28}\text{ gram}=m.$$

But we have seen that there are most probably in 1 c.c. of hydrogen at 0° C. and 760 mm. $2\cdot7\times10^{19}$ molecules or $5\cdot4\times10^{19}$ atoms, and this volume of gas weighs 1/11,200 gram. Hence the weight of an atom of hydrogen is $1\cdot66\times10^{-24}$ gram. Therefore the cathode ray particle has a mass which is 54/100,000, or about $\frac{1}{1850}$th of that of a hydrogen atom.

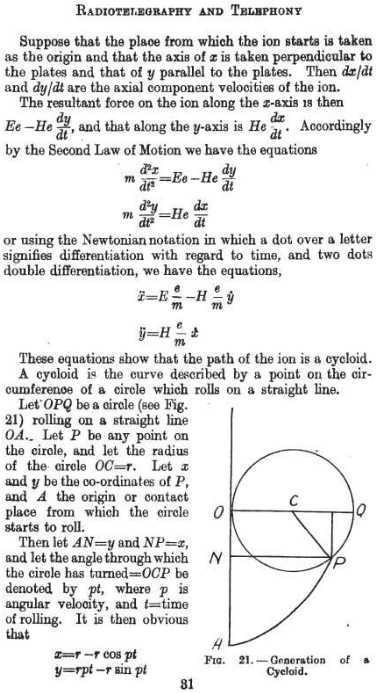
This astonishing experimental achievement of Sir J. J. Thomson revealed therefore that in these cathode ray particles or corpuscles we have masses nearly 2,000 times smaller in mass than atoms of hydrogen, up until then supposed to be the smallest masses in Nature.

8. Sir J. J. Thomson then directed his attention to two other cases in which electricity passes through gases, one of which particularly concerns us here.

If an insulated plate of zinc is charged with negative electricity and is illuminated by ultra-violet light the charge rapidly leaks away to an earth-connected grid or grating placed parallel in front of the zinc plate. Electricity must therefore pass through the air from one surface to the other.

Suppose then that we have two metal plates placed parallel to each other and that we bring them to different potentials. There is then an electric force acting in the space normal to the plate surfaces. If a uniform magnetic field of strength H is created with its lines parallel to the plate surface we shall have electric and magnetic forces perpendicular and parallel respectively to the metal surfaces.

Let an ion start from one of the plates which we shall suppose to be the negative plate and move towards the other positively charged plate under the action of the electric force E. Let d be the distance between the plates, and let them be at a difference of potential V; then $E=V/d$. Let H be the magnetic force parallel to the plates and let e be the ionic charge. Then Ee is the mechanical force on the ion perpendicular to the plates. The ion, however, experiences a deflecting force equal to the product of He and its velocity at that instant and perpendicular to the direction of that velocity.



Suppose that the place from which the ion starts is taken as the origin and that the axis of x is taken perpendicular to the plates and that of y parallel to the plates. Then dx/dt and dy/dt are the axial component velocities of the ion.

The resultant force on the ion along the x-axis is then $Ee - He\frac{dy}{dt}$, and that along the y-axis is $He\frac{dx}{dt}$. Accordingly by the Second Law of Motion we have the equations

$$m\frac{d^2x}{dt^2}=Ee-He\frac{dy}{dt}$$

$$m\frac{d^2y}{dt^2}=He\frac{dx}{dt}$$

or using the Newtonian notation in which a dot over a letter signifies differentiation with regard to time, and two dots double differentiation, we have the equations,

$$\ddot{x}=E\frac{e}{m}-H\frac{e}{m}\dot{y}$$

$$\ddot{y}=H\frac{e}{m}\dot{x}$$

These equations show that the path of the ion is a cycloid.

A cycloid is the curve described by a point on the circumference of a circle which rolls on a straight line.

Let OPQ be a circle (see Fig. 21) rolling on a straight line OA. Let P be any point on the circle, and let the radius of the circle $OC=r$. Let x and y be the co-ordinates of P, and A the origin or contact place from which the circle starts to roll.

Then let $AN=y$ and $NP=x$, and let the angle through which the circle has turned $=OCP$ be denoted by pt, where p is angular velocity, and t=time of rolling. It is then obvious that

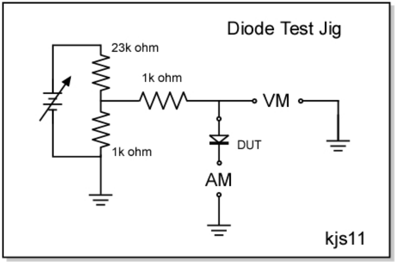
$$x=r-r\cos pt$$
$$y=rpt-r\sin pt$$

FIG. 21.—Generation of a Cycloid.

Diode Testing

Kevin Smith
http://www.lessmiths.com/~kjsmith/crystal/dtest.shtml

So, what is the best diode out there to use? Do crystals always show poor sensitivity compared to germanium? What about Fleming's marvelous device, the vacuum diode? I start by using a test jig, the design shamelessly modified from Dan Petersen in the Nov 2009 Crystal Set Society Newsletter, (if you aren't a member, go sign up to be.. NOW):



This is a very simple circuit allowing power input, attaching a diode for testing, and sampling both the curent and voltage across the diode under test, (DUT). I made a simple modification by adding a voltage divider, about 20:1 at the power input. The power supply can be connected either at the front across the divider, or after the divider in front of the 100k current limiting resistor for higher voltage readings. I get the input voltage from a modest 18V, 2A regulated DC power supply. This unit has both volt and amp controls with digital readouts, nice to use and dosnt take up much room on my desk. Here is a case where I recommend you look at getting a new unit. I looked long and hard on ebay, but found few bargins and few

Differentiate these equations twice with regard to t, and we obtain

$$\ddot{x}=rp^2-p\dot{y}, \quad \ddot{y}=p\dot{x}.$$

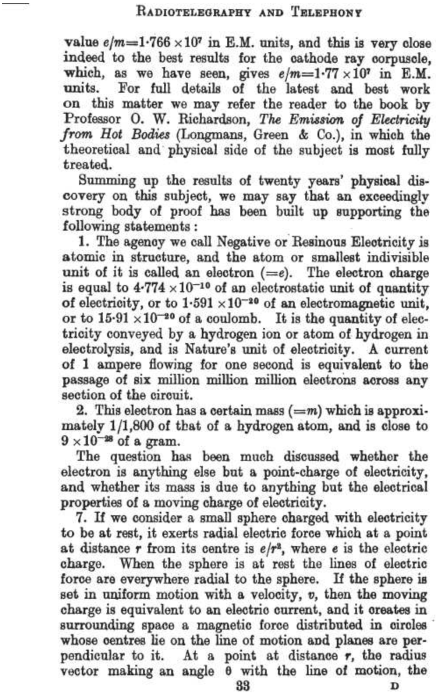
If we compare these two last equations with the above equations of motion of the ion, we see at once they are identical provided we put $p=H\frac{e}{m}$ and $r=\frac{E}{H^2}\frac{m}{e}$. This proves that the path of the ion must be a cycloid.

Hence, if the ion starts from one plate under the action of the two forces due to the electric and magnetic force, it will curl round in a cycloidal path. If, then, the distance between the two plates exceeds twice the radius of the circle, or $\frac{2E}{H^2}\frac{m}{e}$, the particle will never reach the second plate.

Thomson applied the above theorem to the case of the ions emitted by an incandescent carbon filament. He stretched a filament close in front of a metal plate, and placed at a certain distance, d, from it a second parallel metal plate. These plates and filaments were included in a glass vessel very highly exhausted. The filament was connected to the plate just in contact with it, and a difference of potential, V, made between the plates.

Hence the electric force $E=V/d$. Coils of wire were placed outside the tube, and through them a current was sent, so as to make a magnetic force, H, of known and adjustable value parallel to the plates. When the carbon filament was made incandescent it emits, as we have seen, negative ions, and by adjusting the magnetic field it was possible just to prevent these ions reaching the second plate. From measurements of H, V, and d it was then possible to solve the equation $d=\frac{2E}{H^2}\frac{m}{e}$, so as to obtain the value of e/m.

Thomson's experiments made by the above method in 1899 led to a value of e/m for the negative ions emitted by an incandescent carbon filament which was not very different from that obtained from experiments on the cathode ray corpuscle, but in absolute value were too low. More recent measurements by Professor O. W. Richardson gave values $e/m=1{\cdot}45\times10^7$ and $1{\cdot}49\times10^7$, and more recent work still by Bestelmeyer, who used an improved method, has given the



value $e/m = 1{\cdot}766 \times 10^7$ in E.M. units, and this is very close indeed to the best results for the cathode ray corpuscle, which, as we have seen, gives $e/m = 1{\cdot}77 \times 10^7$ in E.M. units. For full details of the latest and best work on this matter we may refer the reader to the book by Professor O. W. Richardson, *The Emission of Electricity from Hot Bodies* (Longmans, Green & Co.), in which the theoretical and physical side of the subject is most fully treated.

Summing up the results of twenty years' physical discovery on this subject, we may say that an exceedingly strong body of proof has been built up supporting the following statements:

1. The agency we call Negative or Resinous Electricity is atomic in structure, and the atom or smallest indivisible unit of it is called an electron ($=e$). The electron charge is equal to $4{\cdot}774 \times 10^{-10}$ of an electrostatic unit of quantity of electricity, or to $1{\cdot}591 \times 10^{-20}$ of an electromagnetic unit, or to $15{\cdot}91 \times 10^{-20}$ of a coulomb. It is the quantity of electricity conveyed by a hydrogen ion or atom of hydrogen in electrolysis, and is Nature's unit of electricity. A current of 1 ampere flowing for one second is equivalent to the passage of six million million million electrons across any section of the circuit.

2. This electron has a certain mass ($=m$) which is approximately 1/1,800 of that of a hydrogen atom, and is close to 9×10^{-28} of a gram.

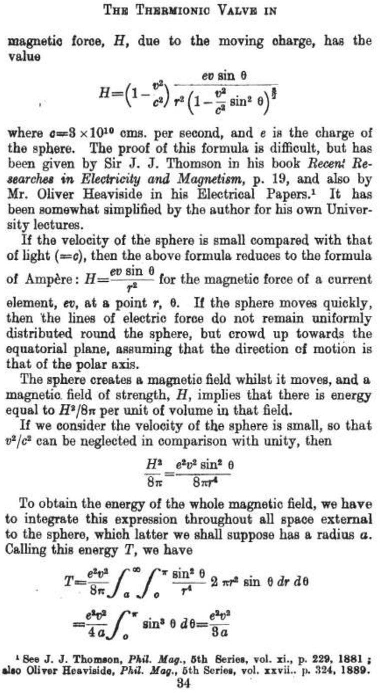
The question has been much discussed whether the electron is anything else but a point-charge of electricity, and whether its mass is due to anything but the electrical properties of a moving charge of electricity.

7. If we consider a small sphere charged with electricity to be at rest, it exerts radial electric force which at a point at distance r from its centre is e/r^2, where e is the electric charge. When the sphere is at rest the lines of electric force are everywhere radial to the sphere. If the sphere is set in uniform motion with a velocity, v, then the moving charge is equivalent to an electric current, and it creates in surrounding space a magnetic force distributed in circles whose centres lie on the line of motion and planes are perpendicular to it. At a point at distance r, the radius vector making an angle θ with the line of motion, the

Article #27 shows detector measurements of how diodes having different values of Is and n perform as weak signal detectors when impedance matched at both input and out put.

#16 Published: 03/28/01; Revised: 02/10/2004

The center tap of the input transformer is not used in this circuit. The triode has grid leak bias. It is not possible to measure this bias with a DMM because of the large grid resistor, but the plate current is only about 280 μA. The diode and triode are referred to the negative end of the filament, but cathode bias is provided for the power pentode. The bias in operation is about -9.3 V, giving a plate current of about 5 mA and a screen current of about 1 mA. The output transformer can be any transformer on hand. I used the P-T31 that has been used in other places, which matches 8Ω to 5 kΩ. The load resistance should preferably be about 12 kΩ. However, it drove a good speaker at considerable volume with a rather small input. A three-tube battery radio could be made with this tube, an IF amplifier stage, and a pentagrid converter, a tube type which will be treated next.



magnetic force, H, due to the moving charge, has the value

$$H=\left(1-\frac{v^2}{c^2}\right)\frac{ev\sin\theta}{r^2\left(1-\frac{v^2}{c^2}\sin^2\theta\right)^{\frac{3}{2}}}$$

where $c=3\times10^{10}$ cms. per second, and e is the charge of the sphere. The proof of this formula is difficult, but has been given by Sir J. J. Thomson in his book *Recent Researches in Electricity and Magnetism*, p. 19, and also by Mr. Oliver Heaviside in his Electrical Papers.[1] It has been somewhat simplified by the author for his own University lectures.

If the velocity of the sphere is small compared with that of light ($=c$), then the above formula reduces to the formula of Ampère: $H=\frac{ev\sin\theta}{r^2}$ for the magnetic force of a current element, ev, at a point r, θ. If the sphere moves quickly, then the lines of electric force do not remain uniformly distributed round the sphere, but crowd up towards the equatorial plane, assuming that the direction of motion is that of the polar axis.

The sphere creates a magnetic field whilst it moves, and a magnetic field of strength, H, implies that there is energy equal to $H^2/8\pi$ per unit of volume in that field.

If we consider the velocity of the sphere is small, so that v^2/c^2 can be neglected in comparison with unity, then

$$\frac{H^2}{8\pi}=\frac{e^2v^2\sin^2\theta}{8\pi r^4}$$

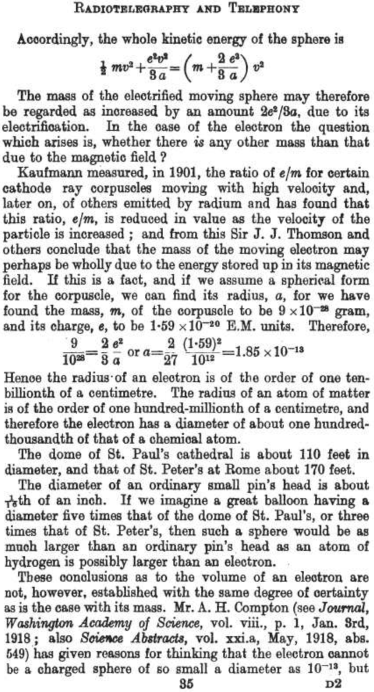
To obtain the energy of the whole magnetic field, we have to integrate this expression throughout all space external to the sphere, which latter we shall suppose has a radius a. Calling this energy T, we have

$$T=\frac{e^2v^2}{8\pi}\int_a^\infty\int_0^\pi\frac{\sin^2\theta}{r^4}\,2\pi r^2\sin\theta\,dr\,d\theta$$

$$=\frac{e^2v^2}{4a}\int_0^\pi\sin^3\theta\,d\theta=\frac{e^2v^2}{3a}$$

---

[1] See J. J. Thomson, *Phil. Mag.*, 5th Series, vol. xi., p. 229, 1881; also Oliver Heaviside, *Phil. Mag.*, 5th Series, vol. xxvii., p. 324, 1889.



Accordingly, the whole kinetic energy of the sphere is

$$\tfrac{1}{2}\,mv^2+\frac{e^2v^2}{3\,a}=\left(m+\frac{2\,e^2}{3\,a}\right)v^2$$

The mass of the electrified moving sphere may therefore be regarded as increased by an amount $2e^2/3a$, due to its electrification. In the case of the electron the question which arises is, whether there *is* any other mass than that due to the magnetic field ?

Kaufmann measured, in 1901, the ratio of e/m for certain cathode ray corpuscles moving with high velocity and, later on, of others emitted by radium and has found that this ratio, e/m, is reduced in value as the velocity of the particle is increased ; and from this Sir J. J. Thomson and others conclude that the mass of the moving electron may perhaps be wholly due to the energy stored up in its magnetic field. If this is a fact, and if we assume a spherical form for the corpuscle, we can find its radius, a, for we have found the mass, m, of the corpuscle to be 9×10^{-28} gram, and its charge, e, to be $1{\cdot}59\times10^{-20}$ E.M. units. Therefore,

$$\frac{9}{10^{28}}=\frac{2}{3}\frac{e^2}{a}\text{ or }a=\frac{2}{27}\,\frac{(1{\cdot}59)^2}{10^{12}}=1{\cdot}85\times10^{-13}$$

Hence the radius of an electron is of the order of one ten-billionth of a centimetre. The radius of an atom of matter is of the order of one hundred-millionth of a centimetre, and therefore the electron has a diameter of about one hundred-thousandth of that of a chemical atom.

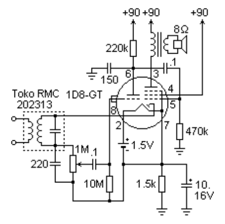
The dome of St. Paul's cathedral is about 110 feet in diameter, and that of St. Peter's at Rome about 170 feet.

The diameter of an ordinary small pin's head is about $\frac{1}{16}$th of an inch. If we imagine a great balloon having a diameter five times that of the dome of St. Paul's, or three times that of St. Peter's, then such a sphere would be as much larger than an ordinary pin's head as an atom of hydrogen is possibly larger than an electron.

These conclusions as to the volume of an electron are not, however, established with the same degree of certainty as is the case with its mass. Mr. A. H. Compton (see *Journal, Washington Academy of Science*, vol. viii., p. 1, Jan. 3rd, 1918 ; also *Science Abstracts*, vol. xxi.a, May, 1918, abs. 549) has given reasons for thinking that the electron cannot be a charged sphere of so small a diameter as 10^{-13}, but

connection. Diode bias is not suitable for high-mu triodes such as the 6AV6 or 6AT6, since they are very sensitive to the bias level. The 6R7 is a medium-mu triode (μ = 16). The 6SR7 is a single-ended equivalent, and will also work in this circuit. The signal generator should be adjusted to peak the output, at 455 kHz. I obtained an audio output of 13 V peak-to-peak with a 30% modulated AM signal of 0.2 V peak-to-peak, for a gain of about 289. The tuned circuit provides a large part of this gain.

The 6AQ6, 6AT6 and 6BF6 are all miniature dual-diode triodes with the same basing as the 6AV6, the 6BF6 being medium-mu and more appropriate for diode bias and transformer coupling. The 6SQ7, 6SR7 and 6ST7 are similar octal tubes, again all with the same basing. This was a very popular and useful tube type, with many options available.

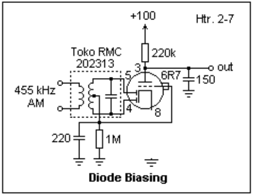


Detector - Audo Amplifier

The 1D8-GT diode-triode-pentode was designed to provide a complete audio system for a battery-powered radio. The circuit is shown at the right. The filament takes 0.1 A at 1.4 V, easily supplied by a D cell. The B+ supply is 90 V, for which batteries were available, consisting of 60 small cells. This circuit has a drain of less than 7 mA, which is quite acceptable, and hardly more than a transistor radio with the same audio output. The filament is hard to see when the tube is in operation. It can just be seen glowing orange in the diode portion of the tube. On one side is the diode with the triode on top; on the other is the pentode, all of which are clearly displayed. The tube cost $3.10, an excellent price considering all the experiments that can be done with it.

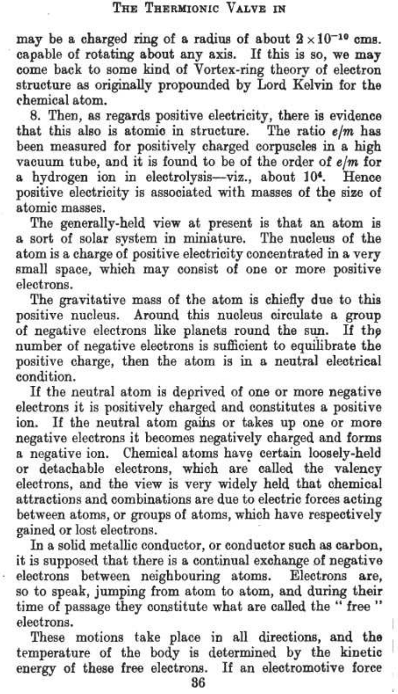
signal carrier frequency until the tuned circuit resonates; in my case, this was 500 kHz. For an input signal from the signal generator of 0.18V peak-to-peak (modulation amplitude 0.04V), I got 26V peak-to-peak at the plate of the 6AT6. The RF ripple was negligible, but there was some 60Hz pickup, not surprising with a high-gain breadboarded circuit out in the open. It was interesting to show the AM signal and the audio output simultaneously on the oscilloscope.

The circuit will function without the tuned circuit, as you can easily demonstrate. The signal generator output must then be increased, because the resonance gain is considerable. The circuit will also function with both diode plates connected to one side of the secondary, and the 1M potentiometer and filter capacitor to the other side. In this case, the ripple frequency will be halved, but the output voltage will be doubled. There is not a great advantage in using a full-wave detector. Look at the DC voltage across the potentiometer as the input amplitude is changed. This voltage, negative with respect to ground, can be used for AVC, automatic volume control, as is discussed elsewhere. With the full-wave detector, it varied from -0.5V for 10V p-p audio output to -1.0V for 30V audio output. In practice, the AVC voltage is further filtered to remove the audio.



Diode Biasing

The rectified signal voltage is of the correct polarity to provide grid bias for the amplifier tube in this circuit. Therefore, the grid of the triode can be connected directly to some point on the diode load resistor that provides the proper bias, in place of the volume control potentiometer and coupling capacitor shown above. This arrangement is called *diode bias*, illustrated by the circuit at the left. AVC is essential when diode bias is used, to keep the bias voltage in the proper range. The audio signal, of course, rides on the bias



may be a charged ring of a radius of about 2×10^{-10} cms. capable of rotating about any axis. If this is so, we may come back to some kind of Vortex-ring theory of electron structure as originally propounded by Lord Kelvin for the chemical atom.

8. Then, as regards positive electricity, there is evidence that this also is atomic in structure. The ratio e/m has been measured for positively charged corpuscles in a high vacuum tube, and it is found to be of the order of e/m for a hydrogen ion in electrolysis—viz., about 10^4. Hence positive electricity is associated with masses of the size of atomic masses.

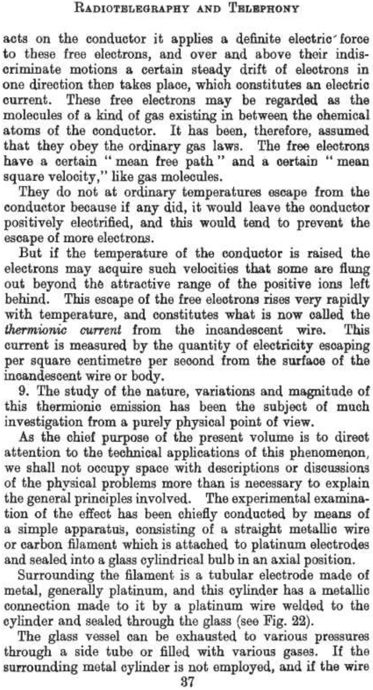
The generally-held view at present is that an atom is a sort of solar system in miniature. The nucleus of the atom is a charge of positive electricity concentrated in a very small space, which may consist of one or more positive electrons.

The gravitative mass of the atom is chiefly due to this positive nucleus. Around this nucleus circulate a group of negative electrons like planets round the sun. If the number of negative electrons is sufficient to equilibrate the positive charge, then the atom is in a neutral electrical condition.

If the neutral atom is deprived of one or more negative electrons it is positively charged and constitutes a positive ion. If the neutral atom gains or takes up one or more negative electrons it becomes negatively charged and forms a negative ion. Chemical atoms have certain loosely-held or detachable electrons, which are called the valency electrons, and the view is very widely held that chemical attractions and combinations are due to electric forces acting between atoms, or groups of atoms, which have respectively gained or lost electrons.

In a solid metallic conductor, or conductor such as carbon, it is supposed that there is a continual exchange of negative electrons between neighbouring atoms. Electrons are, so to speak, jumping from atom to atom, and during their time of passage they constitute what are called the "free" electrons.

These motions take place in all directions, and the temperature of the body is determined by the kinetic energy of these free electrons. If an electromotive force



acts on the conductor it applies a definite electric force to these free electrons, and over and above their indiscriminate motions a certain steady drift of electrons in one direction then takes place, which constitutes an electric current. These free electrons may be regarded as the molecules of a kind of gas existing in between the chemical atoms of the conductor. It has been, therefore, assumed that they obey the ordinary gas laws. The free electrons have a certain "mean free path" and a certain "mean square velocity," like gas molecules.

They do not at ordinary temperatures escape from the conductor because if any did, it would leave the conductor positively electrified, and this would tend to prevent the escape of more electrons.

But if the temperature of the conductor is raised the electrons may acquire such velocities that some are flung out beyond the attractive range of the positive ions left behind. This escape of the free electrons rises very rapidly with temperature, and constitutes what is now called the *thermionic current* from the incandescent wire. This current is measured by the quantity of electricity escaping per square centimetre per second from the surface of the incandescent wire or body.

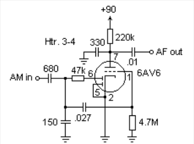
9. The study of the nature, variations and magnitude of this thermionic emission has been the subject of much investigation from a purely physical point of view.

As the chief purpose of the present volume is to direct attention to the technical applications of this phenomenon, we shall not occupy space with descriptions or discussions of the physical problems more than is necessary to explain the general principles involved. The experimental examination of the effect has been chiefly conducted by means of a simple apparatus, consisting of a straight metallic wire or carbon filament which is attached to platinum electrodes and sealed into a glass cylindrical bulb in an axial position.

Surrounding the filament is a tubular electrode made of metal, generally platinum, and this cylinder has a metallic connection made to it by a platinum wire welded to the cylinder and sealed through the glass (see Fig. 22).

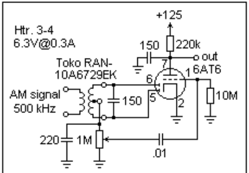
The glass vessel can be exhausted to various pressures through a side tube or filled with various gases. If the surrounding metal cylinder is not employed, and if the wire

and maximum plate dissipation of 0.5 W. The maximum cathode current is not specified, but should not exceed a few milliamperes. The tube has an unusually high plate resistance, and the amplification factor is over 100. It is a good triode for a voltage amplifier. My example gave $g_m = 1.3$ mS, $r_p = 67$k, $\mu = 90$ at about 500 μA plate current, and $V_g = -1.0$ V. The transconductance varies strongly with plate current, reaching 2.2 mS at 1 mA, where $\mu = 116$.



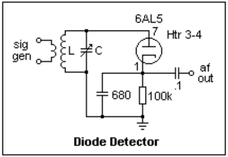
Diode Detector and AF Amplifier

A detector-amplifier circuit is shown at the left. This circuit is fed by a signal generator at AM in, and the audio output is taken from AF out. The amplifier uses grid-leak bias, which effectively clamps the peak of the audio wave at 0 V. The stronger the input signal, the more negative the grid bias, which makes the most of what is there. With an AM input of peak value 0.95 V and modulation amplitude 0.37 V, the peak to peak output was 3 V, for a gain of -8, which is quite good. I used a radio frequency of 2 MHz, and modulation of 1 kHz. At lower radio frequencies, the filtering of the output becomes progressively worse; this could be optimized if desired. This detector gives good fidelity with high sensitivity.



Full-Wave Diode Detector and Amplifier

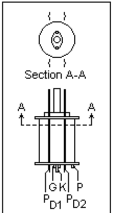
A full-wave diode detector is shown at the right, using transformer input. The 6AT6 is similar to the 6AV6, but its mu is 70 instead of 100. The transformer is a Toko RAN-10A6729EK, available from Digi-Key. It is specified as 0.63 mH, and for 200 kHz. Adjust the bias detector, however, the FET is suitable, and a BJT biased near cutoff makes an excellent detector, as we saw in the page on Amplitude Modulation.



Diode Detector

A diode detector, using a standalone diode, is shown at the left. The output is the same amplitude as the modulation on the carrier that is input, very closely, so the detector could not do any better. Often, the diode was included in the first AF amplifier tube, sharing the same cathode, and dual diodes were also available for full-wave detection, which doubles the output. If you have a tuned circuit at this point, it would be easy to test a diode detector, and high voltages are not required, just the heater power. A solid-state diode would work the same way, but the 0.7 V drop would make it less sensitive, and it would not even respond to weaker signals. Using a Ge diode (1N34A) would help, but not eliminate, the problem. The thermionic diode is ideal in this application.

The typical superheterodyne receiver used a diode detector, followed by an audio voltage amplifier. These functions were usually combined in a single envelope, the diodes and the amplifying triode or pentode sharing the same cathode. A very good tube of this type was the 6AV6, whose structure is shown at the right. The diode plates are at the top of the envelope, with the cathode easily seen between them. The IF output was usually from an air-core, slug-tuned transformer, making it easy to use full-wave rectification. Only one of the diodes could be used for half-wave rectification, which was usually quite adequate. The triode is a high-mu triode with a maximum plate voltage of 300 V,



6AV6 Structure

---

or filament is heated by an electric current passed through it, then the ions or electrons given off by the wire would accumulate to a certain extent in the space, vacuous or gas-filled, round the wire and create a *space electric charge* which would soon prevent any further emission. This explanation of the limitation to the increase of the thermionic emission was first given by Mr. C. D. Child in 1911 (see *Physical Review*, vol. xxxii., p. 498, 1911).

By employing the metal cylinder we can make a definite difference of potential between the heated wire and the cold cylinder, and, therefore, an electric force so directed as to urge the ions from the wire to the embracing cylinder. The arrangement has also the convenience that we can determine the temperature of the incandescent wire by measuring its resistence or ratio of volt-drop down the filament to current through it, or else by making the filament one arm of a Wheatstone's Bridge arrangement.

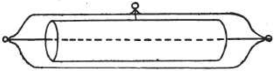


FIG. 22.—Exhausted tube having in it a metal cylinder and concentric incandescent tungsten wire to show the thermionic emission from the wire.

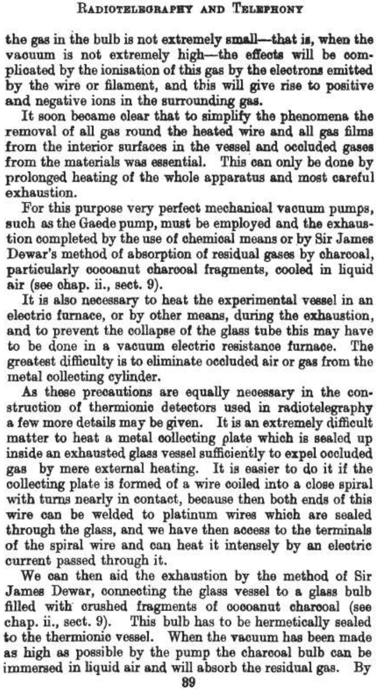
If we have previously determined the resistence of the filament at several standard temperatures we can by interpolation or extrapolution determine its temperature corresponding to other resistances.

Such an apparatus is a convenient modification of the lamps used by the author or by Sir William Preece in examining the Edison effect.

As soon as experiments began to be made with the above apparatus it was found that the observed effects were complicated and depended upon a great many factors, such as (1) the material of the wire or filament heated, (2) its temperature, (3) the gases or impurities occluded in it, (4) the nature of the gas surrounding it, (5) the pressure of this gas, and (6) the previous treatment of this wire as regards heating and exhaustion.

Broadly speaking, we may say that when the pressure of



the gas in the bulb is not extremely small—that is, when the vacuum is not extremely high—the effects will be complicated by the ionisation of this gas by the electrons emitted by the wire or filament, and this will give rise to positive and negative ions in the surrounding gas.

It soon became clear that to simplify the phenomena the removal of all gas round the heated wire and all gas films from the interior surfaces in the vessel and occluded gases from the materials was essential. This can only be done by prolonged heating of the whole apparatus and most careful exhaustion.

For this purpose very perfect mechanical vacuum pumps, such as the Gaede pump, must be employed and the exhaustion completed by the use of chemical means or by Sir James Dewar's method of absorption of residual gases by charcoal, particularly cocoanut charcoal fragments, cooled in liquid air (see chap. ii., sect. 9).

It is also necessary to heat the experimental vessel in an electric furnace, or by other means, during the exhaustion, and to prevent the collapse of the glass tube this may have to be done in a vacuum electric resistance furnace. The greatest difficulty is to eliminate occluded air or gas from the metal collecting cylinder.

As these precautions are equally necessary in the construction of thermionic detectors used in radiotelegraphy a few more details may be given. It is an extremely difficult matter to heat a metal collecting plate which is sealed up inside an exhausted glass vessel sufficiently to expel occluded gas by mere external heating. It is easier to do it if the collecting plate is formed of a wire coiled into a close spiral with turns nearly in contact, because then both ends of this wire can be welded to platinum wires which are sealed through the glass, and we have then access to the terminals of the spiral wire and can heat it intensely by an electric current passed through it.

We can then aid the exhaustion by the method of Sir James Dewar, connecting the glass vessel to a glass bulb filled with crushed fragments of cocoanut charcoal (see chap. ii., sect. 9). This bulb has to be hermetically sealed to the thermionic vessel. When the vacuum has been made as high as possible by the pump the charcoal bulb can be immersed in liquid air and will absorb the residual gas. By

(from 1M to 3M) or grid capacitor (100 pF to 220 pF). The grid bias with no signal was about -0.5 V with a 1M grid resistor.

The circuit works by using the small grid current when the grid is slightly negative. This grid current increases rapidly and very nonlinearly, so square-law detection is possible. The grid resistor establishes a quiescent point around which the signal oscillates. The rf part is bypassed through the grid capacitor, while the af part remains and causes a voltage drop across the grid resistor, which is then amplified in the usual way. With a 100k plate resistor, the output af voltage could approach 1 V peak-to-peak. Another stage of audio amplification would give a quite satisfactory result, but I was hoping for one tube. (The 12AX7 has two triodes in the same envelope--if such a tube were used, the receiver would be, strictly speaking, single tube.) With most other kinds of detectors, such a hope would be quite vain, it must be admitted.

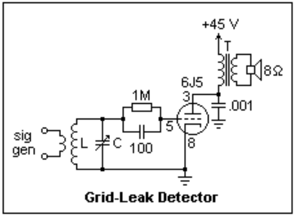
If the input signal amplitude is increased, the grid bias starts to decrease because the grid becomes positive on the peaks, and the detection becomes a little more linear. If the grid is biased to cutoff with a C supply, then there is clear linear detection, since the signal is effectively rectified. Such a circuit is called a grid-bias detector, and the signal amplitude must be restricted so that the grid does not go positive, when distortion would result.

You may notice in the tube manuals that a "maximum grid resistance" is given for a tube; for the 6J5, it is 1M. The reason for this is positive ion current, which may drive the grid more positive in a resistance-coupled amplifier, disturbing the bias. This is not a maximum in the same sense as the maximum plate dissipation or maximum cathode current are, since damage to the tube is not in question. There is no trouble in the grid leak detector, and values of several megohms are permissible.

There is no analogy to the grid-leak detector with FET's, which otherwise behave pretty much like vacuum tubes, because the leakage current is far too small for the desired behavior. As a gate-actual circuits that used a 1V6, but the amplifier shown at the left may be studied. It gave a gain of -14 with a plate current of 357 µA, so the effective transconductance was 298 µS. I substituted a 100k plate resistor, but the gain only increased marginally, to about -17. By experimenting, you may be able to get more gain from the tube. At low plate currents, the amplifier oscillated in an odd manner, and there were other peculiarities seen while fiddling around, but I did not take the time to track them down.

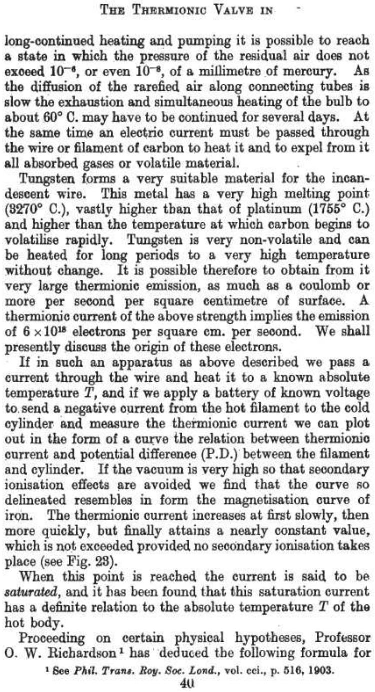
The Grid-Leak and Diode Detectors

Detectors are discussed in Amplitude Modulation, where the two types of square-law and linear are explained, and the grid-leak detector is mentioned. A circuit using a 6J5 triode is shown at the right. The audio output transformer T can be replaced with a 10k or 100k resistor, and the output observed with an oscilloscope. I could find only a 1k to 8Ω transformer, really designed for use with transistors. The circuit works, but I was not impressed by its output. Asking for loudspeaker output from a detector is being very optimistic, but I had some hopes. Perhaps a more suitable transformer would give better results.



Grid-Leak Detector

The tuned circuit can be one from a crystal set, with a loopstick and variable capacitor. The signal generator is coupled by about 9 turns slipped over the loopstick, providing an AM signal about 30% modulated with 1 kHz, in the broadcast band. The output was roughly constant, no matter what the plate voltage (45 to 105 V), input amplitude, value of grid resistor



long-continued heating and pumping it is possible to reach a state in which the pressure of the residual air does not exceed 10^{-6}, or even 10^{-8}, of a millimetre of mercury. As the diffusion of the rarefied air along connecting tubes is slow the exhaustion and simultaneous heating of the bulb to about 60° C. may have to be continued for several days. At the same time an electric current must be passed through the wire or filament of carbon to heat it and to expel from it all absorbed gases or volatile material.

Tungsten forms a very suitable material for the incandescent wire. This metal has a very high melting point (3270° C.), vastly higher than that of platinum (1755° C.) and higher than the temperature at which carbon begins to volatilise rapidly. Tungsten is very non-volatile and can be heated for long periods to a very high temperature without change. It is possible therefore to obtain from it very large thermionic emission, as much as a coulomb or more per second per square centimetre of surface. A thermionic current of the above strength implies the emission of 6×10^{18} electrons per square cm. per second. We shall presently discuss the origin of these electrons.

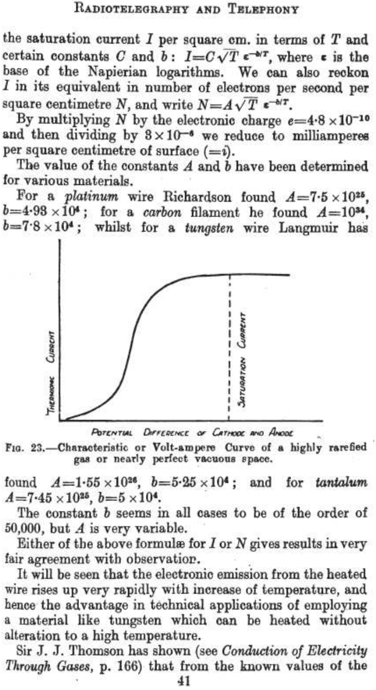
If in such an apparatus as above described we pass a current through the wire and heat it to a known absolute temperature T, and if we apply a battery of known voltage to send a negative current from the hot filament to the cold cylinder and measure the thermionic current we can plot out in the form of a curve the relation between thermionic current and potential difference (P.D.) between the filament and cylinder. If the vacuum is very high so that secondary ionisation effects are avoided we find that the curve so delineated resembles in form the magnetisation curve of iron. The thermionic current increases at first slowly, then more quickly, but finally attains a nearly constant value, which is not exceeded provided no secondary ionisation takes place (see Fig. 23).

When this point is reached the current is said to be *saturated*, and it has been found that this saturation current has a definite relation to the absolute temperature T of the hot body.

Proceeding on certain physical hypotheses, Professor O. W. Richardson[1] has deduced the following formula for

---

[1] See *Phil. Trans. Roy. Soc. Lond.*, vol. cci., p. 516, 1903.



the saturation current I per square cm. in terms of T and certain constants C and b: $I=C\sqrt{T}\,\epsilon^{-b/T}$, where ϵ is the base of the Napierian logarithms. We can also reckon I in its equivalent in number of electrons per second per square centimetre N, and write $N=A\sqrt{T}\,\epsilon^{-b/T}$.

By multiplying N by the electronic charge $e=4{\cdot}8\times10^{-10}$ and then dividing by 3×10^{-6} we reduce to milliamperes per square centimetre of surface $(=i)$.

The value of the constants A and b have been determined for various materials.

For a *platinum* wire Richardson found $A=7{\cdot}5\times10^{25}$, $b=4{\cdot}93\times10^{4}$; for a *carbon* filament he found $A=10^{34}$, $b=7{\cdot}8\times10^{4}$; whilst for a *tungsten* wire Langmuir has found $A=1{\cdot}55\times10^{26}$, $b=5{\cdot}25\times10^{4}$; and for *tantalum* $A=7{\cdot}45\times10^{25}$, $b=5\times10^{4}$.

FIG. 23.—Characteristic or Volt-ampere Curve of a highly rarefied gas or nearly perfect vacuous space.

The constant b seems in all cases to be of the order of 50,000, but A is very variable.

Either of the above formulæ for I or N gives results in very fair agreement with observation.

It will be seen that the electronic emission from the heated wire rises up very rapidly with increase of temperature, and hence the advantage in technical applications of employing a material like tungsten which can be heated without alteration to a high temperature.

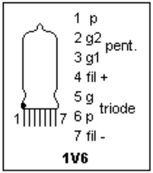
Sir J. J. Thomson has shown (see *Conduction of Electricity Through Gases*, p. 166) that from the known values of the

transconductance varies considerably with plate current, which gives rise to distortion for large signal amplitudes.

These tubes make vacuum-tube experiments very easy without requiring high-voltage supplies, only what is found in a normal transistor lab.

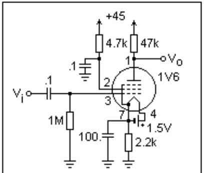
Sub-Miniature Tubes

The smallest regular electron tubes were the *subminiature* tubes, designed for battery-powered portable apparatus, from hearing aids to radiosonde transmitters. Typically, the lead wires were brought out through the press seal without a base, but there was also a subminiature base used for a few tubes. As an example, you can work with the 1V6, a pentode-triode with a filament taking 40 mA at 1.25V (the filament supply can be a D cell). The tube is 40mm x 10mm x 7mm, approximately. The maximum plate voltage is 45V, and typical plate currents are less than 1 mA.



1V6

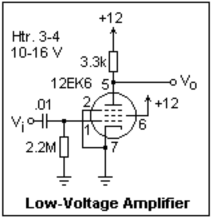
A sketch of the 1V6 and its connections is shown at the right. On the press seal, there is a red dot that identifies what I have called pin 1. The filament is located at the center of the tube, with the pentode on one side and the triode on the other. The triode shows a μ of about 10, r_p = 18.6 kΩ, and g_m = 440 μS. The pentode has g_m as high as 694 μS above 500 μA plate current, but it drops considerably at lower plate currents. The two devices can be tested as usual, taking care not to exceed 45V or 1 mA. Note that the pentode and the triode share the same filamentary cathode.



1V6 Amplifier

Unfortunately, I do not have any

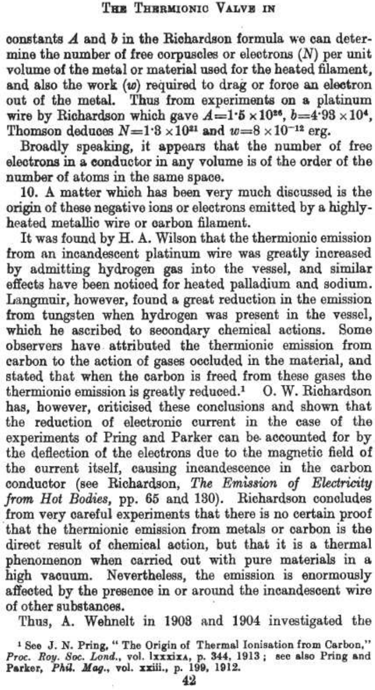
charge grid tetrodes, behaving like triodes. The other tubes are of conventional construction, in general having low plate currents, less than 1 mA in many cases. These include twin-diode triodes (12AE6, 12FK6, 12AJ6), sharp cutoff pentodes (12AF6, 12BL6, 12CX6, 12EK6), remote cutoff pentodes (12CN5, 12DZ6), twin-diode remote cutoff pentode (12F8), pentagrid converter (12AD6), pentagrid (variable gain) amplifier 12EG6, and a twin-diode power screen-grid tetrode, 12J8. The last tube can deliver 20 mW output power, half of what the 12DL8 can do.



Low-Voltage Amplifier

The 12EK6 (also known as 12DZ6 and 12EA6) is a screen-grid pentode for low-voltage use. A voltage amplifier using this tube is shown at the left. This tube was generally used as an IF or RF amplifier, so the load would have been a resonant circuit, not a resistor, giving much higher gain. However, the resistive load is easy to experiment with. There is no voltage to waste for cathode bias, so grid-leak bias is used. When a signal is applied, the bias will adjust itself so that the top of the input waveform is clamped to 0 V. Vary the input amplitude to verify this. This circuit works with an input of up to about 2 V peak-to-peak, perhaps best for an input of around 1.0 V p-p. The output voltage is then about 5.8 V p-p, the plate potential is 6.0 V, plate current 1.8 mA, and gain about -5.5, corresponding to a transconductance of 1.8 mS, about right from measurements of the characteristics and the position of the operating point in this case. The transfer characteristic is rather curved, leading to considerable distortion for larger amplitudes. Nevertheless, it is remarkable that the circuit works so well at such a low voltage.

As a triode (plate, suppressor and screen connected together), the 12EK6 has $\mu = 8.5$, $g_m = 6.3$ mS and $r_p = 1.35$ kΩ. The



constants A and b in the Richardson formula we can determine the number of free corpuscles or electrons (N) per unit volume of the metal or material used for the heated filament, and also the work (w) required to drag or force an electron out of the metal. Thus from experiments on a platinum wire by Richardson which gave $A=1{\cdot}5\times10^{26}$, $b=4{\cdot}93\times10^{4}$, Thomson deduces $N=1{\cdot}3\times10^{21}$ and $w=8\times10^{-12}$ erg.

Broadly speaking, it appears that the number of free electrons in a conductor in any volume is of the order of the number of atoms in the same space.

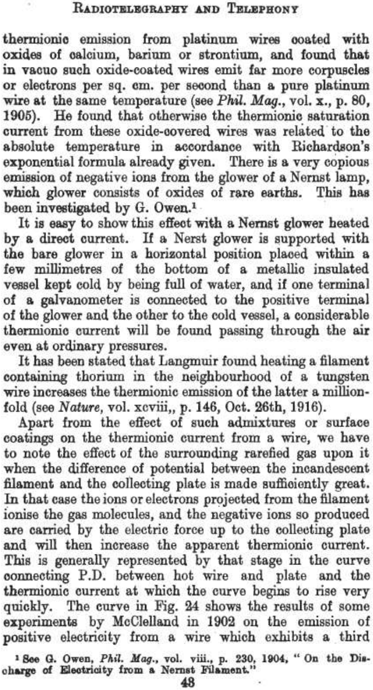
10. A matter which has been very much discussed is the origin of these negative ions or electrons emitted by a highly-heated metallic wire or carbon filament.

It was found by H. A. Wilson that the thermionic emission from an incandescent platinum wire was greatly increased by admitting hydrogen gas into the vessel, and similar effects have been noticed for heated palladium and sodium. Langmuir, however, found a great reduction in the emission from tungsten when hydrogen was present in the vessel, which he ascribed to secondary chemical actions. Some observers have attributed the thermionic emission from carbon to the action of gases occluded in the material, and stated that when the carbon is freed from these gases the thermionic emission is greatly reduced.[1] O. W. Richardson has, however, criticised these conclusions and shown that the reduction of electronic current in the case of the experiments of Pring and Parker can be accounted for by the deflection of the electrons due to the magnetic field of the current itself, causing incandescence in the carbon conductor (see Richardson, *The Emission of Electricity from Hot Bodies*, pp. 65 and 130). Richardson concludes from very careful experiments that there is no certain proof that the thermionic emission from metals or carbon is the direct result of chemical action, but that it is a thermal phenomenon when carried out with pure materials in a high vacuum. Nevertheless, the emission is enormously affected by the presence in or around the incandescent wire of other substances.

Thus, A. Wehnelt in 1903 and 1904 investigated the

---

[1] See J. N. Pring, "The Origin of Thermal Ionisation from Carbon," *Proc. Roy. Soc. Lond.*, vol. lxxxixA, p. 344, 1913; see also Pring and Parker, *Phil. Mag.*, vol. xxiii., p. 199, 1912.



thermionic emission from platinum wires coated with oxides of calcium, barium or strontium, and found that in vacuo such oxide-coated wires emit far more corpuscles or electrons per sq. cm. per second than a pure platinum wire at the same temperature (see *Phil. Mag.*, vol. x., p. 80, 1905). He found that otherwise the thermionic saturation current from these oxide-covered wires was related to the absolute temperature in accordance with Richardson's exponential formula already given. There is a very copious emission of negative ions from the glower of a Nernst lamp, which glower consists of oxides of rare earths. This has been investigated by G. Owen.[1]

It is easy to show this effect with a Nernst glower heated by a direct current. If a Nerst glower is supported with the bare glower in a horizontal position placed within a few millimetres of the bottom of a metallic insulated vessel kept cold by being full of water, and if one terminal of a galvanometer is connected to the positive terminal of the glower and the other to the cold vessel, a considerable thermionic current will be found passing through the air even at ordinary pressures.

It has been stated that Langmuir found heating a filament containing thorium in the neighbourhood of a tungsten wire increases the thermionic emission of the latter a millionfold (see *Nature*, vol. xcviii,, p. 146, Oct. 26th, 1916).

Apart from the effect of such admixtures or surface coatings on the thermionic current from a wire, we have to note the effect of the surrounding rarefied gas upon it when the difference of potential between the incandescent filament and the collecting plate is made sufficiently great. In that case the ions or electrons projected from the filament ionise the gas molecules, and the negative ions so produced are carried by the electric force up to the collecting plate and will then increase the apparent thermionic current. This is generally represented by that stage in the curve connecting P.D. between hot wire and plate and the thermionic current at which the curve begins to rise very quickly. The curve in Fig. 24 shows the results of some experiments by McClelland in 1902 on the emission of positive electricity from a wire which exhibits a third

---

[1] See G. Owen, *Phil. Mag.*, vol. viii., p. 230, 1904, "On the Discharge of Electricity from a Nernst Filament."

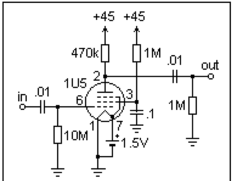
The screen grid potential is above the plate's in this circuit. Pentodes offer the capacity for controlling the plate current through the screen voltage, so that the plate voltage can be what is required. For higher voltages, the screen grid is normally at the same or lower potential as the plate, on the average. The grid voltage cannot be measured accurately with a DMM or scope, since the bias conditions will be disturbed. However, you will find that the amplifier works very well. Measure the gain the usual way, with a function generator and oscilloscope.

Radios for motor cars had 6 V DC available, which was right for 6.3 V heaters, but could not be used for the B supply--even now, 6 V is inconveniently low for transistors. The usual solution was a *vibrator* supply. Contacts on the magnetically-driven vibrator armature converted 6 V DC to alternating current, which was stepped up by a transformer and then rectified to DC again (sometimes by contacts on the vibrator) for the B supply. Vibrators were electrically very noisy, and had short lives, but were widely used until solid-state equivalents became available. They came in cylindrical metal cans, and looked like electrolytic capacitors. The 0Z4, mentioned elsewhere, was a rectifer specifically for vibrator supplies. Another possibility was the *dynamotor*, a motor-generator with a single rotating armature and brushes, which could supply more power than a vibrator and was more reliable. However, they were too expensive for general commercial use, though widely used in the military.

When 12 V became the automotive standard, vibrator supplies or their solid-state equivalents, could still be used. Tubes with 12.6 V heaters were already common. Many had the heater center-tapped, so they could be used equally well on 6.3 V. However, 12 V is high enough to be used directly as the plate supply if the tubes are specially designed. A range of tubes was produced that could be used on 12 V only, without any high voltage at all. We have already discussed the 12DL8 and 12K5 space-charge-grid tetrodes, and how the space-charge grid allows larger plate currents for small plate voltages. There were approximately 15 tube types designed for 12V use, of which only three, the 12DL8, 12DS7 and 12K5 are space-

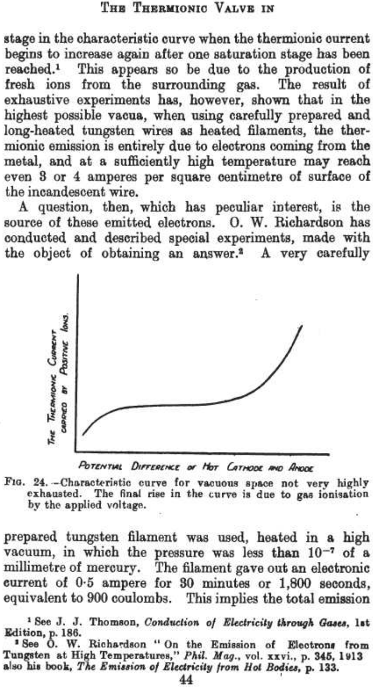
110V, but this can be exceeded a little in testing. I measured the characteristics for plate voltages of 125V and less, at grid voltages of 0.0, -0.5 and -1.0V (relative to the negative end of the filament). The plate current was always less than 1 mA. My results were $\mu = 62$, $g_m = 340\ \mu S$, and $r_p = 182k\Omega$. These values are close to the published values. The characteristics are noticeably curved in this region, so the parameters will vary with plate current. The apparently low value of transconductance is quite reasonable for the small plate currents at which the tube is used.

The amplifier shown gave a voltage gain of G - -40, with an input of 0.4V peak-to-peak. The plate current was about 100 μA, which made the plate voltage 77V and the grid bias -0.26V. The bandwidth of the amplifier was quite good, roughly from 10Hz to 50kHz. It should be noted that the total power drain of this circuit is no more than 83 mW, of which most is the filament power. This is very economical for a normal-sized tube. The tube remains quite cool in service, incidentally.



Pentode Voltage Amplifier

A pentode voltage amplifier with a gain of about -33 is shown at the right, using a 1U5, a sharp-cutoff pentode which comes in a 7-pin miniature package. Note the polarity of the filament supply, which is important, since it supplies a little grid bias as well. Since the voltages and currents are low, you can use the same 1/4W resistors used with transistors. The capacitors must have an appropriate voltage rating, of course. The 10M resistor is a "grid leak" that will prevent the grid from going positive. It charges on the positive excursions of the grid to provide whatever bias is necessary. The plate current was 61 μA, and the screen grid current was 20 μA.



stage in the characteristic curve when the thermionic current begins to increase again after one saturation stage has been reached.[1] This appears so be due to the production of fresh ions from the surrounding gas. The result of exhaustive experiments has, however, shown that in the highest possible vacua, when using carefully prepared and long-heated tungsten wires as heated filaments, the thermionic emission is entirely due to electrons coming from the metal, and at a sufficiently high temperature may reach even 3 or 4 amperes per square centimetre of surface of the incandescent wire.

A question, then, which has peculiar interest, is the source of these emitted electrons. O. W. Richardson has conducted and described special experiments, made with the object of obtaining an answer.[2] A very carefully prepared tungsten filament was used, heated in a high vacuum, in which the pressure was less than 10^{-7} of a millimetre of mercury. The filament gave out an electronic current of 0·5 ampere for 30 minutes or 1,800 seconds, equivalent to 900 coulombs. This implies the total emission

The Thermionic Current carried by Positive Ions.

RADIOTELEGRAPHY AND TELEPHONY

of 54×10^{20} electrons or 3×10^{18} electrons per second. Richardson carefully discusses in this paper, in the light of numerical values, the possibility of these electrons having come from the atoms of the tungsten evaporated, or from the ionisation of the residual gas, and shows that both these suppositions are inadmissible. In one experiment 984,000 electrons were emitted per atom of tungsten evaporated. He came to the conclusion that these electrons could only have come into the tungsten from other portions of the electric circuit, of which it formed part; in other words, that the electrons emitted are the "free" or conductivity electrons of the metal.

11. The subject of the emission of positive ions from incandescent wires has no such great practical interest at present as that of the emission of negative corpuscles or electrons, but reference must briefly be made to it.

We have seen that when a platinum wire is heated to a red heat in vacuo it gives off, at first, positive electricity, and this is quite distinct from any subsequent production of positive ions in the surrounding gas. This positive emission is, however, a short-lived effect. It does not remain constant, but rapidly decays away with time. A wire which has lost the power of positive emission will regain this power if heated in air or in a Bunsen flame. It is clear from measurements made of the ratio, *e/m*, for these positive ions that they are masses of atomic magnitude and appear to owe their origin to gases occluded in the heated wire or resulting from interaction between the atoms of the heated wire and the surrounding gas. The reader desiring to make a further study of this portion of the subject will find a valuable collection of experimental results in Professor O. W. Richardson's book, and in latest editions of Sir J. J. Thomson's book on *Conduction of Electricity through Gases*, and in his smaller book, *The Corpuscular Theory of Matter* (Constable & Co.).

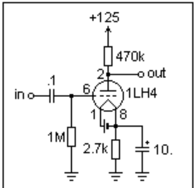
A very readable account of the electron theory of electricity is given in Mr. G. W. de Tunzelmann's book, *A Treatise on Electrical Theory* (C. Griffin & Co.). In Thomson's book on *The Corpuscular Theory of Matter* will be found a particularly full discussion of the electron theory of electric and thermal conduction.

45

Battery Tubes

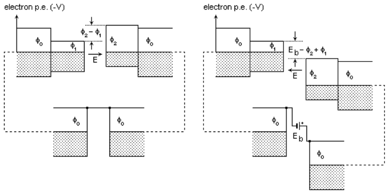
In the early days, nearly all radios (and other electronic apparatus) were powered by batteries, usually primary cells. With the rise of central power distribution, apparatus could be powered (and storage batteries charged) from the AC line, which was a practically unlimited, cheap source so far as radios were concerned. Transformers made high-voltage power supplies easy to build. Low-voltage filaments were largely replaced by 6.3V heaters and unipotential cathodes since power was now cheap. However, there still remained a demand for portable radios beyond the reach of power lines, and these were necessarily powered from batteries. The emphasis here had to be on small power drain, since battery power is expensive. Typical batteries were 1.5V and 3.0 V for filaments ("A" batteries), and 45V or 90V for plate supplies ("B" batteries), both the usual Leclanche "dry" cells. Filaments were generally used, because of their much greater efficiency in mA per watt. Typical battery tubes had filaments taking only 50 mA at 1.4V, only 70 mW. Plate currents were not high, since a few mA would be quite sufficient. For experiments with battery tubes, a D cell in a holder is an adequate filament supply, good for about 100 hours of service. Even an AA cell will do for experiments.

The 1LH4 is a loktal battery triode, which is shown in a voltage amplifier at the left. A similar octal tube is the 1H5-GT, and either will do in this experiment (but the basing is different!). A diode plate is included, connected to pin 4, and using the negative side of the filament as its cathode. The diode is not used in this circuit. The maximum plate voltage is



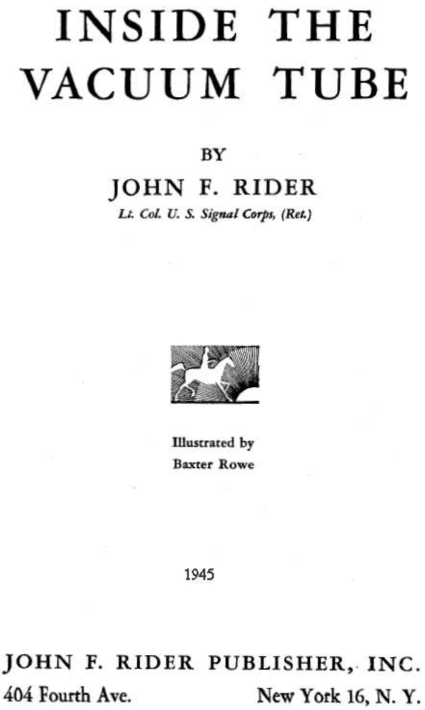
Voltage Amplifier

DMM, it would show 0 V and, of course, no current would flow. However, the Fermi levels of all three metals must line up for equilibrium, making a level surface on which the electrons will not tend to roll one way or the other. It is clear that in this state of equilibrium, the surfaces of metals 1 and 2 will not be at the same electrostatic potential. An oxide-coated cathode has a work function of about 1.0 V, while a nickel plate or grid has a work function of about 5.0 V. When the Fermi levels align, the cathode is 4.0 V positive with respect to the other electrode.



Effects of Contact Potential

At the right, we have connected a source of emf E_b into conductor 0. A source of emf maintains a difference in the Fermi levels equal to its voltage. With the polarity shown, the cathode 1 has now become negative with respect to the anode 2, by an amount equal to the applied voltage less the difference in work functions. If the device is a thermionic diode, current can now flow from cathode to anode. The actual plate voltage is about 4 V less than the meter says, because of the contact potential. In practice, things are a bit more complicated, because of space-charge effects. When you measure the V-I characteristic of a diode, there appears to be a small positive plate voltage when the measured voltage is zero, and a little current flows. The reason is that the electrons are emitted with some kinetic energy, and a negative space charge is created around the cathode. The actual emission to the anode comes from the minimum of this potential well, which is several volts negative, and so the plate may be slightly more positive than this minimum, in spite of contact potentials.



INSIDE THE VACUUM TUBE

Chapter 6

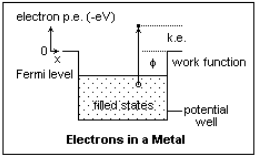
THE DIODE

THE MATERIAL GIVEN thus far in this book has prepared us for what shall follow in this and subsequent chapters. We have, up to now, given certain facts relating to the operation of the vacuum tube: the manner in which and the reasons why, the electrons, so essential to the vacuum tube, are liberated; the basic reasons for the movement of electrons between charged surfaces, that is, the underlying basis for plate current within the vacuum tube. True, we have not as yet, mentioned *types* of vacuum tubes, but the specific type has very little to do with the principles which govern the motion of the electrons.

We are now ready to investigate what happens in the different types of vacuum tubes and to investigate the variation in the magnitude of the inter-electrode electron stream as the result of changes in the strength of the electrostatic fields which exist in the vacuum tube. In practical language, these electrostatic fields are referred to in terms of voltage,—*operating voltages* and *control voltages*,—and the changes in the magnitude of the electron stream within the vacuum tube are referred to as *changes in plate current.* Almost all of the essential conditions normally associated with the operation of the tube are

81

free electrons, but differ by up to a few volts from the true potential differences.

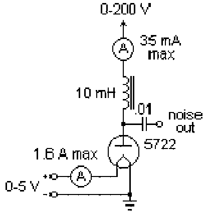


Electrons in a Metal

To understand this, let's review electrons in metals. One or more of the outer electrons of each metal atom is free to wander in the field of the ion cores, effectively binding the metal together. The positive ions create a potential well, as shown in the figure, and the electrons occupy the states of lowest energy. Note that electron energy increases upwards; since electrons are negatively charged, this means that voltage gets more negative upwards. There are not many more states than electrons, so they fill up the states up to some energy called the Fermi energy at 0 K. At ordinary temperatures, there is little difference, since the thermal energy is small compared to the kinetic energy of the electrons near the Fermi level.

If an electron is given enough energy, by thermal agitation or absorption of light, it may be separated completely from the metal and wander freely. The amount of energy necessary to just get outside is called the *work function*. Anything more goes into kinetic energy of the electron. The free electron can now be accelerated or decelerated by electric fields outside the metal in space. Work functions measured by thermionic, photoelectric and contact potential measurements agree roughly, but they depend sensitively on the surface preparation.

What happens in a vacuum tube is illustrated in the figure below. Suppose metal 1 is the cathode and metal 2 is the anode or grid, and the connections are made by a third metal 0 (there could be several such metals, but they all will act like metal 0). At the left, metals 1 and 2 are connected by a wire of metal 0. If metal 0 includes a should be rated at 2 A or more. Increase the filament voltage gradually, looking for the glow. There will be no plate current until the filament current reaches about 1.3 A, but it increases very rapidly beyond this point. The filament glows brilliantly, like an incandescent lamp, since its operating temperature is about 2400K, not the 900K of an oxide-coated filament. The filament current should not be allowed to exceed 1.6 A. If the power supply has current limiting, it can be useful here. By setting the plate voltage at near 200 V, you can see the saturation current as a function of filament current.

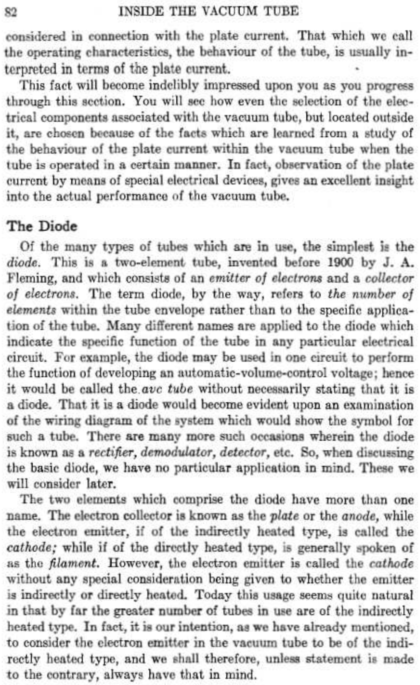


Testing the 5722

For two or more reasonable values of the saturation current, say 5 mA, 12 mA and 20 mA, record the current as a function of plate voltage and plot your results. For $I_f = 1.5$ A, the plate current saturated for about 50 V on the plate, approaching a value of about 12 mA. It is easy to find out what plate voltage to use to ensure saturation when making shot noise in this way. It is very difficult to make noise measurements in the usual breadboarding environment. I thought it just possible to have seen some on my 100 MHz scope with a plate current of 20 mA, without amplification. See the page on Noise for more discussion of noise measurements.

Contact Potential Effects

This is a good place to mention contact potentials, since you will probably run into their effects when experimenting with low-voltage tubes. Because of contact potentials, the voltages you measure with a DMM are not the actual voltages between electrodes, as seen by the



82 INSIDE THE VACUUM TUBE

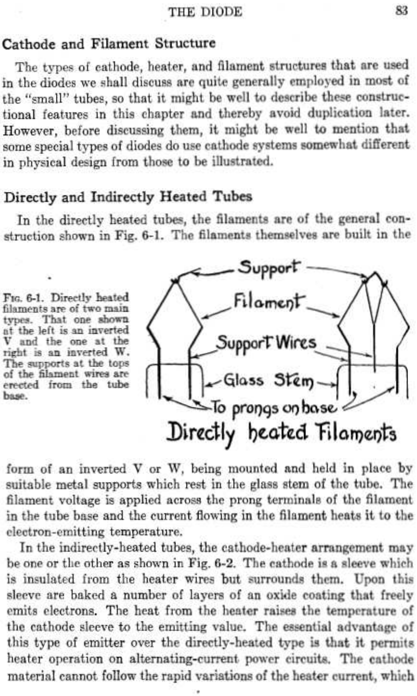
considered in connection with the plate current. That which we call the operating characteristics, the behaviour of the tube, is usually interpreted in terms of the plate current.

This fact will become indelibly impressed upon you as you progress through this section. You will see how even the selection of the electrical components associated with the vacuum tube, but located outside it, are chosen because of the facts which are learned from a study of the behaviour of the plate current within the vacuum tube when the tube is operated in a certain manner. In fact, observation of the plate current by means of special electrical devices, gives an excellent insight into the actual performance of the vacuum tube.

The Diode

Of the many types of tubes which are in use, the simplest is the *diode*. This is a two-element tube, invented before 1900 by J. A. Fleming, and which consists of an *emitter of electrons* and a *collector of electrons*. The term diode, by the way, refers to *the number of elements* within the tube envelope rather than to the specific application of the tube. Many different names are applied to the diode which indicate the specific function of the tube in any particular electrical circuit. For example, the diode may be used in one circuit to perform the function of developing an automatic-volume-control voltage; hence it would be called the *avc tube* without necessarily stating that it is a diode. That it is a diode would become evident upon an examination of the wiring diagram of the system which would show the symbol for such a tube. There are many more such occasions wherein the diode is known as a *rectifier, demodulator, detector*, etc. So, when discussing the basic diode, we have no particular application in mind. These we will consider later.

The two elements which comprise the diode have more than one name. The electron collector is known as the *plate* or the *anode*, while the electron emitter, if of the indirectly heated type, is called the *cathode;* while if of the directly heated type, is generally spoken of as the *filament*. However, the electron emitter is called the *cathode* without any special consideration being given to whether the emitter is indirectly or directly heated. Today this usage seems quite natural in that by far the greater number of tubes in use are of the indirectly heated type. In fact, it is our intention, as we have already mentioned, to consider the electron emitter in the vacuum tube to be of the indirectly heated type, and we shall therefore, unless statement is made to the contrary, always have that in mind.



Cathode and Filament Structure

The types of cathode, heater, and filament structures that are used in the diodes we shall discuss are quite generally employed in most of the "small" tubes, so that it might be well to describe these constructional features in this chapter and thereby avoid duplication later. However, before discussing them, it might be well to mention that some special types of diodes do use cathode systems somewhat different in physical design from those to be illustrated.

Directly and Indirectly Heated Tubes

In the directly heated tubes, the filaments are of the general construction shown in Fig. 6-1. The filaments themselves are built in the

Fig. 6-1. Directly heated filaments are of two main types. That one shown at the left is an inverted V and the one at the right is an inverted W. The supports at the tops of the filament wires are erected from the tube base.

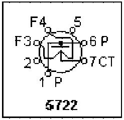
form of an inverted V or W, being mounted and held in place by suitable metal supports which rest in the glass stem of the tube. The filament voltage is applied across the prong terminals of the filament in the tube base and the current flowing in the filament heats it to the electron-emitting temperature.

In the indirectly-heated tubes, the cathode-heater arrangement may be one or the other as shown in Fig. 6-2. The cathode is a sleeve which is insulated from the heater wires but surrounds them. Upon this sleeve are baked a number of layers of an oxide coating that freely emits electrons. The heat from the heater raises the temperature of the cathode sleeve to the emitting value. The essential advantage of this type of emitter over the directly-heated type is that it permits heater operation on alternating-current power circuits. The cathode material cannot follow the rapid variations of the heater current, which

A special kind of diode should be mentioned here, because experiments with it are quite interesting. It is the *noise diode*, intended for the specific purpose of producing wide-band RF noise through the *shot effect*. Shot effect noise is fluctuations in the anode current due to the random collection of electrons. We have already mentioned that the anode current is controlled by the space charge around the filament. It was discovered, to some surprise, that this correlated successive electrons so that they were emitted regularly to maintain a constant current, and therefore the shot effect was nearly completely eliminated. That is, a normal diode has no shot effect noise in its plate current.

The noise diode is designed so that at reasonable plate voltages, all electrons emitted by the filament are immediately drawn to the plate without forming much of a space charge. Since the electrons are emitted randomly, the anode current will show the full shot effect noise. This is done by purposely making the filament to have low emission. To do this, a tungsten filament is used. Noise diodes give us the opportunity to observe a tungsten filament, as well as temperature saturation.

An available noise diode is the 5722, whose basing is shown at the right. The 7-pin miniature tube was made as late as 1977, and now costs about $14, which is probably not much more than when it was new. The maximum plate voltage is given as 200 V, and the maximum plate current as 35 mA, so apparently the plate can dissipate 7 W. The plate has wings that make a good dissipation probable.



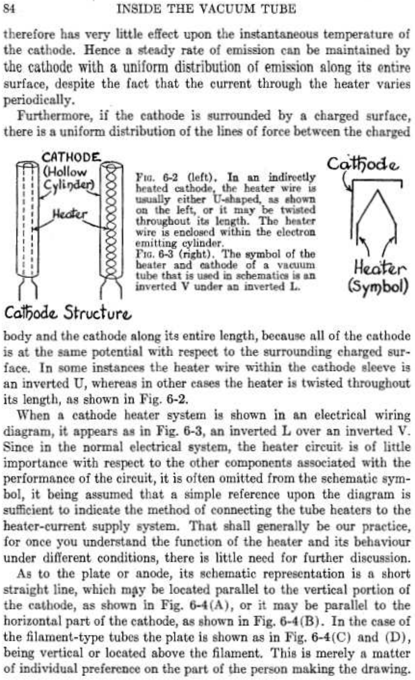
A circuit for testing the 5722 is shown at the left. Note that an RF choke is put in the plate lead to act as a load for the current fluctuations. This choke should be rated for the plate current employed. I connected a variable DC supply to the filament as shown, to pins 3 and 4, leaving the center tap alone. This supply

2, 7 and 9. This tube is designed for the rugged service of a television *damper diode*. During horizontal retrace, the damper diode conducts, charging the boost capacitor while absorbing the large inductive kick. The peak inverse voltage is 6000 V, the peak current 800 mA, and the average current 135 mA. The large-diameter cathode tube and long plate imply a large perveance, which, in fact, is about 2.3 mA/$V^{1.5}$. This tube happens to be very cheap, but would serve as an excellent half-wave rectifier for practically any purpose. There are other damper diodes, such as the 6W4 and the 6AX4GT (perveance 1.42), that would have similar characteristics.

As an example of the small signal diodes that are often combined with a triode or pentode in the same envelope, and share the same cathode, the 6AV6 or 6AT6 furnish good examples. The 6AV6 has its heater at pins 3-4, cathode at pin 2, and the signal diode plates at pins 5 and 6. The maximum current for each diode is 1 mA. I connected the two plates together for measurement, and took the current up to 3 mA, for which a plate voltage of 6.4 V was required. The curve of I against $V^{1.5}$ sagged a little at low currents, but the upper part was quite linear, showing a perveance of 0.085 mA/$V^{1.5}$ for one plate. The incremental resistance was 4.55kΩ, and V/I was 5.05kΩ at 1 mA. The current for one plate obeyed the formula $I = 0.15 + 0.085V^{1.5}$ mA. In this tube (and similar ones) the plates are flat, one on each side of the cathode.

The 1A3 seems to be the smallest signal diode of all. It was designed for portable measuring apparatus. The heater takes 0.15A at 1.4V (a D cell), connected to pins 1 and 7 of the 7-pin miniature envelope. The cathode is at pin 3, the anode at pins 2 and 6. The peak inverse voltage is 330V max., the maximum plate current 5 mA, and the average plate current 0.5 mA DC. Maximum heater-cathode potential is 140V. The anode is only a few millimeters high; most of the envelope contains only vacuum. The measured perveance was 0.075 mA/$V^{1.5}$.

The Noise Diode



84 INSIDE THE VACUUM TUBE

therefore has very little effect upon the instantaneous temperature of the cathode. Hence a steady rate of emission can be maintained by the cathode with a uniform distribution of emission along its entire surface, despite the fact that the current through the heater varies periodically.

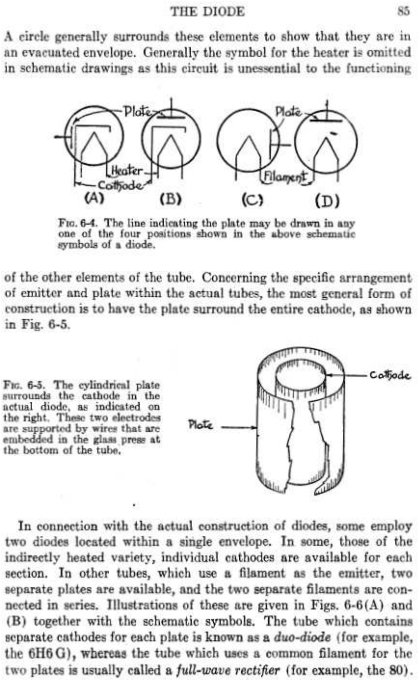
Furthermore, if the cathode is surrounded by a charged surface, there is a uniform distribution of the lines of force between the charged

FIG. 6-2 (left). In an indirectly heated cathode, the heater wire is usually either U-shaped, as shown on the left, or it may be twisted throughout its length. The heater wire is enclosed within the electron emitting cylinder.
FIG. 6-3 (right). The symbol of the heater and cathode of a vacuum tube that is used in schematics is an inverted V under an inverted L.

body and the cathode along its entire length, because all of the cathode is at the same potential with respect to the surrounding charged surface. In some instances the heater wire within the cathode sleeve is an inverted U, whereas in other cases the heater is twisted throughout its length, as shown in Fig. 6-2.

When a cathode heater system is shown in an electrical wiring diagram, it appears as in Fig. 6-3, an inverted L over an inverted V. Since in the normal electrical system, the heater circuit is of little importance with respect to the other components associated with the performance of the circuit, it is often omitted from the schematic symbol, it being assumed that a simple reference upon the diagram is sufficient to indicate the method of connecting the tube heaters to the heater-current supply system. That shall generally be our practice, for once you understand the function of the heater and its behaviour under different conditions, there is little need for further discussion.

As to the plate or anode, its schematic representation is a short straight line, which may be located parallel to the vertical portion of the cathode, as shown in Fig. 6-4(A), or it may be parallel to the horizontal part of the cathode, as shown in Fig. 6-4(B). In the case of the filament-type tubes the plate is shown as in Fig. 6-4(C) and (D), being vertical or located above the filament. This is merely a matter of individual preference on the part of the person making the drawing.



Plate

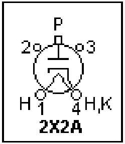
A circle generally surrounds these elements to show that they are in an evacuated envelope. Generally the symbol for the heater is omitted in schematic drawings as this circuit is unessential to the functioning of the other elements of the tube. Concerning the specific arrangement of emitter and plate within the actual tubes, the most general form of construction is to have the plate surround the entire cathode, as shown in Fig. 6-5.

FIG. 6-4. The line indicating the plate may be drawn in any one of the four positions shown in the above schematic symbols of a diode.

FIG. 6-5. The cylindrical plate surrounds the cathode in the actual diode, as indicated on the right. These two electrodes are supported by wires that are embedded in the glass press at the bottom of the tube.

In connection with the actual construction of diodes, some employ two diodes located within a single envelope. In some, those of the indirectly heated variety, individual cathodes are available for each section. In other tubes, which use a filament as the emitter, two separate plates are available, and the two separate filaments are connected in series. Illustrations of these are given in Figs. 6-6(A) and (B) together with the schematic symbols. The tube which contains separate cathodes for each plate is known as a *duo-diode* (for example, the 6H6 G), whereas the tube which uses a common filament for the two plates is usually called a *full-wave rectifier* (for example, the 80).

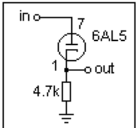
The 7Y4 is a typical small full-wave rectifier with an indirectly-heated cathode, like the more common 6X4 (miniature) and 6X5 (octal). This "Loktal" tube is inexpensive. Many of the common rectifier diodes are rather costly, for the curious reasons associated with the current tube market. The heater, taking 6.3V at 0.5A, is connected to pins 1-8 (as with all Loktal tubes). The cathode is pin 7, and the plates are pins 3 and 6. The peak inverse voltage is 1250 V, the peak current 180 mA, and the average dc current 70 mA. The heater-cathode voltage should not exceed 450 V. Measure the plate voltage for currents up to, say, 50 mA, and plot the results as for the 6H6. Again, we find a straight line and a perveance of 0.58 mA/V$^{1.5}$. Note that the plate voltage varies considerably as the current changes, from 4 V at 7 mA, to 16 V at 40 mA. Compare these voltages with those for a mercury-vapor *phanotron* as discussed in the next section. The 7Z4 is a somewhat larger full-wave rectifier (with perveance 0.40), the Loktal equivalent to the types 80 or 5Y3 that are now much more expensive.



An excellent diode for observing the Langmuir-Child law is the 2X2A. This tube has a 4-pin base like the 82 phanotron discussed below, and the large, bell-like anode is brought out to a cap at the top of the ST envelope. The oxide-coated cathode thimble is easily seen. The heater takes 2.5V at 1.75A, so it can use the same transformer as the type 82. The rated DC current is 7.5 mA, and the maximum voltage is 4500V. A plate voltage of about 60V is needed to reach 7.5 mA plate current, so measurements can be made over a wide range of voltages. Plot your results as $I^{2/3}$ vs. V. A straight line will be found, that intercepts the V axis at -1.2V. The perveance of the 2X2 is found to be 0.0165 mA/V$^{3/2}$. The unusually low value is due to the large cathode-anode spacing.

The 6V3-A is a strange miniature tube with a cap on top that is the cathode connection. Its heater, connected to pins 4 and 5 of the 9-pin miniature base, takes 1.75 A at 6.3 V. The plate is connected to pins

V can be resisted, and the DC plate current should not exceed 9 mA. Peak currents can go up to 45 mA if necessary, however. I measured the perveance as 2.42 mA/$V^{1.5}$, for one plate, a large value. The 6AL5 gives 9 mA with a plate voltage of only about 2.5 V! The heater, connected to H-H, pins 3 and 4, takes 0.3 A at 6.3 V.



Signal Rectifier

Try the 6AL5 in the circuit shown at the left, which is a basic signal rectifier with a 4.7k load resistor. Feed it with the signal generator, and compare the output and input with the oscilloscope. Try input peak-to-peak voltages of only 2 V or so. You will notice that there is no "diode drop" with the 6AL5--it acts like a perfect diode, rectifying down to small voltages. We know how to do this with a semiconductor diode and an op-amp, but here it's done quite simply. The 6AL5 has an incremental resistance of only about 237 Ω, and is nearly linear. It is easy to run a plate voltage versus plate current curve with a low-voltage power supply. Keep the load resistor, and subtract the voltages at plate and cathode to find the plate voltage.

The 6H6 is an octal dual signal diode like the 6AL5, in a unique small metal envelope. The heater is connected to pins 2-7, the cathodes to 4 and 8, the plates to 3 and 5. 3 and 4 are one diode, 8 and 5 the other, and completely independent. It can be used for any reasonable service, such as AM detection, as a full-wave rectifier, or as a voltage doubler, so long as the current per plate is 8 mA or lower, and inverse voltages do not exceed 420 V. The voltage between heater and cathodes should not exceed 330 V. Measure the plate current as a function of the plate voltage up to 10 mA (the plate voltage will be about 7 V), and plot the current against the 3/2 power of the voltage. I obtained a rather straight line, showing agreement with Langmuir-Child, with a permeance of 0.5 mA/$V^{1.5}$. At 8 mA, the incremental resistance was 590Ω, and V/I = 785Ω. The 12H6 and 7H6 are similar tubes with different heater ratings and basing.

The justification for such a distinction between the two tubes is due solely to construction and not utility, for the duo-diode can be arranged for use as a full-wave rectifier without any trouble. However, the fact that separate cathodes are available in the duo-diode gives it certain operating capabilities which are not possessed by the tube which has the two separate plates, but a single source of electrons. In the case of the duo-diode, there may be only a single heater winding serving the two cathodes.

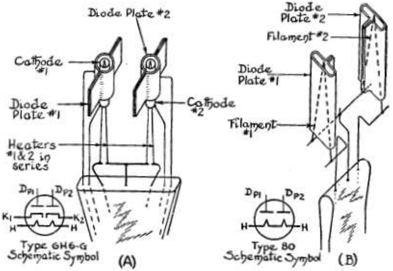


FIG. 6-6. The duo-diode tube shown in (A) has a cathode for each of its two plates and the 80 type rectifier shown in (B) has but a single continuous filament for both of its two plates.

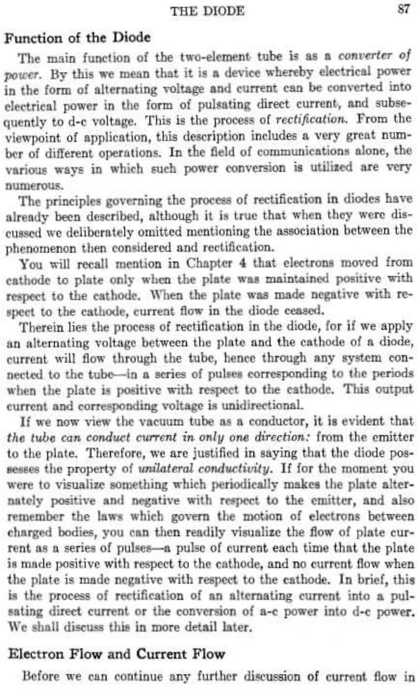
The presence of more than one diode structure in an envelope does not in any way alter the considerations surrounding the basic two-element tube, and this applies equally well to the tube with the two plates but a single filament. Whatever is said about the single diode applies equally well to the other section. The same is true if the two plates of the two diodes are connected in parallel by some electrical connection and two cathodes are operated as one. The only difference resulting from such an arrangement is a change in the characteristics of the tube, but not in the basic principles of operation. Just what we mean by this in actual numerical values will be shown later in this chapter.



THE DIODE 87

Function of the Diode

The main function of the two-element tube is as a *converter of power*. By this we mean that it is a device whereby electrical power in the form of alternating voltage and current can be converted into electrical power in the form of pulsating direct current, and subsequently to d-c voltage. This is the process of *rectification*. From the viewpoint of application, this description includes a very great number of different operations. In the field of communications alone, the various ways in which such power conversion is utilized are very numerous.

The principles governing the process of rectification in diodes have already been described, although it is true that when they were discussed we deliberately omitted mentioning the association between the phenomenon then considered and rectification.

You will recall mention in Chapter 4 that electrons moved from cathode to plate only when the plate was maintained positive with respect to the cathode. When the plate was made negative with respect to the cathode, current flow in the diode ceased.

Therein lies the process of rectification in the diode, for if we apply an alternating voltage between the plate and the cathode of a diode, current will flow through the tube, hence through any system connected to the tube—in a series of pulses corresponding to the periods when the plate is positive with respect to the cathode. This output current and corresponding voltage is unidirectional.

If we now view the vacuum tube as a conductor, it is evident that *the tube can conduct current in only one direction:* from the emitter to the plate. Therefore, we are justified in saying that the diode possesses the property of *unilateral conductivity.* If for the moment you were to visualize something which periodically makes the plate alternately positive and negative with respect to the emitter, and also remember the laws which govern the motion of electrons between charged bodies, you can then readily visualize the flow of plate current as a series of pulses—a pulse of current each time that the plate is made positive with respect to the cathode, and no current flow when the plate is made negative with respect to the cathode. In brief, this is the process of rectification of an alternating current into a pulsating direct current or the conversion of a-c power into d-c power. We shall discuss this in more detail later.

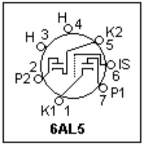
Electron Flow and Current Flow

Before we can continue any further discussion of current flow in

and other interesting things. They do work rather well, and it is good to make their acquaintance.

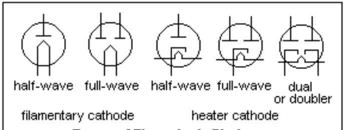
The forward voltage (in the direction of current flow) of a diode is always relatively low, less than 15 V or so. The plate current is roughly proportional to the 3/2 power of the anode-cathode voltage (Langmuir-Child law), and the proportionality factor is called the *perveance*. The perveance depends on the geometry of the tube, increasing with larger area and closer spacing. It's remarkable that most diodes agree with Langmuir-Childs so well, in spite of different geometries. Since the voltages are low, contact potentials may affect your measurements. Contact potentials are discussed below in the section on low-voltage tubes. The easiest way to find the perveance is to plot $I^{2/3}$ against V, and to draw the best straight line. The intercept gives the value of the "true" zero plate voltage, and the slope, raised to the 3/2 power, is the perveance. Perveances range from 0.02 to 2.4 $mA/V^{3/2}$ for a representative assortment of 12 diodes of all types. There is no turn-on voltage drop for a thermionic diode, as there is for a silicon diode. Conduction begins immediately when the plate is positive with respect to the cathode, and stops immediately when the plate goes negative. It is easy to measure the V-I characteristic of a diode with a low-voltage DC supply, a voltmeter and an ammeter. I use a 100Ω resistor in series to make adjustment easier and safer. Thermionic diodes are not as easy to destroy as semiconductor diodes, and will take a good deal of abuse.

The 6AL5 dual diode, whose basing is shown at the right (7-pin miniature socket), is a typical signal diode. IS is an internal shield between the diodes. The two diodes and the shield are easily seen through the glass envelope, and you should notice how close the plates are to the cathodes. The close spacing means a large perveance, so only small plate voltages are required. Don't connect this tube directly across high voltages! A peak inverse voltage of 330



Diodes

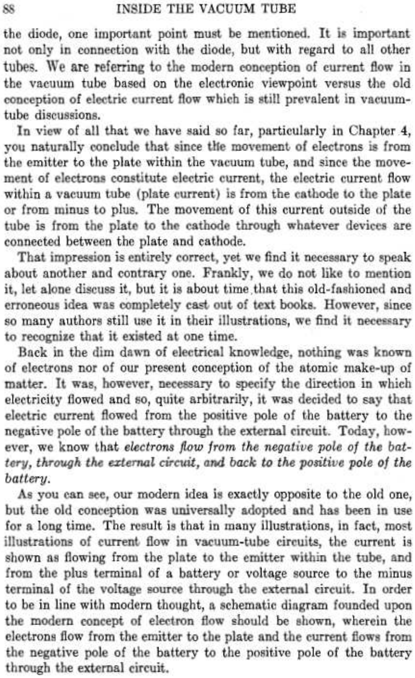
Thermionic diodes, like semiconductor diodes, are divided into *signal* diodes that handle small currents at low voltages, and *rectifier* diodes that handle large currents, often with large inverse voltages. A diode has an electron-emitting cathode and an electron-receiving anode or plate. The arrangments of cathodes and plates in commercial tubes, and what they are called, are shown in the figure. Signal diodes are also often added to a triode or pentode, sharing the same cathode and with one or two plates. Current flows only from plate to cathode, and this unidirectional conduction is the purpose of a diode. Diodes cannot amplify.



Types of Thermionic Diodes

Signal diodes always have indirectly-heated cathodes, so they are easy to use. It is only necessary to make sure that the heater-cathode voltage does not exceed specified limits, usually a few hundred volts. Rectifier diodes often have filamentary oxide-coated cathodes, since these cathodes are more efficient when large currents are needed, requiring less power. We are considering only vacuum diodes, *kenotrons*, in this section. Thermionic gas diodes, or *phanotrons*, will be treated below, since they have rather different properties.

Thermionic diodes have now been completely superseded by semiconductor diodes, largely for economic reasons, physical size and the need for a filament supply. A silicon diode capable of carrying 1 A is available for $0.04 or so, and takes up very little room. However, diodes can teach us a lot about thermionic emission



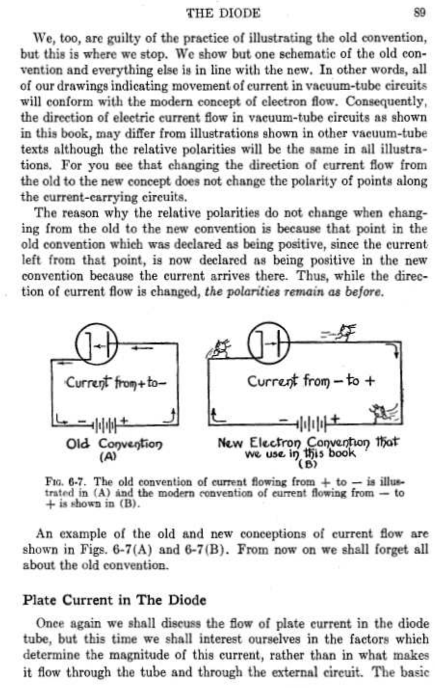
the diode, one important point must be mentioned. It is important not only in connection with the diode, but with regard to all other tubes. We are referring to the modern conception of current flow in the vacuum tube based on the electronic viewpoint versus the old conception of electric current flow which is still prevalent in vacuum-tube discussions.

In view of all that we have said so far, particularly in Chapter 4, you naturally conclude that since the movement of electrons is from the emitter to the plate within the vacuum tube, and since the movement of electrons constitute electric current, the electric current flow within a vacuum tube (plate current) is from the cathode to the plate or from minus to plus. The movement of this current outside of the tube is from the plate to the cathode through whatever devices are connected between the plate and cathode.

That impression is entirely correct, yet we find it necessary to speak about another and contrary one. Frankly, we do not like to mention it, let alone discuss it, but it is about time that this old-fashioned and erroneous idea was completely cast out of text books. However, since so many authors still use it in their illustrations, we find it necessary to recognize that it existed at one time.

Back in the dim dawn of electrical knowledge, nothing was known of electrons nor of our present conception of the atomic make-up of matter. It was, however, necessary to specify the direction in which electricity flowed and so, quite arbitrarily, it was decided to say that electric current flowed from the positive pole of the battery to the negative pole of the battery through the external circuit. Today, however, we know that *electrons flow from the negative pole of the battery, through the external circuit, and back to the positive pole of the battery.*

As you can see, our modern idea is exactly opposite to the old one, but the old conception was universally adopted and has been in use for a long time. The result is that in many illustrations, in fact, most illustrations of current flow in vacuum-tube circuits, the current is shown as flowing from the plate to the emitter within the tube, and from the plus terminal of a battery or voltage source to the minus terminal of the voltage source through the external circuit. In order to be in line with modern thought, a schematic diagram founded upon the modern concept of electron flow should be shown, wherein the electrons flow from the emitter to the plate and the current flows from the negative pole of the battery to the positive pole of the battery through the external circuit.



We, too, are guilty of the practice of illustrating the old convention, but this is where we stop. We show but one schematic of the old convention and everything else is in line with the new. In other words, all of our drawings indicating movement of current in vacuum-tube circuits will conform with the modern concept of electron flow. Consequently, the direction of electric current flow in vacuum-tube circuits as shown in this book, may differ from illustrations shown in other vacuum-tube texts although the relative polarities will be the same in all illustrations. For you see that changing the direction of current flow from the old to the new concept does not change the polarity of points along the current-carrying circuits.

The reason why the relative polarities do not change when changing from the old to the new convention is because that point in the old convention which was declared as being positive, since the current left from that point, is now declared as being positive in the new convention because the current arrives there. Thus, while the direction of current flow is changed, *the polarities remain as before.*

FIG. 6-7. The old convention of current flowing from + to − is illustrated in (A) and the modern convention of current flowing from − to + is shown in (B).

An example of the old and new conceptions of current flow are shown in Figs. 6-7(A) and 6-7(B). From now on we shall forget all about the old convention.

Plate Current in The Diode

Once again we shall discuss the flow of plate current in the diode tube, but this time we shall interest ourselves in the factors which determine the magnitude of this current, rather than in what makes it flow through the tube and through the external circuit. The basic

A tube designated simply 6N7 will be a metal-envelope octal tube with a 6.3V heater. A 6N7GT will have a cylindrical glass envelope. A 6N7G would have a shouldered glass envelope of the graceful shape designated ST. The electrical characteristics of such tubes were the same, whatever the envelope shape.

A very important part of vacuum-tube technology was bringing the metal leads through the glass envelope. Coefficients of expansion must be exactly matched, and the seal must be strong. Originally, tubes had bases (usually Bakelite) to support the contact pins mechanically, taking the strain off the pressed-glass seal, which was made of lead glass. Around 1935, the metal envelope was developed, but there was still a base. The all-glass "miniature" tube was made possible by the "button seal" that supported the contact pins mechanically as well as bringing them through the glass, allowing the base to be eliminated and tube size to be reduced. The insides, or "cage," was the same size as in previous tubes, however. It is supported on its leads, which are welded to the contact pins before the envelope is fused in place and evacuated. The button seal is also used, in a larger form, on tubes designated by GB at the end of the type designation, and by Loktals. The final step in manufacture was "flashing" the getter, usually barium or magnesium, to perfect the vacuum by adsorption of any remaining gases, leaving a shiny coating. This was generally done by heating a loop inductively by RF from outside.

7, and often to pins 3-4 on 7-pin, or 4-5 on 9-pin, miniature tubes. Sometimes halves of the heater can be connected in series or parallel, for two different voltages. Sockets were originally mounted in holes punched in aluminum chassis, secured by locking rings or by screws and nuts with a mounting plate. The chassis was, not surprisingly, the ground or common.

The "Loktal" tube was an excellent idea that was never universally adopted, mainly because miniature tubes took over in the 1950's. Since loktal was a trade name, RCA used "lock-in" instead, and you sometimes see "loctal." The loktal tube has an 8-pin button-seal (like the seal on miniature and octal GTB tubes). A natural metal base (of some aluminum alloy, apparently) shields the base of the tube and has a central pin with a circumferential locking groove. The pins project only 6 mm, and are 1.4 mm in diameter, much smaller than octal pins, so the locking action guarantees that the tube will stay in the socket in spite of the small pins. The tubes are roughly the same size as an octal GT tube. Most are one size, but a few power tubes have a slightly longer envelope. There are no grid caps on any Loktal tube, and the heater connections are always to pins 1 and 8. Among the thoughtful features of loktal design, the type number appears in a hexagon on the top of the tube where it is visible from above, not on the side as on octal tubes. There is a dimple on the base corresponding to the key of the central pin, making the tube easy to orient for insertion. It seems that a lot of getter was used, so the tops of the envelope appear heavily silvered. The available types are only those used in AM and FM receivers. There are, nevertheless, enough types for a broad variety of experiments, and the prices are not excessive, so you may want to standardize on Loktals. Type numbers beginning with 7 have 6.3 V heaters, while type numbers beginning with 14 have 12.6 V heaters. There are some 7xx and 14xx tubes that are not Loktal, and some tubes that actually take a 7 V heater supply. One loktal rectifier, the 5AZ4 (a 5Y3 equivalent), has a 5 V filament. Loktal tubes designed specifically for battery-powered equipment had 1.4V filaments. The type numbers began with "1L." There were also rectifier and beam power loktals with 35, 50 and 70-volt heaters for AC/DC sets with series heater connections.

reasons for the flow of current between the elements of the tube have already been discussed in Chapter 4, so that we need merely illustrate the similarity between the diode and the two-element structures previously illustrated. This is done in Figs. 6-8(A), (B), and (C). Since we shall speak about the flow of current through the circuit, a meter M is included in each illustration.

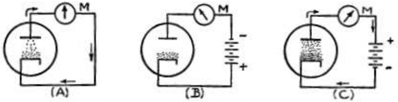


FIG. 6-8. High-speed electrons arriving at the plate form a small plate current, even though no potential is applied to the plate; this is shown in (A). No plate current results when the potential on the plate is negative, as shown in (B), and a current flows that is greater than that of (A) when a positive potential is applied to the plate; this is shown in (C).

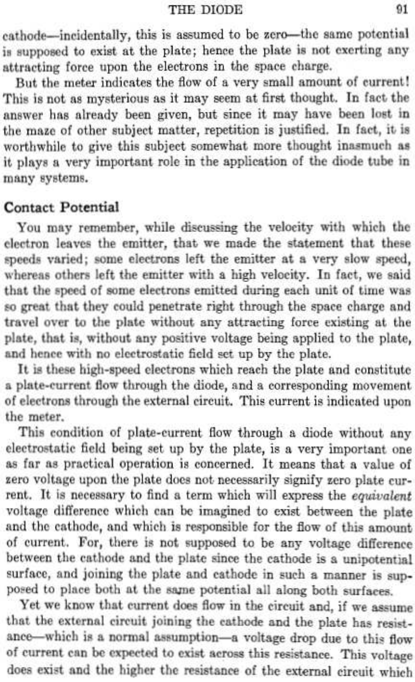
In each of these illustrations, the cathode is the equivalent of the emitter discussed in Chapter 4, and the plate is the equivalent of the positively charged surface. The battery shown in Fig. 6-8(C) is the voltage source used in Chapter 4 which made the charged surface positive with respect to the plate. In the case of Fig. 6-8(B), the battery makes the plate negative with respect to the cathode.

The dots shown between the cathode and the plate in Figs. 6-8(A), 6-8(B), and 6-8(C), correspond to the space charge discussed in Chapter 4. In Fig. 6-8(C), the plate voltage is of such magnitude that a flow of plate current occurs. In Fig. 6-8(B), the plate having been made negative with respect to the cathode, the plate current is zero, and the space charge can be seen concentrated in the neighborhood of the cathode just as described in Chapter 4.

We now come to Fig. 6-8(A), which has not been mentioned. Basically, the conditions existing in this circuit correspond to what has been described in Chapter 4 but, as you can see, the battery has been omitted and the plate is joined to the cathode. What happens in this circuit? In the first place, since the plate and the cathode are joined and no voltage source is connected between the plate and cathode, presumably no difference of potential exists between these two elements. Since the two are joined, whatever the voltage may be at the



THE DIODE 91

cathode—incidentally, this is assumed to be zero—the same potential is supposed to exist at the plate; hence the plate is not exerting any attracting force upon the electrons in the space charge.

But the meter indicates the flow of a very small amount of current! This is not as mysterious as it may seem at first thought. In fact the answer has already been given, but since it may have been lost in the maze of other subject matter, repetition is justified. In fact, it is worthwhile to give this subject somewhat more thought inasmuch as it plays a very important role in the application of the diode tube in many systems.

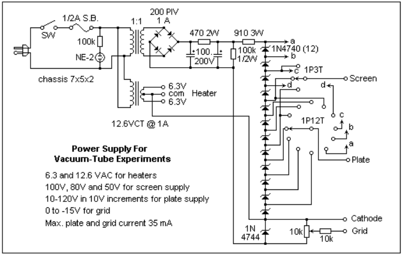
Contact Potential

You may remember, while discussing the velocity with which the electron leaves the emitter, that we made the statement that these speeds varied; some electrons left the emitter at a very slow speed, whereas others left the emitter with a high velocity. In fact, we said that the speed of some electrons emitted during each unit of time was so great that they could penetrate right through the space charge and travel over to the plate without any attracting force existing at the plate, that is, without any positive voltage being applied to the plate, and hence with no electrostatic field set up by the plate.

It is these high-speed electrons which reach the plate and constitute a plate-current flow through the diode, and a corresponding movement of electrons through the external circuit. This current is indicated upon the meter.

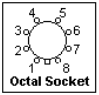
This condition of plate-current flow through a diode without any electrostatic field being set up by the plate, is a very important one as far as practical operation is concerned. It means that a value of zero voltage upon the plate does not necessarily signify zero plate current. It is necessary to find a term which will express the *equivalent* voltage difference which can be imagined to exist between the plate and the cathode, and which is responsible for the flow of this amount of current. For, there is not supposed to be any voltage difference between the cathode and the plate since the cathode is a unipotential surface, and joining the plate and cathode in such a manner is supposed to place both at the same potential all along both surfaces.

Yet we know that current does flow in the circuit and, if we assume that the external circuit joining the cathode and the plate has resistance—which is a normal assumption—a voltage drop due to this flow of current can be expected to exist across this resistance. This voltage does exist and the higher the resistance of the external circuit which



Power Supply For Vacuum-Tube Experiments

6.3 and 12.6 VAC for heaters
100V, 80V and 50V for screen supply
10-120V in 10V increments for plate supply
0 to -15V for grid
Max. plate and grid current 35 mA



Vacuum tubes come with metal or glass envelopes, and in latter days with either the familiar octal arrangment of 8 pins, or as miniature glass tubes with 7 or 9 pins. There were earlier bases with four, five or six pins. Later, 12-pin miniature "compactron" or "duodecal" tubes were used in TV sets. Miniature tubes were not miniature, simply tubes with a button seal and all-glass envelope closely fitting a normal-sized cage. Subminiature tubes were actually miniature. Sometimes connections to grid, plate or (rarely) cathode were made to caps at the top of the tubes. In small tubes, these caps have a diameter of 1/4". The pins are numbered consectively clockwise, starting from the left of the index key for the octal, or to the left of the wider space, for the miniature, always looking at the bottom of the tube. This is shown for the octal base at the left. Pin numbers are given in the circuit schematics here. Most sockets have pin numbers marked. You will need to get sockets for the tubes you study, one for each type of socket. Solder wires to the tab at each pin that can be inserted in the solderless breadboard. I use the resistor color code for the pin numbers. A convenient octal socket fixture is available that comes with screw terminals for making connections. It was intended for relays, but is very useful for tube experiments. Heater connections for octal tubes are typically (not always!) to pins 2 and put in a box with an on-off switch and convenient terminals. Ground the heater supply (at a center tap if one is provided) to the B+ ground, to avoid excess voltages between heater and cathode. If you have a 12.6V CT (center-tapped) secondary, you can supply both 6.3 and 12.6 V heaters. Many 12.6V miniature tubes can also be connected for 6.3V. Tubes whose designations begin with "1" have filaments that can be supplied from a single D cell. Obtain a holder for the cell so connections are easy. 6.3 V was chosen to be compatible with 6 V car batteries, but the supply is usually AC. Many rectifier diodes use a 5 V filament or heater supply, apparently for historical reasons.

A "C" supply, for the grid bias in measuring characteristics, can be any isolated low-voltage supply of say, 15V, and a potentiometer can be used to pick off a variable voltage, since little current is involved. A separate high-voltage supply for screen grids may also be convenient, though it is easy to pick off the necessary voltages with a Zener or a VR tube from the main B+ supply. This cannot be done, of course, if the B+ voltage is adjusted using a variable transformer.

An all-in-one economical supply for vacuum-tube measurements is shown below. It uses an inexpensive isolation transformer from All Electronics, and can be made for about $30.00. The most expensive single part is the aluminum chassis. The grid potentiometer could be a precision 10-turn pot, but this would be expensive, and an ordinary carbon or plastic potentiometer (1/2 W or better) will be satisfactory. The maximum plate voltage of 120V and maximum plate current of 35 mA is adequate for many measurements. If you use a three-wire line cord, ground the chassis to the green wire. If you use only a two-wire line cord, it is probably better not to ground the chassis.

connects the plate to the cathode, the more easily it can be measured. As to just what you would call this voltage, the best that we can do is to refer to the name by which it is known, namely, *"contact potential."*

The use of this term to identify this voltage is not wholly correct, yet, for want of a better name, it is used in commercial tube literature, and we shall therefore use it on those grounds.

Determination of Diode Behaviour

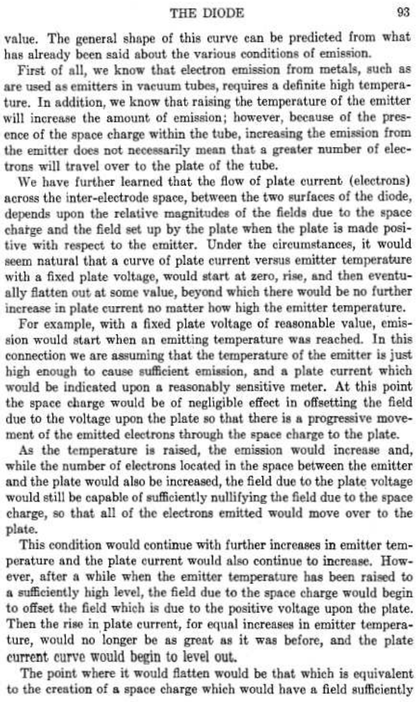
All of this information about the flow of current in a diode, with a positive, a negative, and zero voltage at the plate, merely supplements the facts given in Chapter. 4. What we wish to determine is the behaviour of the diode when those conditions which cause the flow of plate current are varied. Only then can we establish facts relative to the manner in which the diode is used.

What are the conditions which determine the amount of plate-current flow in the diode? Since the magnitude of plate current is partly dependent upon the emission of electrons from the cathode or filament of the tube, the temperature of the emitter is a factor. In accordance with what was said in Chapter 4, the electrostatic field set up at the plate influences the effectiveness of the space charge, and hence affects the plate current. Consequently, we see that the value of the plate voltage has an effect upon the amount of plate current flowing through the tube.

We must therefore establish characteristic curves, or behaviour curves, showing the variation in plate current with emitter temperature and also characteristic curves showing the variation in plate current with plate voltage. These are the two basic characteristic curves of the diode, although, strange as it may seem, that which can be considered the more basic, namely, the emitter temperature—plate current characteristic curve, is infrequently used. In fact, tube manufacturers do not usually show such curves in their tube specifications, the reason being that tubes are designed to be used at a specific value of emitter temperature, as determined by the voltage applied across the filament or heater.

Emitter Temperature—Plate Current Characteristic

To establish the manner in which the plate current of the diode varies with the emitter temperature, it is necessary to set up a circuit using a diode wherein it is possible to create various emitter temperatures and to maintain the voltage applied to the plate at a constant



value. The general shape of this curve can be predicted from what has already been said about the various conditions of emission.

First of all, we know that electron emission from metals, such as are used as emitters in vacuum tubes, requires a definite high temperature. In addition, we know that raising the temperature of the emitter will increase the amount of emission; however, because of the presence of the space charge within the tube, increasing the emission from the emitter does not necessarily mean that a greater number of electrons will travel over to the plate of the tube.

We have further learned that the flow of plate current (electrons) across the inter-electrode space, between the two surfaces of the diode, depends upon the relative magnitudes of the fields due to the space charge and the field set up by the plate when the plate is made positive with respect to the emitter. Under the circumstances, it would seem natural that a curve of plate current versus emitter temperature with a fixed plate voltage, would start at zero, rise, and then eventually flatten out at some value, beyond which there would be no further increase in plate current no matter how high the emitter temperature.

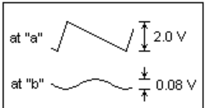
For example, with a fixed plate voltage of reasonable value, emission would start when an emitting temperature was reached. In this connection we are assuming that the temperature of the emitter is just high enough to cause sufficient emission, and a plate current which would be indicated upon a reasonably sensitive meter. At this point the space charge would be of negligible effect in offsetting the field due to the voltage upon the plate so that there is a progressive movement of the emitted electrons through the space charge to the plate.

As the temperature is raised, the emission would increase and, while the number of electrons located in the space between the emitter and the plate would also be increased, the field due to the plate voltage would still be capable of sufficiently nullifying the field due to the space charge, so that all of the electrons emitted would move over to the plate.

This condition would continue with further increases in emitter temperature and the plate current would also continue to increase. However, after a while when the emitter temperature has been raised to a sufficiently high level, the field due to the space charge would begin to offset the field which is due to the positive voltage upon the plate. Then the rise in plate current, for equal increases in emitter temperature, would no longer be as great as it was before, and the plate current curve would begin to level out.

The point where it would flatten would be that which is equivalent to the creation of a space charge which would have a field sufficiently

satisfactory for anything but power amplifiers. If supplied from a variable transformer, it becomes a variable supply for all voltages from 0 to 300. Note very carefully that one side of the supply is connected to the AC line, and this must be the grounded side, for your safety, and to avoid ground loops. You cannot ground the positive terminal of this supply to get a negative voltage supply (for use as a C supply, for instance). An isolation transformer, if you have one, would eliminate this hazard. If you don't have an isolation transformer, use a polarized plug to guarantee that the white wire is connected to the circuit ground. If you have a good ground, consider the old trick of connecting only one wire in the power cord, and using the ground to complete the circuit. It is best to observe the power ratings of the resistors and the voltage ratings of the capacitors. This circuit has been tested, except for the fuse. If the 0.5A slow-blow fuse fails, try a 1.0A. This fuse is to turn things off if a capacitor fails; nothing valuable is protected here, but it saves mess.



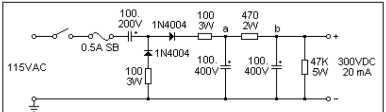
Effect of Ripple Filter

The RC ripple filter is worth the expense. Waveforms are shown at the left. The waveform at node "a" is the familiar one for a "tank" capacitor, and the ripple is fairly large. Since the impedance of a 100 µF capacitor is only 26Ω at 60 Hz, the ripple is reduced by a factor of almost 25. At 300V output and a load of 12 mA, the ripple is less than 0.1V, a very satisfactory result. Note that all that is left in the ripple is the 60 Hz component. The filter would work even better on a full-wave rectifier, but here it is very satisfactory, better and more economical than larger capacitors. Of course, a filter choke could be used for an even better result and less voltage drop, but this would double the cost of the supply.

You will also need a heater transformer, which can be quite small if supplying only one tube that requires 0.3A. The transformer can be loads, should not be used, since they are autotransformers and do not provide isolation. They are, in fact, quite dangerous things, and should be used with great care. The supply was built in a 5" x 7" x 3" aluminum box, with an octal socket for the VR tube on top. The socket can be left vacant when the fixed voltage output is not required.

The voltage regulator requires a certain minimum current (about 5 mA) to function properly. If you are only drawing a few milliamperes from the supply, connect a 12k bleeder resistor across the output. Otherwise, the regulator will not adjust down to the lower voltages. Or, 220Ω and 10k fixed resistors, and a 15k pot, could be used at the voltage regulator, which would draw the necessary minimum current. The VR tube can be replaced by a high-voltage Zener diode.

A 25W isolation transformer is available at the date of writing from All Electronics (See the Your Laboratory page for a link) for $4.50. This transformer is surplus from the Power One firm, and is an excellent value. Solder a jumper between tabs 1 and 3, and another between tabs 2 and 4. The 120V input is connected between 1-3 and 2-4. The output tabs are marked B. This transformer would work well in the circuit above, or it could be put in a box and wired with line cord and output receptacle as a general isolation transformer. It should supply 200 mA without trouble, ample for our purposes.



Voltage-Doubler B+ Supply

An idea for an inexpensive B+ supply is shown at the right. The greatest expense is for the capacitors, which will cost about $15. It is based on a half-wave voltage doubler, and gives 300V for a 115V rms input. It cannot supply large currents, but is perfectly

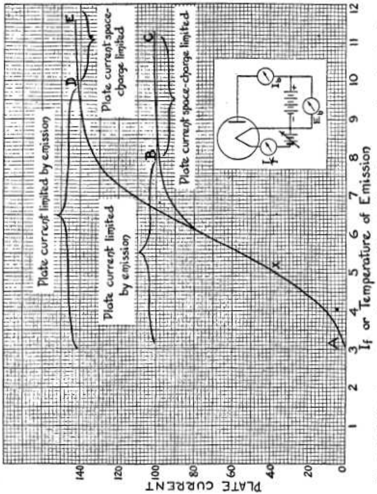


FIG. 6-9. Emitter temperature—plate current characteristic. These curves show that the plate current does not increase appreciably above a certain value even though the temperature of the emitter is increased.

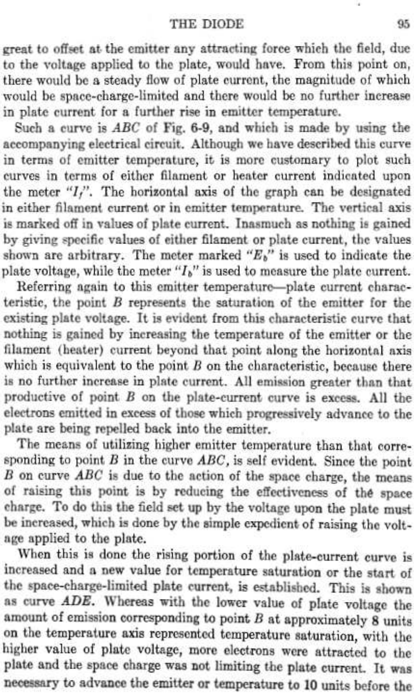


great to offset at the emitter any attracting force which the field, due to the voltage applied to the plate, would have. From this point on, there would be a steady flow of plate current, the magnitude of which would be space-charge-limited and there would be no further increase in plate current for a further rise in emitter temperature.

Such a curve is *ABC* of Fig. 6-9, and which is made by using the accompanying electrical circuit. Although we have described this curve in terms of emitter temperature, it is more customary to plot such curves in terms of either filament or heater current indicated upon the meter "I_f". The horizontal axis of the graph can be designated in either filament current or in emitter temperature. The vertical axis is marked off in values of plate current. Inasmuch as nothing is gained by giving specific values of either filament or plate current, the values shown are arbitrary. The meter marked "E_b" is used to indicate the plate voltage, while the meter "I_b" is used to measure the plate current.

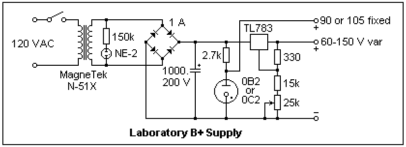
Referring again to this emitter temperature—plate current characteristic, the point *B* represents the saturation of the emitter for the existing plate voltage. It is evident from this characteristic curve that nothing is gained by increasing the temperature of the emitter or the filament (heater) current beyond that point along the horizontal axis which is equivalent to the point *B* on the characteristic, because there is no further increase in plate current. All emission greater than that productive of point *B* on the plate-current curve is excess. All the electrons emitted in excess of those which progressively advance to the plate are being repelled back into the emitter.

The means of utilizing higher emitter temperature than that corresponding to point *B* in the curve *ABC*, is self evident. Since the point *B* on curve *ABC* is due to the action of the space charge, the means of raising this point is by reducing the effectiveness of the space charge. To do this the field set up by the voltage upon the plate must be increased, which is done by the simple expedient of raising the voltage applied to the plate.

When this is done the rising portion of the plate-current curve is increased and a new value for temperature saturation or the start of the space-charge-limited plate current, is established. This is shown as curve *ADE*. Whereas with the lower value of plate voltage the amount of emission corresponding to point *B* at approximately 8 units on the temperature axis represented temperature saturation, with the higher value of plate voltage, more electrons were attracted to the plate and the space charge was not limiting the plate current. It was necessary to advance the emitter or temperature to 10 units before the

well. All the usual resistors and potentiometers are not afraid of 150V, so long as power ratings are observed. 1W and 1/2W resistors may be required in some places. Capacitors must be able to stand the voltages across them; many of those used with transistors will not be adequate. Keep a separate kit of capacitors rated at 100 V and above for this work. High-voltage capacitors are not needed everywhere, only in the plate circuits and for coupling from plate circuits.

The circuit of the laboratory B+ supply that I use for vacuum tubes is shown at the right, and the supply itself is shown in the photograph below. It provides a regulated variable 60-150 V output, and a regulated fixed voltage output (for screen supply) created by a VR tube. VR tubes can be exchanged for different voltages. The MagneTek N-51X 115 V-115 V isolation transformer is available from Antique Electronics (see references), and a cheaper one from All Electronics. The transformer secondary has a DC resistance of 22Ω, which limits the surge current satisfactorily without having to add a series resistor. By no means eliminate the isolation transformer and use the 120 V household supply directly, because of the ground hazard. A variable transformer (Variac) is an *autotransformer* that does not isolate the output from the power line ground. I earnestly recommend that you do not work on AC circuits without isolating them from the service ground. The 110/220 adapters commonly available in 50W and 300W sizes, used for shavers and other small



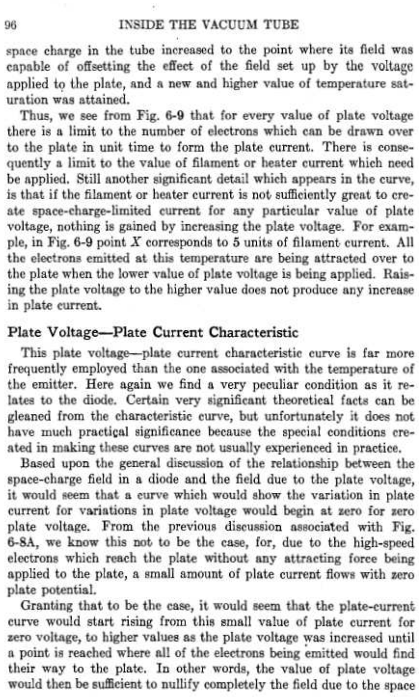
Laboratory B+ Supply

through the discharge in the "normal glow" region, in which the glow does not completely cover the cathode, and expands to accommodate more current. Tubes were manufactured for voltages of 75, 90, 105 and 150 that were used like Zener diodes, handling from 5 to 40 mA. There is more information on glow discharges in Relaxation Oscillators, and on Zeners in Voltage Regulators. VR tubes are treated here because of their association with vacuum tubes, and the higher voltages involved.

Experiments

Vacuum tubes generally operate at higher voltages than transistor circuits. Like transistors, vacuum tubes are happier at higher voltages, which for receiving-type tubes, typically would be, say, 200 to 250V. It was once quite common to make DC power supplies for such voltages, using a transformer with a center-tapped secondary (say 200-0-200V), and a rectifier with double anodes and a common cathode, feeding a filter consisting of capacitors of 8 or 16 μF, and a choke of 10 H or so. It was not convenient to make a bridge rectifier with vacuum diodes (three separate filament transformers are necessary), so full-wave rectification with a center-tapped secondary was usual. These days it is rather difficult (and expensive) to acquire all these things, with the possible exception of the capacitors, which are now available up to millifarads at voltages up to 450 V.

The voltages normally used with receiving tubes are not high enough to be really dangerous, though a shock will not improve your day. If you are eager for new experiences, I can save you the trouble of finding out by saying that a DC shock is kind of like a hammer blow, not the zap of an AC shock, and does not paralyze, as an AC shock does. Shocks are given by current, not simple contact, so a good and old rule is to work with one hand in your pocket around high voltage. Always turn things off before making any adjustments or changes, of course, and be neat. Avoid touching bare metal. With these precautions and normal care, you will be fine. The solderless breadboard, DMM and oscilloscope can handle these voltages quite



space charge in the tube increased to the point where its field was capable of offsetting the effect of the field set up by the voltage applied to the plate, and a new and higher value of temperature saturation was attained.

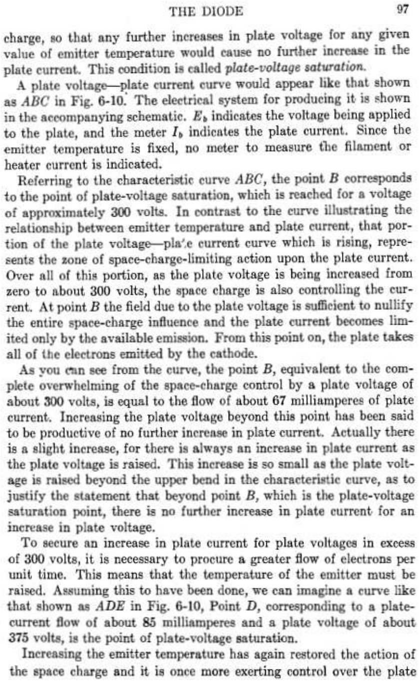
Thus, we see from Fig. 6-9 that for every value of plate voltage there is a limit to the number of electrons which can be drawn over to the plate in unit time to form the plate current. There is consequently a limit to the value of filament or heater current which need be applied. Still another significant detail which appears in the curve, is that if the filament or heater current is not sufficiently great to create space-charge-limited current for any particular value of plate voltage, nothing is gained by increasing the plate voltage. For example, in Fig. 6-9 point *X* corresponds to 5 units of filament current. All the electrons emitted at this temperature are being attracted over to the plate when the lower value of plate voltage is being applied. Raising the plate voltage to the higher value does not produce any increase in plate current.

Plate Voltage—Plate Current Characteristic

This plate voltage—plate current characteristic curve is far more frequently employed than the one associated with the temperature of the emitter. Here again we find a very peculiar condition as it relates to the diode. Certain very significant theoretical facts can be gleaned from the characteristic curve, but unfortunately it does not have much practical significance because the special conditions created in making these curves are not usually experienced in practice.

Based upon the general discussion of the relationship between the space-charge field in a diode and the field due to the plate voltage, it would seem that a curve which would show the variation in plate current for variations in plate voltage would begin at zero for zero plate voltage. From the previous discussion associated with Fig. 6-8A, we know this not to be the case, for, due to the high-speed electrons which reach the plate without any attracting force being applied to the plate, a small amount of plate current flows with zero plate potential.

Granting that to be the case, it would seem that the plate-current curve would start rising from this small value of plate current for zero voltage, to higher values as the plate voltage was increased until a point is reached where all of the electrons being emitted would find their way to the plate. In other words, the value of plate voltage would then be sufficient to nullify completely the field due to the space



THE DIODE 97

charge, so that any further increases in plate voltage for any given value of emitter temperature would cause no further increase in the plate current. This condition is called *plate-voltage saturation.*

A plate voltage—plate current curve would appear like that shown as *ABC* in Fig. 6-10. The electrical system for producing it is shown in the accompanying schematic. E_b indicates the voltage being applied to the plate, and the meter I_b indicates the plate current. Since the emitter temperature is fixed, no meter to measure the filament or heater current is indicated.

Referring to the characteristic curve *ABC*, the point *B* corresponds to the point of plate-voltage saturation, which is reached for a voltage of approximately 300 volts. In contrast to the curve illustrating the relationship between emitter temperature and plate current, that portion of the plate voltage—plate current curve which is rising, represents the zone of space-charge-limiting action upon the plate current. Over all of this portion, as the plate voltage is being increased from zero to about 300 volts, the space charge is also controlling the current. At point *B* the field due to the plate voltage is sufficient to nullify the entire space-charge influence and the plate current becomes limited only by the available emission. From this point on, the plate takes all of the electrons emitted by the cathode.

As you can see from the curve, the point *B*, equivalent to the complete overwhelming of the space-charge control by a plate voltage of about 300 volts, is equal to the flow of about 67 milliamperes of plate current. Increasing the plate voltage beyond this point has been said to be productive of no further increase in plate current. Actually there is a slight increase, for there is always an increase in plate current as the plate voltage is raised. This increase is so small as the plate voltage is raised beyond the upper bend in the characteristic curve, as to justify the statement that beyond point *B*, which is the plate-voltage saturation point, there is no further increase in plate current for an increase in plate voltage.

To secure an increase in plate current for plate voltages in excess of 300 volts, it is necessary to procure a greater flow of electrons per unit time. This means that the temperature of the emitter must be raised. Assuming this to have been done, we can imagine a curve like that shown as *ADE* in Fig. 6-10, Point *D*, corresponding to a plate-current flow of about 85 milliamperes and a plate voltage of about 375 volts, is the point of plate-voltage saturation.

Increasing the emitter temperature has again restored the action of the space charge and it is once more exerting control over the plate

gain in response to increased negative grid bias, which was used for AGC (automatic gain control) in IF amplifiers. The 6SK7 was a very popular remote cutoff pentode used as an RF and IF amplifier. The 6SJ7, on the other hand, was a *sharp-cutoff* pentode, used as an audio voltage amplifier. The amplification factor has little significance with pentodes, as with transistors, and transconductance is the important parameter. The screen grid also acted as an electrostatic shield between control grid and plate, reducing the Miller capacitance to extremely small values, 0.003 pF in the 6SK7. If the screen and suppressor grid are connected to the plate, the pentode operates as a triode.

A very curious and ingenious kind of tube was the *electron-ray* tube, used on receivers to give a visual indication of the accuracy of tuning to a station. Don't confuse it with the *cathode-ray* tube that uses a guided electron beam for oscilloscopes and TV receivers. It showed a luminous disk, with a dark sector. The dark sector was made as small as possible to achieve accurate tuning. It worked from the AGC (automatic gain control) voltage of the receiver. This is a feedback signal that tries to keep the signal amplitude constant at the output of the intermediate frequency amplifiers, increasing the gain for weak signals and decreasing it for strong. It is usually a negative voltage produced by rectifying the IF output. The tube has a thermionic cathode and a conical anode or *target* covered with cathodoluminescent phosphor (like a CRT), which glows from the 3 or 4 mA of plate current that flows when it is across 125V or more (up to 250). Control electrodes, of which there are two on opposite sides of the 6AF6, make two dark sectors that are widest when at 0V, and narrow as the control voltage approaches the target voltage. The control voltage is typically provided by the plate of a triode controlled by the AVC, such that full negative AVC cuts off the triode and makes the sector as small as possible. All this was cheaper and more graphic than a pointer meter.

Another kind of tube that we'll look at here is the glow-tube voltage regulator. The voltage across a glow discharge depends on the gas and the cathode material, and is almost idependent of the current

Although tetrodes worked as expected, they had a serious defect. It happens that speedy electrons colliding with the plate knock out *secondary* electrons. In a triode, these are rapidly sucked back to the positive plate, and the same happened in a tetrode when the plate potential was higher than the screen grid potential. In normal operation however, especially with large voltage gain, the plate voltage has a large swing, and can become less positive than the screen grid. Now all these secondary electrons (and some of the primary ones, too) are attracted to the screen grid, and there is a definite sag in the characteristic in this region. To prevent this, it is necessary to establish an electric field at the plate that is always directed toward the plate, to suppress the escape of secondary electrons. This is provided by a third grid, the *suppressor grid*, which is usually connected to the cathode. The tube with three grids: control, screen and suppressor, or grids 1, 2 and 3, is called a *pentode*, which turns out to be a superior voltage amplifier, fully equivalent to a transistor. A typical small pentode, the 6SJ7, has a plate resistance of over a megohm, and a transconductance of 1.6 mS.

An ingenious modification of the pentode has electrodes that shape and concentrate the electron beam instead of a suppressor grid, the negative space charge of the electrons doing the same work. These are called *beam power* tubes, and were good for power work, as the name indicates. A typical example, the 6L6, had a transconductance as high as 6.0 mS, and the smaller 6V6 about 4.0 mS. Both types were widely used for high-fidelity audio amplifiers, and tube amplifiers still have proponents. The same tubes were used in small amateur radio transmitters, which shows the versatility of vacuum tubes.

Receiving pentodes were also classified as *sharp cutoff* or *remote cutoff*, an example of designing tubes to fit their applications. A remote cutoff pentode had a grid with variable spacing, so that areas of wider spacing let electrons through when the grid was made more negative, when areas of smaller spacing were cut off. This effectively reduced the transconductance of the tube, decreasing its

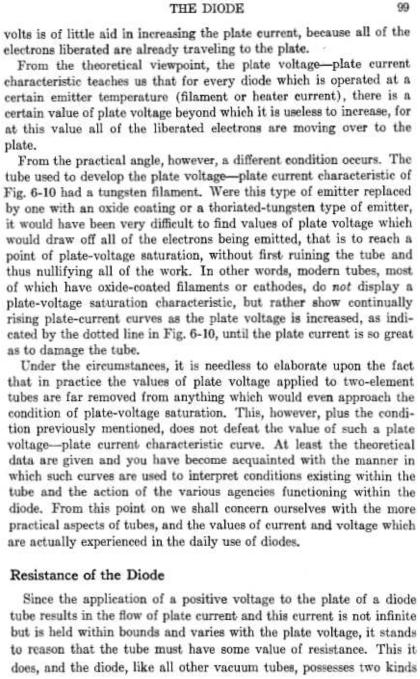
Plate current limited by emission
Plate current space-charge limited
Plate current limited by emission

FIG. 6-10. Plate voltage—plate current characteristic. These curves show that the plate current does not increase appreciably above certain values no matter how much the plate voltage is raised, as only a limited number of electrons are emitted.

current against the field due to the plate voltage, until that voltage reached a value of approximately **375** volts. At that point the plate current represented the total number of electrons emitted per unit time by the emitter. Further raising of the plate voltage beyond **375**



volts is of little aid in increasing the plate current, because all of the electrons liberated are already traveling to the plate.

From the theoretical viewpoint, the plate voltage—plate current characteristic teaches us that for every diode which is operated at a certain emitter temperature (filament or heater current), there is a certain value of plate voltage beyond which it is useless to increase, for at this value all of the liberated electrons are moving over to the plate.

From the practical angle, however, a different condition occurs. The tube used to develop the plate voltage—plate current characteristic of Fig. 6-10 had a tungsten filament. Were this type of emitter replaced by one with an oxide coating or a thoriated-tungsten type of emitter, it would have been very difficult to find values of plate voltage which would draw off all of the electrons being emitted, that is to reach a point of plate-voltage saturation, without first ruining the tube and thus nullifying all of the work. In other words, modern tubes, most of which have oxide-coated filaments or cathodes, do *not* display a plate-voltage saturation characteristic, but rather show continually rising plate-current curves as the plate voltage is increased, as indicated by the dotted line in Fig. 6-10, until the plate current is so great as to damage the tube.

Under the circumstances, it is needless to elaborate upon the fact that in practice the values of plate voltage applied to two-element tubes are far removed from anything which would even approach the condition of plate-voltage saturation. This, however, plus the condition previously mentioned, does not defeat the value of such a plate voltage—plate current characteristic curve. At least the theoretical data are given and you have become acquainted with the manner in which such curves are used to interpret conditions existing within the tube and the action of the various agencies functioning within the diode. From this point on we shall concern ourselves with the more practical aspects of tubes, and the values of current and voltage which are actually experienced in the daily use of diodes.

Resistance of the Diode

Since the application of a positive voltage to the plate of a diode tube results in the flow of plate current and this current is not infinite but is held within bounds and varies with the plate voltage, it stands to reason that the tube must have some value of resistance. This it does, and the diode, like all other vacuum tubes, possesses two kinds

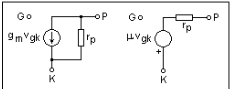
It's easy to see that the maximum voltage gain achievable with a triode is μ, if the load resistance is much higher than the plate resistance. The rule we derived for the gain of a transistor amplifier as the ratio of the collector and emitter resistances holds here as well, expressed by $\mu = g_m r_p$. The quantity analogous to r_e is $1/g_m$, which is 333Ω for the 6J5. Mu is a rather modest number, so triodes are not good for high voltage gain. They make very good power amplifiers, however, since large currents can be controlled. Using the Thévenin source, the gain of a usual common-cathode amplifier (analogous to a common-emitter amplifier) is simply a voltage divider problem. There must be a plate resistor in series with the plate, or else the voltage would never change, but it should be as large as possible, and has only a small effect on the gain. We shall examine these circuits in detail in the experiments, but this provides the background.

In order to provide higher voltage gain, the plate resistance must be reduced somehow. We recall that with a transistor, the analogous collector resistance was very large, and there was no problem with voltage gain. The plate resistance is the result of the effect of plate voltage on the space charge. This effect is not necessary for control, which is provided by the control grid, so what we need is to eliminate the effect of the plate voltage on the space charge. This is done by introducing another grid, the *screen grid* between the control grid and the plate. If this grid is held at a constant potential, the space charge is "screened" from the effects of changes in plate voltage. The screen grid is usually bypassed to ground by a capacitor, whose reactance at the lower corner frequency should be smaller than the resistance connecting the screen grid to B+. Some, but few, electrons are removed by the screen grid, since it is again a coil of fine wire. With this change, the plate characteristics become (nearly) horizontal lines, as for the transistor, and the plate resistance becomes large, approaching a megohm. The resulting tube is called a *screen-grid tetrode*.

voltage electrolytic. Only part of the cathode resistor can be bypassed if some feedback is desired.

A typical triode, of which the 6J5 is chosen here as the example, has a $\mu = 20$, $r_p = 6.7k$ and $g_m = 3.0$ mS. Of course, the relation $\mu = g_p m_p$ always holds. The value of transconductance may seem small, compared to a transistor, but it should be remembered that it refers to a high-voltage plate circuit, and that the input impedance is infinite, so the power amplification is extremely large. The 6J5 is called a "medium-mu" triode. The similar 6SL7, a "high mu" triode, has $\mu = 70$, $r_p = 44k$ and $g_m = 1.6$ mS. The 6SL7 is a *dual* triode, two independent valves sharing the same heater. The dual version of the 6J5 is the 6SN7.

The maximum plate voltage of the 6J5 is 300V, and the maximum plate current is 20 mA. Its maximum *plate dissipation* is 2.5W (product of average plate current and average plate voltage). This gives an idea of the ratings of receiving tubes used as voltage amplifiers. As power amplifiers, the allowable plate currents can be quite a bit larger, and hundreds of watts output is possible with relatively small tubes. The interelectrode capacitances of the 6J5 are on the order of 3.4 pF, and are significant at high frequencies.



Triode Equivalent Circuits

The small-signal equivalent circuits for the triode are shown at the right. The Norton source circuit is exactly the one for the FET. In the case of the triode, the plate resistance is always important, and cannot be neglected. The other circuit is just the Thévenin source corresponding to the Norton source. It shows the significance of the amplification factor, and is useful for triodes because of the rather small plate resistance. We did not find the Th%eacute;venin source for transistors very useful, and did not introduce a parameter analagous to the amplification factor for this reason.

---

of opposition to the flow of current: *d-c plate resistance and a-c plate resistance.* Of these two classifications, the latter is by far the most important.

D-C Plate Resistance of the Diode

As the name indicates, the d-c plate resistance of the diode is that opposition to the flow of current which is offered by the tube when a d-c voltage is applied to the plate. It is that quantity which can be determined by the application of Ohm's law for resistance, employing the applied d-c plate voltage and the measured value of d-c plate current as the known quantities in the equation.

For example, Fig. 6-11 illustrates a typical plate voltage—plate current characteristic for a typical 6H6 duo-diode tube, using just one pair of elements. By one pair of elements is meant one cathode and its associated plate. The plate voltage applied to the tube is shown upon the horizontal axis of the graph and the resultant plate current is shown upon the vertical axis. While this is the same as is found in the plate voltage—plate current characteristic curve illustrated in Fig. 6-10, the general shape of the two characteristic curves is quite different. This comes about as the result of the special conditions mentioned in connection with Fig. 6-10. The curve shown in Fig. 6-11 is a closer approach to the actual curve with which you will work.

You will remember that we qualified the conditions indicated in the curve of Fig. 6-10 to the extent that the plate-voltage saturation points were not to be expected when using oxide-coated filament or cathode type tubes. The 6H6 is an oxide-coated tube and it is evident in Fig. 6-11 that plate-voltage saturation is a long way off. In fact, judging by the values of plate current which prevail for the comparatively low values of plate voltage, it is doubtful if the plate-voltage saturation point could ever be reached. More than likely the tube would be damaged long before that value could be reached by the application of sufficient plate voltage.

With a comparatively low value of plate voltage, say 28 volts, applied to the plate, the formidable value of about 66.4 milliamperes of current already flows in the tube. And judging by the slope of the plate-current curve, the steep portion is yet to come, that is, if we increased the plate voltage above 32 volts. There is little doubt that were this plate voltage increased to say 50 or 60 volts, the plate current would rise to such a value as to destroy the tube. This does not mean that diodes are not used at plate-voltage values greater than 32 volts. Much higher values of plate voltage are employed, but when

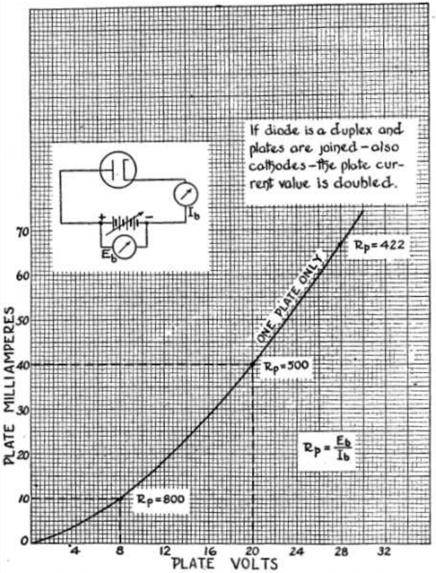


FIG. 6-11. Plate voltage—plate current characteristic for a typical 6H6 diode tube.

A vacuum tube carrying a current I with a plate voltage V dissipates power VI, just as if it were a resistor. However, the process is different. In a resistor, an electron gives up small amounts of energy to the lattice as it is accelerated and then is scattered. In a vacuum tube, the electron acquires a kinetic energy as it is accelerated, which it gives up all at once when it collides with the plate. It is not really correct to ascribe this to the "plate resistance," as some texts do, which is an incremental ratio. Since the plate is in a vacuum, the resulting heat can only be radiated or conducted down the supports. Much of the radiated heat is infrared, which is absorbed by the glass tube envelope. Note how plates are blackened to raise their emissivity and often provided with fins. Really large tubes had plates externally exposed capable of air or water cooling with elaborate seals to the glass parts. *Plate dissipation* is always a limiting factor in power applications.

The line marked *load line* shows the difference between the supply voltage V_{bb} and the voltage drop in a resistance R_L in series with the tube at any plate current, giving the plate voltage directly. The series resistance is mainly a plate resistor, but if there is a cathode resistor (for purposes of biasing) it should be included. There are generally different load lines for static (DC) and dynamic (AC) operation. As the grid voltage is varied, the plate current and voltage vary along the load line. The quiescent or operating point can be selected at some point along the DC load line, and so the DC grid bias can be found. This grid bias can be obtained from a C battery or equivalent, or from a cathode resistor, just as an emitter resistor is used with a transistor.

A cathode bias resistor is often bypassed by a capacitor if its negative feedback effect is not desired in dynamic operation. The reactance of the capacitor at the lower corner frequency should be equal to the resistance looking into the cathode (normally $1/g_m$ in parallel with the cathode resistor). The size of the cathode resistor has only a small effect on the size of the bypass capacitor. The capacitor never has a large voltage across it, and can be a low-types can have quite different (though similar) characteristics, so characteristic curves are much more important.

Let's begin with idealized plate characteristics for a triode, shown at the right. These are curved lines, but we represent them by straight lines for ease of understanding the various slopes and distances involved, which will be constant. Actual characteristics are not really far from straight lines, anyway. There is one curve for each grid voltage represented, which differ by a constant amount, here 2V. The horizontal distance between them, represented by the line labelled μ, is the amount the plate voltage must increase to hold the plate current constant; it represents the relative influence of plate and grid on plate current, and is the *amplification factor*. The vertical distance between them shows how much the plate current changes for a change in grid voltage. The ratio is a conductance, called the *transconductance*, denoted by g_m, measured in siemens (mho). The slope of the curves is the ratio g_m/μ, called the *plate conductance* g_p. With vacuum tubes, the reciprocal r_p was always used, called the *plate resistance*. Since actual characteristics are curved, these quantities vary for different currents and voltages.

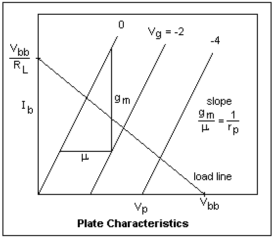

Plate Characteristics

What we desire to represent is a function of two independent variables $I_p(V_p,V_g)$, which can be represented as a surface in three dimensions. Our various characteristic curves are orthogonal views along one or another of the axes. There are three such views possible, each directly related to one of the three parameters, of which we generally use only two, the ones mentioned here.

that is done other elements which tend to keep the plate current to a safe value are also used in the circuit. Such additions will be discussed later.

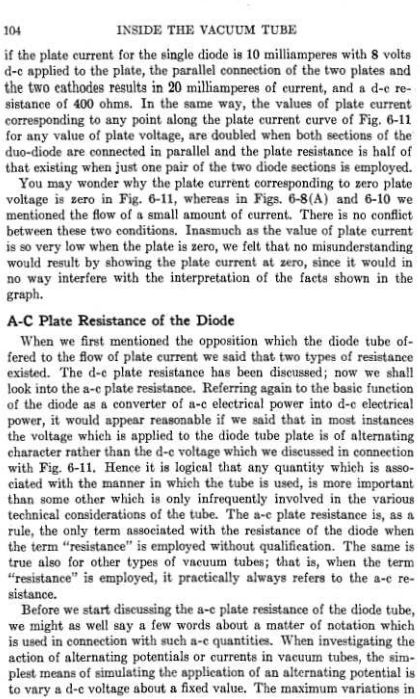
As we discussed earlier in this text, the plate-current curve of a diode, like that of other vacuum tubes, is of great importance. In this particular instance it serves to furnish information relative to the opposition offered by the tube to the flow of plate current; in other words, it furnishes information about the d-c resistance of the tube. For example, with **8** volts d-c E_b applied to the plate, the plate current I_b, as shown upon the vertical axis, is **10** milliamperes or **0.01** ampere. According to the Ohm's law, these values of plate voltage and plate current represent a d-c plate resistance of

$$R_p = \frac{E_b}{I_b} = \frac{8}{.01} = 800 \text{ ohms}$$

With **20** volts d-c applied to the plate of the tube, we note from the curve that the plate current is **40** milliamperes or **0.04** ampere. This corresponds to a d-c resistance equal to **20/.04 = 500** ohms. With **28** volts d-c applied to the plate, the plate current according to the curve is **66.4** milliamperes or **0.064** ampere and the equivalent d-c resistance is **28/.0664 = 422** ohms.

Examining these three values of d-c plate resistance for three values of applied d-c plate voltage, we note a peculiar condition. The opposition which *the diode offers to the flow of the plate current is not constant*, as we are ordinarily accustomed to experiencing in conventional d-c systems. Said differently, *the resistance offered by the diode to the flow of the plate current is not linear*. Judging by the relationship between the plate voltage, plate current, and the equivalent d-c resistance, it appears that the resistance of the diode *decreases* as the plate voltage is increased, and *increases* as the plate voltage is decreased. Were the resistance of the diode linear over the entire range of plate voltage, the plate-current curve would be a straight line instead of the curved line appearing in Fig. 6-11. Such a straight line would indicate that the d-c plate resistance remained constant over whatever range of plate voltage and plate current is embraced by the upper and lower limits of the straight line.

Of further interest in connection with the plate voltage—plate current characteristic given in Fig. 6-11, is the condition created when the two plates of this duo-diode tube are joined in parallel and the two cathodes are connected in parallel. The plate current for such parallel connection is equal to twice the amount that would occur if the same value of plate voltage were applied to a single pair of elements. Thus,



if the plate current for the single diode is 10 milliamperes with 8 volts d-c applied to the plate, the parallel connection of the two plates and the two cathodes results in 20 milliamperes of current, and a d-c resistance of 400 ohms. In the same way, the values of plate current corresponding to any point along the plate current curve of Fig. 6-11 for any value of plate voltage, are doubled when both sections of the duo-diode are connected in parallel and the plate resistance is half of that existing when just one pair of the two diode sections is employed.

You may wonder why the plate current corresponding to zero plate voltage is zero in Fig. 6-11, whereas in Figs. 6-8(A) and 6-10 we mentioned the flow of a small amount of current. There is no conflict between these two conditions. Inasmuch as the value of plate current is so very low when the plate is zero, we felt that no misunderstanding would result by showing the plate current at zero, since it would in no way interfere with the interpretation of the facts shown in the graph.

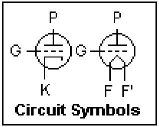
A-C Plate Resistance of the Diode

When we first mentioned the opposition which the diode tube offered to the flow of plate current we said that two types of resistance existed. The d-c plate resistance has been discussed; now we shall look into the a-c plate resistance. Referring again to the basic function of the diode as a converter of a-c electrical power into d-c electrical power, it would appear reasonable if we said that in most instances the voltage which is applied to the diode tube plate is of alternating character rather than the d-c voltage which we discussed in connection with Fig. 6-11. Hence it is logical that any quantity which is associated with the manner in which the tube is used, is more important than some other which is only infrequently involved in the various technical considerations of the tube. The a-c plate resistance is, as a rule, the only term associated with the resistance of the diode when the term "resistance" is employed without qualification. The same is true also for other types of vacuum tubes; that is, when the term "resistance" is employed, it practically always refers to the a-c resistance.

Before we start discussing the a-c plate resistance of the diode tube, we might as well say a few words about a matter of notation which is used in connection with such a-c quantities. When investigating the action of alternating potentials or currents in vacuum tubes, the simplest means of simulating the application of an alternating potential is to vary a d-c voltage about a fixed value. The maximum variations in

was arbitrary. Filaments were customarily used, especially in power and rectifier tubes, because they gave more current per watt of heating power. The indirectly heated, equipotential cathode that could be supplied by AC rather than by battery power was widely used after 1930.

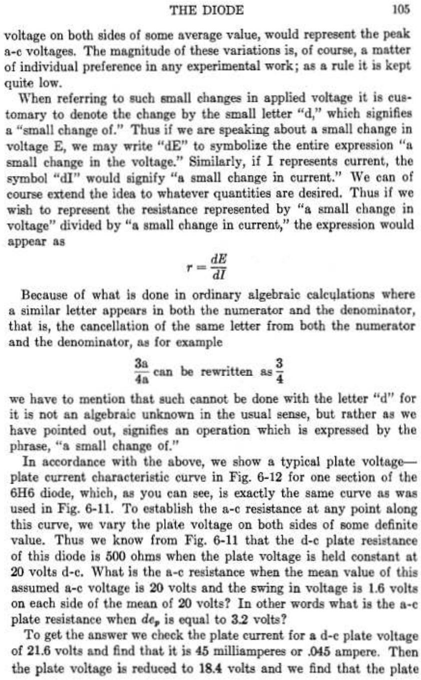
A tube with just cathode and anode is called a *diode*, a term that has survived into the semiconductor age. Diodes were used for power or signal rectification, just like their semiconductor relatives. A "full-wave" diode has two anodes. When a control grid is provided, the tube is called a *triode*, and is used for amplification. Let's first study the peculiar circuit behavior of triodes, which will lead us to the reason for the addition of more grids, and the creation of the *pentode*, which turns out to act very much like a transistor.



Circuit symbols for a triode are shown at the right, and other tube symbols are derived from it. The connections are plate P, grid G, and cathode K or filament F, F'. These are analogous to the collector, base and emitter of a transistor, with the same polarities and direction of current flow as an NPN transistor. The circle is a part of the symbol. Grid connections can be to the right or left of the symbol, as convenient. A gas tube is indicated by a dot in the lower right-hand part of the circle. The heater of an indirectly heated cathode is usually not shown. A cold cathode (operating by positive-ion bombardment) is shown as a small circle. There are examples of these symbols below.

The important variables are the independent variables V_p and V_g, the plate and grid voltages (with respect to the cathode), and the dependent variable I_p, the plate current. A plot of I_p against V_p for a fixed value of V_g is called a *plate characteristic*, and a plot of I_b against V_g for a fixed value of V_p is called a *transfer characteristic*. From a family of either characteristics, the complete circuit behavior of the tube can be predicted. Unlike transistors, tubes of different usually). Inside is a tungsten heater wire insulated from the cathode with BeO or alundum (aluminum oxide) ceramic insulation. These cathodes must be heated only to about 850K (a dull red) to emit electrons in the amount necessary. Most receiving tubes require 6.3V or 12.6V for their heaters, at about 0.30A or 0.15A, respectively. Every tube type is identified by a type number, such as 6J5, where the first number indicates the heater voltage. 6 means 6.3V, 12 means 12.6V. Heaters are very forgiving of variations in voltage, but it is best to try to use the recommended voltages. AC is generally used, supplied from a small transformer. It is necessary to make sure that the difference in voltage between heater and cathode does not exceed 90V, so the heater AC supply should be grounded. It is usual to ground the center tap on the transformer for this purpose. Tubes for battery radios have plain filaments that are both heater and emitter, and must be supplied with DC. Their type numbers begin with "1" and are intended to be used with a standard dry cell of 1.5V. Larger tubes for high voltages have to use thoriated-tungsten filaments at 2000K,a bright yellow, to avoid damage from positive-ion bombardment, small as it may be. Heaters are sometimes called filaments, and the heater supply the filament supply, out of linguistic inertia.

Before the 1930's, each manufacturer used arbitrary designations for his tubes, and there was no uniformity or system. Tubes were first systematically identified in the U.S. by three-digit numbers, where the first digit denoted the manufacturer. For example, a type x10 was a power triode, a type x36 a screen-grid tetrode, where x was the manufacturer's number (usually omitted). Later, a new system was introduced where the first digit gave the filament or heater voltage, and the last digit gave the number of functional electrodes. This scheme was introduced by the RMA (Radio Manufacturer's Association) in 1934. A letter between these digits was assigned in order of introduction. For example, a 2A3 was a power triode with a 2.5 V filament (this popular tube is, remarkably, still in use for hi-fi amplifiers because of its low distortion!). This system was not comprehensive enough, and in the final system, the first number designated the heater voltage, but the remainder of the designation



voltage on both sides of some average value, would represent the peak a-c voltages. The magnitude of these variations is, of course, a matter of individual preference in any experimental work; as a rule it is kept quite low.

When referring to such small changes in applied voltage it is customary to denote the change by the small letter "d," which signifies a "small change of." Thus if we are speaking about a small change in voltage E, we may write "dE" to symbolize the entire expression "a small change in the voltage." Similarly, if I represents current, the symbol "dI" would signify "a small change in current." We can of course extend the idea to whatever quantities are desired. Thus if we wish to represent the resistance represented by "a small change in voltage" divided by "a small change in current," the expression would appear as

$$r = \frac{dE}{dI}$$

Because of what is done in ordinary algebraic calculations where a similar letter appears in both the numerator and the denominator, that is, the cancellation of the same letter from both the numerator and the denominator, as for example

$$\frac{3a}{4a} \text{ can be rewritten as } \frac{3}{4}$$

we have to mention that such cannot be done with the letter "d" for it is not an algebraic unknown in the usual sense, but rather as we have pointed out, signifies an operation which is expressed by the phrase, "a small change of."

In accordance with the above, we show a typical plate voltage—plate current characteristic curve in Fig. 6-12 for one section of the 6H6 diode, which, as you can see, is exactly the same curve as was used in Fig. 6-11. To establish the a-c resistance at any point along this curve, we vary the plate voltage on both sides of some definite value. Thus we know from Fig. 6-11 that the d-c plate resistance of this diode is 500 ohms when the plate voltage is held constant at 20 volts d-c. What is the a-c resistance when the mean value of this assumed a-c voltage is 20 volts and the swing in voltage is 1.6 volts on each side of the mean of 20 volts? In other words what is the a-c plate resistance when de_p is equal to 3.2 volts?

To get the answer we check the plate current for a d-c plate voltage of 21.6 volts and find that it is 45 milliamperes or .045 ampere. Then the plate voltage is reduced to 18.4 volts and we find that the plate

Symbolic expression for a-c plate resistance

FIG. 6-12. The a-c plate resistance of a diode can be determined from the plate voltage—plate current characteristic as explained in the accompanying text.

current is 35 milliamperes or .035 ampere. We now have the two limits of voltage and the two limits of current. Then the symbol "de_p" represents the *change in plate voltage* or the difference between 21.6 and 18.4 or 3.2 volts. And the symbol "di_p" represents the corresponding *change in plate current* or the difference between .045 and .035 or .010 ampere. The a-c plate resistance r_p then can be expressed as

$$r_p = \frac{de_p}{di_p} = \frac{21.6 - 18.4}{0.045 - 0.035} = \frac{3.2}{0.010} = 320 \text{ ohms}$$

This value of 320 ohms is the a-c plate resistance for a value of plate voltage which fluctuates between 18.4 and 21.6 volts, whereas

can take over a large part of the electron emission at the cathode. Such tubes make efficient rectifiers, and the gas pressure can be quite low, as in some rectifiers, or rather high, as in a mercury-arc rectifier. In receiving tubes, positive ion collisions can destroy the delicate, high-efficiency cathode surface. Positive ions also cause small currents to negative electrodes that otherwise might be expected to carry no current at all. For all these reasons, receiving tubes have a high vacuum.

The electric field at the space charge that controls the current does not have to be created by the anode alone. A third electrode, the *grid*, is placed between the cathode and the anode, closer to the cathode. It is made of a spiral of fine wire, so electrons can pass through without hindrance. When it is made negative, it opposes the effect of the anode in creating an electric field, but does not attract any electrons, and so draws no current (except for the positive-ion current mentioned above). If it is made sufficiently negative, it can *cut off* the plate current entirely. If it is made positive, it can enhance the plate current, but then draws some *grid current* itself. The grid provides a sensitive control, using negligible power, of the large plate current, so the vacuum tube is a powerful amplifying device.

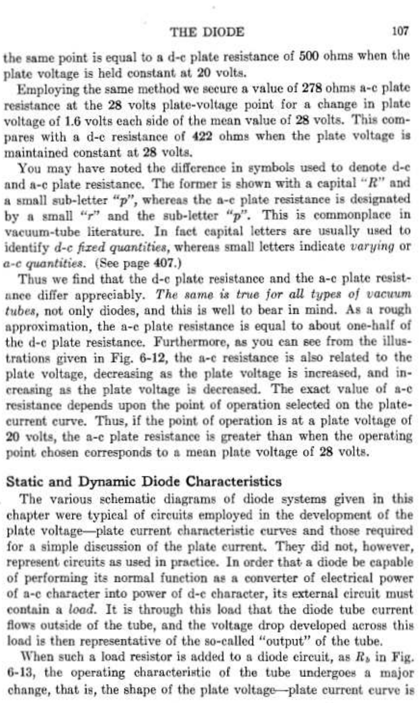
Early radio sets were battery-powered (domestic electrification was in its infancy, and absent in rural areas, when radio began), and a convention was established for identifying the batteries required. The filaments required low voltages at high currents (2W or more each), and their supply was called the A battery. The plates required high voltages at small currents, perhaps 90V at a few mA, and their supply was called the B battery. Grid bias was required, to hold the grids negative, demanding low voltages at small currents, and the corresponding battery was the C battery. The notations A and C were later little-used (except for actual battery radios), but the plate supppy came to be generally known as B+, and the letter B appears in subscripts of quantities referring to the plate circuit.

The cathodes of receiving tubes consist of a sleeve of nickel alloy coated with a compound of alkaline-earth oxides (Ba and Sr, did these cathodes have a long life, but were also *equipotential*, making circuit design simpler. Thoriated tungsten remained for transmitting tubes, where a rugged emitter was necessary because of the higher plate voltages, but even here tungsten was the only suitable choice for really high voltages, to avoid damage from positive-ion bombardment.

The rate of emission of electrons from a heated metal is given by the Richardson-Dushman equation, $i = AT^2e^{-b/T}$ A/cm^2, where T is the absolute temperature in K, and A and b are constants typical of the emitter. For tungsten, A = 60 and b = 52,400K, while average values for an oxide cathode are A=0.01, b = 11,600. The exponential factor has by far the largest influence, so emission increases rapidly with temperature. This makes thermionic cathodes very suitable even for heavy currents. In all tubes, electrons are emitted in far greater numbers than required; most simply return to the cathode.

The electrons emitted by the thermionic cathode form a negative *space charge* cloud around the cathode, dense enough that if no electrons are removed by attraction to the anode, the rate of emission is equal to the rate of return. When the anode is made positive, some of the electrons are attracted to it out of the space-charge cloud, and a *thermionic current* results. The amount of this current is given by $I = A\ V^{3/2}$, where V is the voltage from anode to cathode. This is called the Langmuir-Child law, and shows that electric field at the space charge produced by the anode controls the electron current. The cathode emits electrons copiously, so much that there are always enough electrons available to satisfy Langmuir-Child. Of course, at a sufficiently high anode voltage, the current may *saturate*, when all the emitted electrons are attracted to the anode, but this never occurs in normal operation, so small variations in cathode temperature have no effect. The current in a vacuum tube is said to be *space-charge controlled*.

If enough gas is present in the tube, the positive ions can counterbalance the negative electron space charge, robbing the anode of control and greatly increasing the current. Also, the positive ions



the same point is equal to a d-c plate resistance of 500 ohms when the plate voltage is held constant at 20 volts.

Employing the same method we secure a value of 278 ohms a-c plate resistance at the 28 volts plate-voltage point for a change in plate voltage of 1.6 volts each side of the mean value of 28 volts. This compares with a d-c resistance of 422 ohms when the plate voltage is maintained constant at 28 volts.

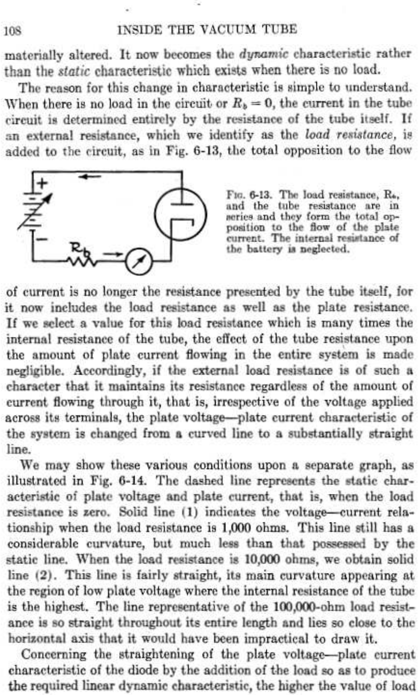
You may have noted the difference in symbols used to denote d-c and a-c plate resistance. The former is shown with a capital "*R*" and a small sub-letter "*p*", whereas the a-c plate resistance is designated by a small "*r*" and the sub-letter "*p*". This is commonplace in vacuum-tube literature. In fact capital letters are usually used to identify *d-c fixed quantities*, whereas small letters indicate *varying* or *a-c quantities*. (See page 407.)

Thus we find that the d-c plate resistance and the a-c plate resistance differ appreciably. *The same is true for all types of vacuum tubes*, not only diodes, and this is well to bear in mind. As a rough approximation, the a-c plate resistance is equal to about one-half of the d-c plate resistance. Furthermore, as you can see from the illustrations given in Fig. 6-12, the a-c resistance is also related to the plate voltage, decreasing as the plate voltage is increased, and increasing as the plate voltage is decreased. The exact value of a-c resistance depends upon the point of operation selected on the plate-current curve. Thus, if the point of operation is at a plate voltage of 20 volts, the a-c plate resistance is greater than when the operating point chosen corresponds to a mean plate voltage of 28 volts.

Static and Dynamic Diode Characteristics

The various schematic diagrams of diode systems given in this chapter were typical of circuits employed in the development of the plate voltage—plate current characteristic curves and those required for a simple discussion of the plate current. They did not, however, represent circuits as used in practice. In order that a diode be capable of performing its normal function as a converter of electrical power of a-c character into power of d-c character, its external circuit must contain a *load*. It is through this load that the diode tube current flows outside of the tube, and the voltage drop developed across this load is then representative of the so-called "output" of the tube.

When such a load resistor is added to a diode circuit, as R_b in Fig. 6-13, the operating characteristic of the tube undergoes a major change, that is, the shape of the plate voltage—plate current curve is



materially altered. It now becomes the *dynamic* characteristic rather than the *static* characteristic which exists when there is no load.

The reason for this change in characteristic is simple to understand. When there is no load in the circuit or $R_b = 0$, the current in the tube circuit is determined entirely by the resistance of the tube itself. If an external resistance, which we identify as the *load resistance*, is added to the circuit, as in Fig. 6-13, the total opposition to the flow of current is no longer the resistance presented by the tube itself, for it now includes the load resistance as well as the plate resistance. If we select a value for this load resistance which is many times the internal resistance of the tube, the effect of the tube resistance upon the amount of plate current flowing in the entire system is made negligible. Accordingly, if the external load resistance is of such a character that it maintains its resistance regardless of the amount of current flowing through it, that is, irrespective of the voltage applied across its terminals, the plate voltage—plate current characteristic of the system is changed from a curved line to a substantially straight line.

FIG. 6-13. The load resistance, R_b, and the tube resistance are in series and they form the total opposition to the flow of the plate current. The internal resistance of the battery is neglected.

We may show these various conditions upon a separate graph, as illustrated in Fig. 6-14. The dashed line represents the static characteristic of plate voltage and plate current, that is, when the load resistance is zero. Solid line (1) indicates the voltage—current relationship when the load resistance is 1,000 ohms. This line still has a considerable curvature, but much less than that possessed by the static line. When the load resistance is 10,000 ohms, we obtain solid line (2). This line is fairly straight, its main curvature appearing at the region of low plate voltage where the internal resistance of the tube is the highest. The line representative of the 100,000-ohm load resistance is so straight throughout its entire length and lies so close to the horizontal axis that it would have been impractical to draw it.

Concerning the straightening of the plate voltage—plate current characteristic of the diode by the addition of the load so as to produce the required linear dynamic characteristic, the higher the value of load

positive ions, which can cause emission of electrons or even heat the cathode the required amount for thermionic emission. All receiving tubes employ thermionic emission, though we will note certain examples of *cold cathodes* in special cases. These were not usually really cold, but heated by ion bombardment rather than by a current supplied externally. The space in which the electrons move is not completely devoid of gas, so some gas molecules may be *ionized* by collision with speedy electrons, when an electron is knocked off, leaving a *positive ion*. The positive ions move in the opposite direction to the electrons (but their current is in the same direction, since they are of opposite charge). The effect of positive ions in a receiving tube is very small, because of the very high vacuum that is used.

Self-heated electron emitters are called *filaments*. The carbon filaments of the Edison Effect were soon replaced by metallic emitters, usually tantalum or tungsten, which were used by Fleming and de Forest. In Germany, Arthur Wehnelt discovered in 1903 that barium or calcium oxides baked on a platinum base emitted copiously, and used these *oxide-coated* emitters on vacuum rectifiers evolved from discharge tubes, which he patented in 1904. However, the use of *soft* tubes, which contained residual gas, demanded the use of rugged tungsten filaments, which dominated in 1910-20. These filaments used low voltages and high currents, and had a short life because of the high temperatures required for adequate emission. Most radio sets had a rheostat to adjust the filament current properly. Wehnelt emitters would have been quickly destroyed by positive-ion bombardment in these tubes. Apparently by accident, thoriated tungsten wire was used in a trial at the GE factory in Harrison, NJ in 1920 on a UV201 tube. Thoriated tungsten gave 75 mA/W of filament power, while tungsten gave only 1.75. Thoriated-tungsten filaments became popular for receiving tubes, such as the UV201A, which was an improved UV201, around 1924. Its filament required 0.25 A at 5 V, while the UV201's had required 1.0 A. Since tubes were now all *hard*, or high-vacuum tubes, indirectly heated oxide-coated cathodes, which gave copious emission at low temperatures, were used almost exclusively in receiving tubes after 1930. Not only "triode" was not used until much later, after it threated to become a trade name), in which a third electrode, the grid, was introduced to control the electron stream. This made a more sensitive detector, but the amplifying property was not used at first, and de Forest, who did not understand well what was going on, defended gassy tubes with their gas amplification. The introduction of high vacuum, as well as improved materials and processes, especially metal-to-glass seals, created a very useful amplifying device that allowed great developments in radio, telephony and sound reproduction. Schottky suggested a screen grid between the plate and control grid to make the electron tube useful at higher frequencies in 1919 (and actually made tubes with a second grid, but this was for space-charge control), but this was only realized by Hull and Williams in 1928 in radio receivers. The metal tube was introduced in 1935, but glass envelopes never disappeared and were constantly improved. The final pattern of electron tube was the "miniature" or all-glass type, which became the predominant receiving-type tube after about 1945. Transistors were invented in 1948, and in the next decade were improved to the point where they could take over most of the amplifying applications of electron tubes at much lower cost, and with greater reliability. Electron tubes remain in use as cathode-ray tubes, magnetrons, X-ray tubes, and for handling large powers. They were remarkable devices, using many sophisticated materials and processes, yet were widely available at low cost. We shall look here mainly at examples of *receiving tubes*, the smaller amplifying devices that have been completely replaced by semiconductors in current practice, but nevertheless will deepen our knowledge of electronics, while being fascinating to study. The name "receiving" comes from their use in radio receivers, their principal commercial application, but refers to all small vacuum tubes for general electronic purposes. For the cathode-ray tube and making your own oscilloscope, see The Cathode-Ray Tube.

The electrons move from the cathode (K), the negative electrode, to the anode or *plate* (P), the positive electrode. Conventional current is in the opposite direction. The electrons are liberated at the cathode by heat--thermionic emission--or as a result of bombardment by

resistance, the straighter is this dynamic curve. At the same time, however, the lower is the amount of plate current which flows in the circuit. This is not harmful, provided that the value of the load resistance is kept within reasonable limits.

Having read all of this information about the difference between the static and the dynamic plate voltage—plate current characteristics, and the effort to make this curve straight, you may wonder why this is done. The primary reason is that when the diode characteristic is straight, its action in certain portions of radio communication systems is substantially free from the production of distortion and this is greatly to be desired. There are, however, various applications of the diode, in which the exact nature of this characteristic is not of particular significance, although it should be understood that some straightening action takes place concurrently with the use of a load, and some sort of a load is required in order to make the diode of practical value.

It is also of importance to realize that the higher the load resistance used in a diode circuit, the greater is the permissible voltage which may be applied to the plate without fear of causing the flow of such high values of current that will damage the tube. You can see from the plate current values shown in Figs. 6-11 and 6-12 that the application of several hundred volts to the plate will cause the flow of such very high values of plate current as to damage the tube, unless high values of load resistance are used, which reduce the plate current to permissible values.

A-C Applied to the Diode Plate

It is necessary to speak briefly about the application of an alternating voltage to the plate of the diode. The reason is that everything we have said so far has shown d-c voltage applied to the plate, although we mentioned that the basic function of the diode was as a converter of a-c power into d-c power. The characteristics we have mentioned and developed by means of d-c voltages upon the plate are those which exist when a-c voltages are applied to the plate, for, in

Plate current flows during positive alternation and plate is positive with respect to cathode. Plate current does not flow when plate is negative with respect to the cathode. Thus output current and voltage is unidirectional although input is alternating.

Theory of Vacuum Tubes

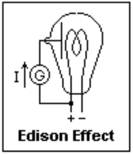
http://mysite.du.edu/~etuttle/electron/elect27.htm#Diodes

Miniature vacuum tubes with cathodes of high-field-emitting carbon nanotubes are currently under study at Agere Systems in Murray Hill, NJ. A triode with amplification factor of 4 has been constructed, with an anode-cathode spacing of 220 μm, and a pentode is planned. Vacuum tubes may return to electronic technology! See *Physics Today*, July 2002, pp. 16-18.



Devices in which a stream of electrons is controlled by electric and magnetic fields have many applications in electronics. Because a vacuum must be provided in the form of an evacuated enclosure in which the electrons can move without collisions with gas molecules, these devices were called *vacuum tubes* or *electron tubes* in the US, and *thermionic valves* in Britain. In 1883, Thomas Edison observed that a current flowed between the filament of an incandescent lamp and a plate in the vacuum near it (see figure at the right), when the plate was connected to the positive end of the filament, but not when the plate was connected to the negative side (the plate was actually between the two legs of the filament). No important application was made of this unexplained *Edison Effect* at the time. In 1899, J. J. Thomson showed that the current was due to a stream of negatively-charged particles, electrons, that could be guided by electric and magnetic fields. Fleming patented the *diode* in 1904 (B.P. 24850), where a filament and plate were arranged in the same envelope in a rather low vacuum, which could be used as a rectifier, or as a rather insensitive radio detector. In 1907, Lee de Forest patented the *triode* (which he called the Audion; the term *d*. A linear dynamic characteristic is desired for the diode, principally because it assures proportionality between applied plate voltage and output current. This affords freedom from distortion in many circuits that use the diode, although, in other applications, distortion is of secondary importance. The most important consideration is the use of a load; a *load* is necessary if a diode is to be of practical use.

27. Uses

a. Since current flow in the diode is unidirectional, one of its most prominent uses is as a rectifier or converter of alternating current into direct current. In figure 36, an alternating voltage is used as the plate voltage. During the positive alternations of the input voltage, the plate is positive relative to the cathode, and plate current i_p flows through the tube and load resistance R_L. The current develops a voltage drop across the load. At every instant the output voltage (in volts) is:

$$e \text{ output} = (i_p \times R_L) - (i_p \times r_p)$$

where R_L is the load resistance in ohms
- r_p is the a-c resistance of the diode in ohms
- i_p is the instantaneous current in amperes.

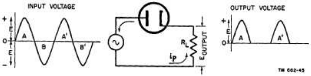


Figure 36. Diagram illustrating unidirectional current flow in diode.

b. If load resistance R_L is very much greater than r_p, the internal tube resistance, the effect of the latter is negligible and i_p times r_p of the preceding formula can be neglected.

c. Concerning the action in figure 36, it can be seen that the changes in current amplitude follow the instantaneous changes in applied plate voltage. This becomes evident when the input plate-voltage alternations, A and A', are compared with the output voltage pulsations, A and A'. These pulsations have the same shape as the two positive alternations of the applied voltage. The absence of conduction in the tube during the two negative alternations, B and B', of the input voltage is caused by the diode plate being negative with relation to the cathode during these periods. If the input voltage has a frequency of 60 cps (cycles per second), the output current pulses will occur 60 times per second, each lasting for a period equal to one-half of each input cycle.

d. Both single- and dual-section diodes have many other uses, developed later in this manual. All of these depend on the principle of unilateral conduction through the tube.

28. Types

High-vacuum diode tubes are available in various types (fig. 37), differing principally in physical dimensions and shape. They differ internally as well but not in the fundamental arrangement of the electrodes. The physical dimensions are related to the magnitudes of voltages applied to the plate and the currents flowing through the tube during operation. Tubes used in circuits which handle signal voltages of relatively low values are known as signal diodes. Another general category is that of power diodes or vacuum-tube rectifiers which handle high values of voltage and current. Each of these types is intended for special application and they are not interchangeable. Signal diodes are restricted to signal circuits. Power diodes generally are used in power circuits, except where certain signal systems entail relatively high voltages, and circuit operation demands an action similar to rectification.

29. Electron Transit Time

a. The time required for an electron to traverse the distance from the cathode to the plate of a diode, or other kinds of electron tubes, is

the final analysis, the tube operates only on one half of the a-c voltage wave, that is, during that time when the plate is positive with respect to the cathode. Therefore, the conditions which exist in the tube during that positive half cycle can be simulated by the application of d-c voltages.

b. With no load in the circuit, or when R_L equals 0, the resistance in the circuit is the resistance of the tube; also, the small resistances of the battery and meter are present, but these can be neglected. But when an external resistance, the *load resistance,* is added (fig. 34), the total opposition to plate-current flow includes that of the tube itself and also that of the load. When the load resistance is many times the value of the internal resistance of the tube, the tube resistance offers only a negligible percentage of the opposition to plate-current flow. Consequently, if the external load resistance maintains its value regardless of the amount of current flowing through it, the plate-current plate-voltage characteristic of the system is changed from a curved line into a substantially straight line.

c. These various conditions can be noted on a separate graph (fig. 35). The dashed line represents the static characteristic—that is, when there is no load resistance. Solid line 1 illustrates the voltage-current relationship when the load resistance is 1,000 ohms. This line possesses some curvature, but it is considerably less than that of the static line. Solid line 2 is obtained with a load resistance of 10,000 ohms. This line is almost straight; some curvature appears in the region of low plate voltage where the internal resistance of the tube is highest. A line representing a value of 100,000 ohms is so straight throughout its length that it lies too close to the horizontal axis, and it cannot be drawn clearly on the graph. Therefore, the higher the load resistor value, the straighter is the dynamic curve, and the lower is the amount of plate current flowing in the circuit. This is not a disadvantage, provided the load resistance is maintained within reasonable limits.

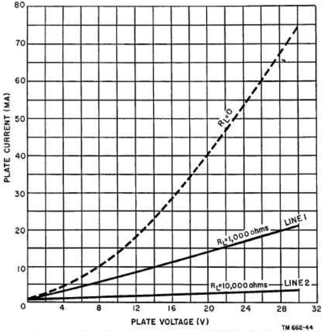

Figure 35. Plate-current plate-voltage characteristic curves of diode having different load values.

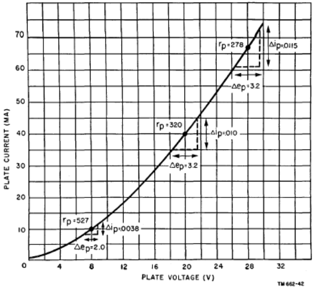

Figure 33. Plate-current plate-voltage characteristic which can be used to determine the a-c plate resistance of a diode.

lected on the characteristic curve. Consequently, if the point of operation is at a plate voltage of 20 volts, the a-c plate resistance is greater than when the operating point chosen corresponds to a mean plate voltage of 28 volts.

26. Static and Dynamic Diode Characteristics

a. The discussion of diodes thus far has been for static conditions and not for actual operating conditions. For a diode, or any tube, to be able to perform its normal function, its external circuit must contain a *load*. It is through this load that the diode current flows outside the tube, and the *voltage drop developed across this load then represents the output of the tube.* With such a load, represented by a resistance R_L (fig. 34), the operating characteristic of the tube is changed materially. The plate-current plate-voltage curve is altered noticeably, and it represents the *dynamic* characteristic rather than the *static* characteristic which applies when there is no load.

CHAPTER 2

THERMIONIC EMISSION; THE HIGH-VACUUM THERMIONIC DIODE

The operation of the majority of electron tubes is dependent upon thermionic emission. The theory of thermionic emission is therefore of great importance in the study of electron tubes. It is the purpose of this chapter to discuss the basic principles of thermionic emission, the construction of practical emitters, and the flow of electron space current in high-vacuum tubes containing two electrodes.

2-1. Theory of Thermionic Emission.—Richardson's theory of the emission of electrons from hot bodies is in many respects analogous to the kinetic theory of vaporization.[1] Heat possessed by a metal is believed to be stored not only in the kinetic energy of random motion of atoms and molecules, but also in the kinetic energy of free electrons. As a result of collisions between electrons or between electrons and atoms or molecules, the speed and direction of motion of a given electron are constantly changing. At any instant there will be, close to the surface of the metal, some electrons that have a component of velocity toward the surface of such magnitude that the corresponding kinetic energy is equal to or exceeds the electron affinity. If these electrons reach the surface without colliding with atoms, they will pass through the surface. At room temperatures the number of electrons meeting this requirement is extremely small, and hence no thermionic emission is detectable. As the temperature of the emitter is increased, however, the average velocity of the free electrons increases. The number having velocity components toward the surface sufficient to allow them to escape, therefore, increases with temperature. Reduction of electron affinity reduces the velocity toward the surface necessary to allow an electron to escape, and so increases the number

---

when one pair of the two diode portions is used. This will be found to be true in all multiple-section diodes.

h. The absence of plate-current saturation points similar to those appearing in figures 29 and 30 is due to the use of oxide-coated emitters in this tube. An application as low as 32 volts to the plate results in a fairly high value of plate current, almost 70 ma. Judging by the shape of the characteristic, the saturation point is a long way off. The tube probably would be damaged long before the plate-current curve would flatten because of the application of sufficient plate voltage to attract all the emitted electrons. This does not mean that diodes are not used at plate voltages exceeding 32 volts; they are used with very high voltages, many tens of thousands of volts, but when so used, diodes are specially designed.

25. A-c Plate Resistance of Diode

a. The a-c plate resistance of the diode is defined as the resistance of the path between cathode and plate to the flow of *an alternating current* inside the tube. Such is the definition meant when the term *resistance* is used without qualification for the diode and all other electron tubes. As will be seen later, it is an important term and is closely related to operating conditions.

b. The a-c plate resistance is the ratio of a small change in plate voltage by the corresponding change in plate current. Expressed in an equation

$$r_p = \frac{\triangle e_p}{\triangle i_p}$$

in which r_p is the a-c plate resistance in ohms, $\triangle e_p$ represents a small change in plate voltage, and $\triangle i_p$ represents a corresponding small change in plate current caused by the plate voltage change. The Greek letter $\triangle$ signifies a *small change of*.

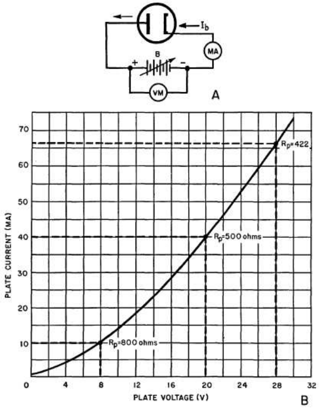
c. Figure 33 shows a plate-current plate-voltage characteristic curve identical to the one in B of figure 32 and obtained from the circuit in A of figure 32, where one section of a 6H6 diode is used. To establish the *a-c resistance* at any point along the curve, the plate voltage is varied on both sides of it at some definite value. B of figure 32 shows that the d-c plate resistance, R_p for this diode is 500 ohms when the plate voltage is held constant at 20 volts dc. Suppose it is desired to find the a-c resistance when the mean value of this assumed a-c voltage is 20 volts, and the variation or *swing* is arbitrarily chosen at 1.6 volts on either side of the 20-volt point; that is, when $\triangle e_p$ equals 3.2 volts (fig. 33).

d. To compute r_p, the change in plate current for the given change in d-c plate voltage first must be found from the curve. At 21.6 (20 plus 1.6) volts, the plate current is 45 ma or .045 ampere. At 18.4 (20 minus 1.6) volts the plate current is 35 ma or .035 ampere. These provide the two limits of voltage and current. Consequently,

$$r_p = \frac{\triangle e_p}{\triangle i_p} = \frac{21.6 - 18.4}{.045 - .035} = \frac{3.2}{.010} - 320 \text{ ohms.}$$

e. The value of 320 ohms given above is the a-c plate resistance for a plate voltage which varies between 18.4 and 21.6 volts, whereas the same point is equal to a d-c plate resistance of 500 ohms when the plate voltage is held constant at 20 volts. Using the same method, 278 ohms a-c plate resistance is obtained at the 28-volt plate-voltage point for a change in plate voltage of 1.6 volts each side of the mean value of 28 volts, whereas the d-c resistance is 422 ohms when the plate voltage is maintained constant at 28 volts. Similarly, r_p is shown equal to 527 ohms when the 8-volt plate-voltage point varies *1* volt on either side of the 8-volt mean value. If 1.6 volts is used in the latter case instead of 1 volt, r_p still remains relatively close to 527 ohms. However, it must be kept in mind that the smaller the change in plate voltage, the more accurate are the results. This is because of the nonlinearity of the characteristic curve about this small change. In the former two cases, the curve is fairly linear and 1.6 volts are used arbitrarily. Normally, for linear operation, the operating point for this curve is chosen with an r_p equal to about 320 ohms.

f. It can be seen that an appreciable difference exists between d-c plate resistance and a-c plate resistance, the latter being approximately one-half of the former. This is, in general, true for all types of vacuum tubes. Furthermore, as figure 33 shows, the a-c resistance also is related to the plate voltage, *decreasing* as plate voltage is *increased*, and *increasing* as plate voltage is *decreased*. The *exact value of a-c resistance depends on the point of operation se-*



TM 662-41

Figure 32. Plate-current plate-voltage characteristic for type 6H6 tube, using only one diode section.

as the plate voltage increases, and *increases* as the plate voltage is decreased. It has a nonlinear behavior. If the relationship of plate voltage and plate current were linear over the entire range of plate voltage, the plate-current curve would be a straight line instead of having a curved characteristic. A straight line would indicate that the d-c plate resistance remained constant over the full range of plate voltage.

g. Another significant fact in connection with the $E_b = I_b$ characteristic curve is the condition resulting when the two sections of this duo-diode are connected in parallel, and the two cathodes also are joined in parallel. The plate current in this case becomes twice the amount obtained when the same value of plate voltage is applied to a single pair of elements. Accordingly, the values at any point along the plate-current curve are doubled when both sections of the duo-diode are paralleled. The plate resistance, therefore, becomes half of that existing

---

having the requisite velocity. Thermionic emission of electrons therefore increases with increase of temperature and with reduction of electron affinity. Measurable emission is observed at temperatures above 1000°K.

Electrons that escape will have resultant velocities made up of the excess perpendicular to the surface, plus the original components parallel to the surface, which are not altered by the surface forces. If the emitted electrons are not drawn away by an external field, they will form a space charge, the individual particles of which are moving about with random velocities. Because the initial average normal velocity of the electrons after emission is away from the surface and because of the mutual repulsion of like charges, electrons drift away from the surface. Collisions between electrons cause some of them to acquire velocity components toward the emitter, where they may reenter the surface with a gain of kinetic energy equal to the electron affinity. Another factor responsible for the return of electrons to the emitter is the electrostatic field set up by the negative space charge and, if the emitter is insulated, by the positive charge that it acquires as the result of loss of electrons. This field increases with the density of space charge, and equilibrium is established when only enough electrons can move away from the surface to supply the loss by diffusion of the space charge. If diffusion can then be prevented, just as many electrons return to the metal in unit time as leave it. Figure 2-1 gives a rough picture of the electron distribution under equilibrium conditions.

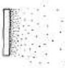


FIG. 2-1.—Distribution of electrons near an emitting surface.

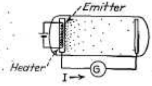

FIG. 2-2.—Flow of anode current as the result of diffusion of electrons from cathode to anode without the application of anode voltage (Edison effect).

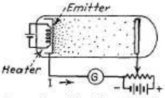

FIG. 2-3.—Use of anode voltage to increase anode current.

If a second, cold electrode is placed near the emitting surface in vacuum and connected to the emitter through a galvanometer, as shown in Fig. 2-2, the meter will indicate the small current resulting from the drift of electrons from the emitter to the second electrode. These electrons return to the emitter through the galvanometer and prevent the emitter from becoming positively charged. This phenomenon, first observed by Edison, is called the *Edison effect*. When the second electrode is made positive with respect to the emitter by the addition of a battery, as shown in Fig. 2-3, the current is increased. As the voltage is gradually raised, it is found that at any emitter temperature there is a more or less definite voltage beyond which the current is nearly constant, all emitted electrons being drawn to the collector. This current is called the *saturation current*, and the corresponding voltage, the *saturation voltage*. The lack of increase of current beyond saturation voltage is spoken of as *voltage saturation*. Saturation current varies with the temperature and electron affinity of the emitter. The negative emitter in Fig. 2-3 is called the *cathode;* and the positive collector, the *anode* or *plate*. An electron tube containing only a cathode and an anode is called a *diode*. Although the electrons move from cathode to anode, the current, according to convention, is said to flow from anode to cathode within the tube.

2-2. Richardson's Equation.—By means of classical kinetic theory, and by thermodynamic theory, Richardson derived two slightly different equations for saturation current as a function of temperature.[1] It is not possible experimentally to determine which of Richardson's equations is correct, but this was later done theoretically by M. v. Laue, S. Dushman, and A. Sommerfeld. The equation that is now believed to be correct is

$$I_s = AT^2\epsilon^{-w/kT} \qquad (2\text{-}1)$$

in which I_s is the saturation current per unit area of emitter, T is the absolute temperature, w is the electron affinity of the emitter, k is Boltzmann's universal gas constant, and A is a constant, probably universal for pure metals. The value of k is 8.63×10^{-5} volt/deg and the theoretical value of A for pure metals is 60.2. The form of the curve that represents Richardson's equation, shown in Fig. 2-4, is determined practically entirely by the exponential factor.

It is important to note that Richardson's equation holds only for the saturation current and that the anode voltage must,

---

[1] RICHARDSON, *loc. cit.*

---

considerably larger, since the plate current is larger, than that of the tungsten types. Oxide-coated emitters release so many electrons that it is practically impossible to find plate voltages which will draw off all of these electrons without ruining the tube. Consequently, most modern tubes which use oxide-coated cathodes do not display a plate-voltage saturation characteristic, but rather show continually rising plate-current curves as the plate voltage is increased as shown in figure 31. Note from the curves that as the operating temperature of the cathode increases, the plate current increases. In addition, this increase will have a more noticeable effect on the oxide-coated cathodes since the solid and dashed lines are much farther apart in the higher operating temperatures than in the lower ones.

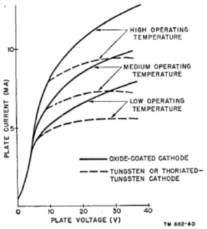

Figure 31. Plate-current emitter-temperature characteristic curves of diode with different types of emitters.

24. D-c Plate Resistance of Diode

a. Since the application of a positive voltage to the plate of a diode results in the flow of plate current, and since some form of control of the magnitude of plate current for different values of voltage exists in the tube, it is entirely proper to view the current control mechanism, whatever may be its nature, as being the equivalent of a resistance. Electrical fundamentals teach that the control of current in a system issues from some form of opposition to the current flow present in the system.

b. Such opposition exists in all electron tubes, among which is the diode. It stems from many factors, such as the spacing between the electrodes, their physical size, the conditions of emission, the conditions of the space charge, and, in general, the energy wasted while the electrons are traversing the space within the tube. Tube resistance is of two kinds: *d-c plate resistance* and *a-c plate resistance*, each of which will be explained. The former usually is symbolized as R_p and the latter as r_p.

c. The d-c plate resistance of the diode is that opposition to plate current flow offered by the tube when a d-c voltage is applied to the plate. It can be calculated from Ohm's law, $R=E/I$, with the plate voltage and the plate current inserted as the known factors in the equation.

d. Referring to figure 32, B shows a typical plate-current plate-voltage characteristic for a type 6H6 duo-diode tube, using only one pair of the two pairs of elements contained inside the envelope—that is one cathode and its associated plate. With 8 volts dc applied to the plate, in A, the plate current, I_b, is seen to be 10 ma, or .01 ampere. (The notation E_b is used as the varying constant voltage between the plate and cathode. This may or may not be the same value as E_{bb}.) Applying Ohm's law for d-c circuits, these values of plate voltage and plate current represent a d-c plate resistance of

$$R_p - \frac{E_b}{I_b} - \frac{8}{.01} = 800 \text{ ohms.}$$

e. Similarly, with 20 volts dc applied to the plate, the curve shows a plate current of 40 ma, or .04 ampere. This corresponds to a d-c resistance of $20/.04 = 500$ ohms. With 28 volts dc applied to the plate, the plate current on the curve is 66.4 ma or .0664 ampere, and the d-c resistance is $28/.0664 - 422$ ohms.

f. Examination of these figures, and also of the shape of the characteristic curve, shows that the resistance offered by the diode to the flow of plate current is *not* constant, as is ordinarily the case when resistance is present in a conventional d-c circuit. The characteristic shows that the resistance of the diode *decreases* therefore, be high enough at all times so that all emitted electrons are drawn to the anode. If the anode voltage is fixed at some value E_1, while the temperature is raised, then at some temperature the current will begin to be limited by space charge in a manner similar to that when there is no accelerating voltage. Further increases of temperature will then have no effect upon the current. This temperature is called the *saturation temperature*, and the failure of the current to increase at higher temperature is spoken of as *temperature saturation*. If the emitter were homogeneous and the electrostatic field constant over the surface of the emitter, the advent of saturation would be abrupt, as indicated at point A. Actually, because of variations of temperature and electron affinity and of electrostatic field, saturation does not take place over the whole cathode surface at the same temperature, and so experimentally determined curves bend over gradually, as shown by the dotted curves. At higher anode voltage E_2, saturation occurs at a higher temperature. If the voltage is increased with temperature, then the current will continue to rise with temperature until the temperature becomes sufficiently high to vaporize the emitter.

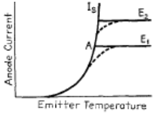

FIG. 2-4.—Curves of anode current *vs.* emitter temperature at two values of anode voltage. The left-hand curve, I_s, represents saturation emission current.

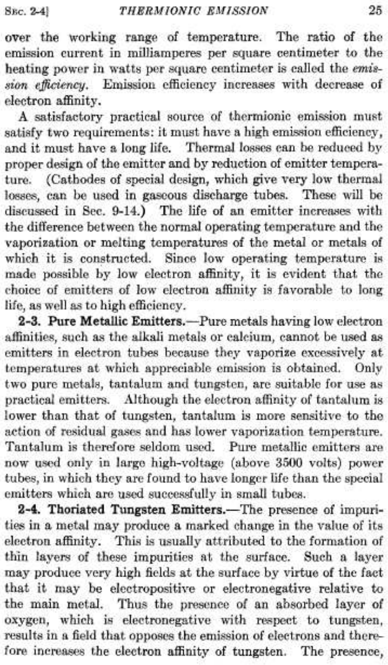
Since only those electrons which have relatively high energies can escape from the metal, thermionic emission necessarily results in the reduction of the average energy of the remaining electrons and molecules, and hence of temperature of the emitter. Heat must be supplied continuously to the emitter in order to prevent its temperature from falling as the result of emission. The cooling effect of emission current is plainly visible in filaments in which the emission current is comparable with the heating current, as in the type 30 tube.

Richardson's equation shows that the emission current which can be obtained at any temperature varies inversely with the electron affinity. Because of the exponential form of the equation, small changes in temperature or electron affinity result in large changes of emission current. A 15 per cent reduction of electron affinity produces an eight- or tenfold increase of emission



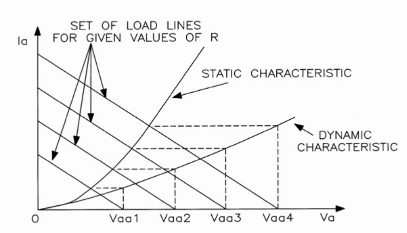
SEC. 2-4] *THERMIONIC EMISSION* 25

over the working range of temperature. The ratio of the emission current in milliamperes per square centimeter to the heating power in watts per square centimeter is called the *emission efficiency*. Emission efficiency increases with decrease of electron affinity.

A satisfactory practical source of thermionic emission must satisfy two requirements: it must have a high emission efficiency, and it must have a long life. Thermal losses can be reduced by proper design of the emitter and by reduction of emitter temperature. (Cathodes of special design, which give very low thermal losses, can be used in gaseous discharge tubes. These will be discussed in Sec. 9-14.) The life of an emitter increases with the difference between the normal operating temperature and the vaporization or melting temperatures of the metal or metals of which it is constructed. Since low operating temperature is made possible by low electron affinity, it is evident that the choice of emitters of low electron affinity is favorable to long life, as well as to high efficiency.

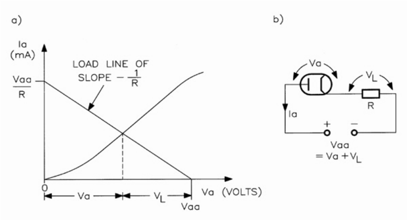
2-3. Pure Metallic Emitters.—Pure metals having low electron affinities, such as the alkali metals or calcium, cannot be used as emitters in electron tubes because they vaporize excessively at temperatures at which appreciable emission is obtained. Only two pure metals, tantalum and tungsten, are suitable for use as practical emitters. Although the electron affinity of tantalum is lower than that of tungsten, tantalum is more sensitive to the action of residual gases and has lower vaporization temperature. Tantalum is therefore seldom used. Pure metallic emitters are now used only in large high-voltage (above 3500 volts) power tubes, in which they are found to have longer life than the special emitters which are used successfully in small tubes.

2-4. Thoriated Tungsten Emitters.—The presence of impurities in a metal may produce a marked change in the value of its electron affinity. This is usually attributed to the formation of thin layers of these impurities at the surface. Such a layer may produce very high fields at the surface by virtue of the fact that it may be electropositive or electronegative relative to the main metal. Thus the presence of an absorbed layer of oxygen, which is electronegative with respect to tungsten, results in a field that opposes the emission of electrons and therefore increases the electron affinity of tungsten. The presence,



Obtaining the dynamic characteristic for a diode valve and its load.

The points on the dynamic characteristic are obtained by projecting, horizontally, the intersection of a load line and the static characteristic until it in turn intersects a vertical line drawn from a supply voltage value. Since the dynamic characteristic is drawn for a range of values of the supply voltage, this implies that the latter is varying, in other words it is an alternating supply rather than DC, as is the case in rectification.



(a) The load line for a diode valve. (b) the diode in series with a linear resistive load.

The second image shows the diode in series with its load and defines the voltages and currents in question. A 'load line' of slope -l/R is drawn between the two points: Ia = Vaa/R Va = 0 and Ia = 0, Va = Vaa. As in solid state practice, the end points of a load line define zero conduction and maximum conduction, the latter being dependent upon the values of supply voltage and load resistance. Any other points on the load line imply intermediate levels of conduction. By dropping a construction line from the intersection of the load line and the static characteristic, we can see how the total supply voltage Vaa is divided into the two separate voltages Va (the voltage across the diode) and Vl (the voltage across the load).

The Dynamic Characteristic

By taking a number of different values of supply voltage Vaa (as would happen if the supply was alternating, for example) and assuming a constant value for the load Rl then, by drawing a separate load line for each value of supply voltage, the dynamic characteristic can be obtained, as shown below.

on the other hand, of a monatomic layer of thorium atoms or ions on the surface of tungsten reduces its electron affinity remarkably. It is of interest to note that the electron affinity of thoriated tungsten may be even lower than that of pure thorium (see Table 1-II).

The reduction of the electron affinity of tungsten as the result of introduction of small amounts of thorium was first observed by Langmuir in 1914 in the course of a study of the properties of tungsten filaments.[1] Thorium oxide is introduced into tungsten during the process of manufacture in order to improve its physical properties. Subsequent high temperature converts a portion of the thorium oxide into metallic thorium, which diffuses to the surface. Investigations by Dushman, Becker, and others[2] indicated that the lowest value of w and the highest value of the constant A in Richardson's equation are obtained when the tungsten is completely, or perhaps very nearly, covered with a single layer of thorium atoms.

Thoriated tungsten shows no increase of emission over that of pure tungsten until it is *activated*. The activation process is performed after evacuation of the tube. It consists first in "flashing" the emitter for a few moments at a temperature of 2500 to 2800°K. This high temperature reduces some of the thorium oxide to thorium. The temperature is then kept for some minutes at about 2200°K, which allows the metallic thorium to diffuse to the surface. The best value of diffusing temperature is determined by the rates of diffusion of thorium to the surface, and of evaporation from the surface. If the temperature is too high, the evaporation exceeds the diffusion, resulting in deactivation. The emitter is normally operated at temperatures that do not exceed 2000°K, which is sufficiently low so that evaporation of thorium from the surface is negligible. If the emitter is accidentally operated at such a high temperature that the whole supply of thorium diffuses to the surface and evaporates, it can be reactivated by repeating the original activation process. This may be done several times before all the thorium oxide is used up.

A useful tool in the study of the phenomenon of activation is the "electron microscope."[1] This consists of the emitter and means for accelerating the electrons and for focusing them upon a screen[2] which fluoresces under the impact of electrons. It has been shown that the action of electromagnetic and electrostatic fields upon electron beams is similar to the action of lenses upon light.[3] Thus it is possible to obtain on the screen a sharp enlarged image which shows clearly the individual points of emission of the cathode.[4] Similar results are achieved by use of a straight filament at the axis of a cylindrical glass tube, the inner surface of which is covered with a fluorescent material.[5] The coated surface, which acts as the anode, is maintained at a positive potential of several thousand volts by means of a wire helix coiled inside the tube in contact with the coating. Electrons emitted by the filament are attracted radially toward the anode coating, where they produce a magnified image of the electron emission at the surface of the filament. Figure 2-5 gives a series of photographs of the screen of such a tube, showing the activation of thoriated tungsten. (The bright vertical line is caused by light from the filament, and the dark lines by the shadow of the helix.)

The presence of even small amounts of gas has a very destructive effect upon a thoriated tungsten emitter. This may result either from direct chemical action, such as oxidation, or from the removal of thorium from the surface by the bombardment of positive ions. The sensitiveness of thoriated emitters to the

and is the value of resistance obtained by dividing a small change in anode voltage by the corresponding change in anode current. It is therefore the reciprocal of the slope of the static characteristic, and varies with the operating point, although fairly constant over much of the space charge limited region. This is a real value of resistance, since it represents the opposition of the valve to alternating quantities.

Series Circuit Operation

It is usual to operate a diode valve, which is clearly a non-linear device, in series with a resistive load, the latter being a linear device. It is possible to predict how the voltages and current in the circuit will vary by using a graphical construction.

Above three curves have been drawn for different values of cathode temperature, although in practice, as explained earlier, the cathode is held at a constant temperature.

It is interesting to note that:

A) The current is not exactly zero when the anode voltage is zero, but has a value (Iao) of a few micro-amperes. This is known as the 'splash current' and is the result of a few high energy electrons that manage to cross the inter-electrode gap even without an attracting potential.

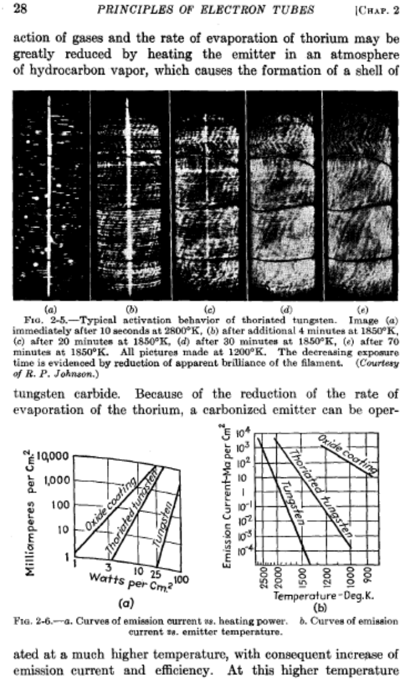
B) In the space-charge limited region, the characteristic is nearly linear (actually following the 'three-halves' power law: Ia is proportional to Va-3/2).

C) In the temperature limited region there is little change in la even though there are large changes in Va. This is because the anode is collecting electrons at the same rate as they are being emitted by the cathode.

D) No significant current flows when the anode is negative with respect to the cathode.

The Anode Slope Resistance ra

It is worth introducing this parameter at this time since it is one that we shall make use of later in discussing the performance of more complex valves. It is defined as shown below,
Defining anode slope resistance for a diode valve.



action of gases and the rate of evaporation of thorium may be greatly reduced by heating the emitter in an atmosphere of hydrocarbon vapor, which causes the formation of a shell of

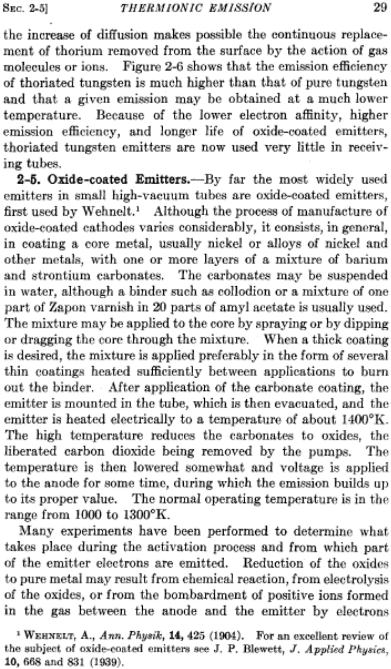
ated at a much higher temperature, with consequent increase of emission current and efficiency. At this higher temperature



the increase of diffusion makes possible the continuous replacement of thorium removed from the surface by the action of gas molecules or ions. Figure 2-6 shows that the emission efficiency of thoriated tungsten is much higher than that of pure tungsten and that a given emission may be obtained at a much lower temperature. Because of the lower electron affinity, higher emission efficiency, and longer life of oxide-coated emitters, thoriated tungsten emitters are now used very little in receiving tubes.

2-5. Oxide-coated Emitters.—By far the most widely used emitters in small high-vacuum tubes are oxide-coated emitters, first used by Wehnelt.[1] Although the process of manufacture of oxide-coated cathodes varies considerably, it consists, in general, in coating a core metal, usually nickel or alloys of nickel and other metals, with one or more layers of a mixture of barium and strontium carbonates. The carbonates may be suspended in water, although a binder such as collodion or a mixture of one part of Zapon varnish in 20 parts of amyl acetate is usually used. The mixture may be applied to the core by spraying or by dipping or dragging the core through the mixture. When a thick coating is desired, the mixture is applied preferably in the form of several thin coatings heated sufficiently between applications to burn out the binder. After application of the carbonate coating, the emitter is mounted in the tube, which is then evacuated, and the emitter is heated electrically to a temperature of about 1400°K. The high temperature reduces the carbonates to oxides, the liberated carbon dioxide being removed by the pumps. The temperature is then lowered somewhat and voltage is applied to the anode for some time, during which the emission builds up to its proper value. The normal operating temperature is in the range from 1000 to 1300°K.

Many experiments have been performed to determine what takes place during the activation process and from which part of the emitter electrons are emitted. Reduction of the oxides to pure metal may result from chemical reaction, from electrolysis of the oxides, or from the bombardment of positive ions formed in the gas between the anode and the emitter by electrons

---

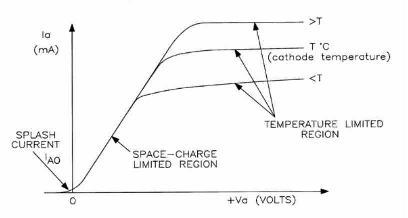
The flow of current in a diode valve.

Diode Static Characteristics

We now start getting into the ways in which specifications for thermionic devices are presented. For the diode, these illustrate clearly the dependence of anode current upon anode voltage.

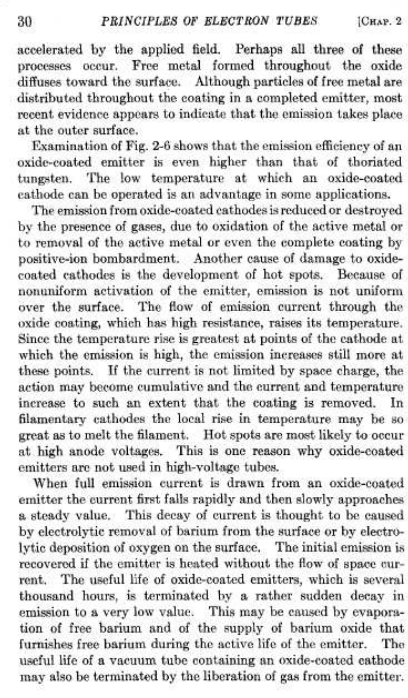


The static characteristic of a diode valve.

Since electrons are negative charged particles, they will only be attracted to the anode if this is given a positive potential with respect to the cathode. This explains why the valve only conducts in one direction, from cathode to anode, and not vice versa. It also explains the choice of the word 'valve' to describe the device, since a valve is, by definition, a one-way device. The Americans, however, never cottoned on to this terminology and always refer to them as 'vacuum tubes'.

The magnitude of the current flowing in a diode depends upon the number of electrons emitted and the magnitude of the voltage applied to the anode (known as the anode voltage Va). The amount of electron emission depends upon the temperature of the cathode, which is fixed by the voltage supply to the heater, this being a constant value. The only true variable is, therefore, the anode voltage. The action of the latter in controlling the anode current can be explained as follows.

As we now know from the foregoing, the cathode is normally surrounded by a cloud of electrons known as the space charge. With zero anode voltage there is no current flow, and there is a state of equilibrium between the electrons being emitted and those falling back onto the cathode's surface, The application of a small positive voltage to the anode causes some of the space charge electrons to be attracted to the anode, resulting in a small anode current flow. The gaps created by these electrons leaving the space charge are filled by further emission from the cathode. Electrons arriving at the anode flow to the positive supply terminal, while at the same time an equal number of electrons leave the negative supply terminal for the cathode. This gives rise to a continuous current flow around the circuit, which may be detected by an ammeter placed in, say, the anode lead. The picture below shows an illustration of this.



accelerated by the applied field. Perhaps all three of these processes occur. Free metal formed throughout the oxide diffuses toward the surface. Although particles of free metal are distributed throughout the coating in a completed emitter, most recent evidence appears to indicate that the emission takes place at the outer surface.

Examination of Fig. 2-6 shows that the emission efficiency of an oxide-coated emitter is even higher than that of thoriated tungsten. The low temperature at which an oxide-coated cathode can be operated is an advantage in some applications.

The emission from oxide-coated cathodes is reduced or destroyed by the presence of gases, due to oxidation of the active metal or to removal of the active metal or even the complete coating by positive-ion bombardment. Another cause of damage to oxide-coated cathodes is the development of hot spots. Because of nonuniform activation of the emitter, emission is not uniform over the surface. The flow of emission current through the oxide coating, which has high resistance, raises its temperature. Since the temperature rise is greatest at points of the cathode at which the emission is high, the emission increases still more at these points. If the current is not limited by space charge, the action may become cumulative and the current and temperature increase to such an extent that the coating is removed. In filamentary cathodes the local rise in temperature may be so great as to melt the filament. Hot spots are most likely to occur at high anode voltages. This is one reason why oxide-coated emitters are not used in high-voltage tubes.

When full emission current is drawn from an oxide-coated emitter the current first falls rapidly and then slowly approaches a steady value. This decay of current is thought to be caused by electrolytic removal of barium from the surface or by electrolytic deposition of oxygen on the surface. The initial emission is recovered if the emitter is heated without the flow of space current. The useful life of oxide-coated emitters, which is several thousand hours, is terminated by a rather sudden decay in emission to a very low value. This may be caused by evaporation of free barium and of the supply of barium oxide that furnishes free barium during the active life of the emitter. The useful life of a vacuum tube containing an oxide-coated cathode may also be terminated by the liberation of gas from the emitter.

2-6. Cesiated Tungsten Emitters.—A fourth type of emitter, not used commercially in thermionic tubes, is produced by depositing a monatomic layer of cesium on tungsten. Because the ionizing potential of cesium vapor is less than the electron affinity of tungsten, the tungsten removes an electron from a cesium atom which strikes it, leaving a positive ion which is held to the tungsten surface by the resulting electrostatic field. The force of adhesion is even greater if the tungsten is first covered with a monatomic layer of oxygen, which is electronegative with regard to tungsten. The strong electrostatic field between the cesium ions and the tungsten or oxygen reduces the electron affinity to the comparatively low value of 0.7 electron volt or less. Because cesium melts at a temperature only slightly above room temperature, the cesium vapor is obtained by merely introducing a small amount of cesium into the evacuated tube, the subsequent vaporization being sufficient to coat the filament.

The low electron affinity of the tungsten-oxygen-cesium emitter makes possible high emission currents at a temperature of only 1000°K. This type of emitter has several disadvantages, however, which make it impractical for use in commercial tubes. As the result of the high vapor pressure of cesium at operating temperatures of the tube, the characteristics of the tube are influenced by tube temperature. Too high temperature vaporizes the cesium, causing temporary reduction in emission, or even removal of the oxygen layer with permanent reduction of emission. Except at very low anode voltages, ionization of the cesium vapor occurs, resulting in fluctuations of anode current. The presence of positive ions is also detrimental to the action of amplifier tubes for other reasons, which will be discussed (Secs. 2-8, 6-5, 10-16).

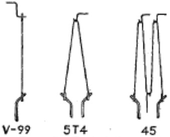


FIG. 2-7.—Typical filamentary cathodes. (*Courtesy of Radio Corporation of America.*)

2-7. Mechanical Construction of Cathodes.—Cathodes used in high-vacuum thermionic tubes are divided into two general classes, filamentary and indirectly heated. Figure 2-7 shows the form of typical filamentary cathodes. Early vacuum tubes used only filamentary cathodes. When filamentary cathodes are operated on alternating current, the stray alternating

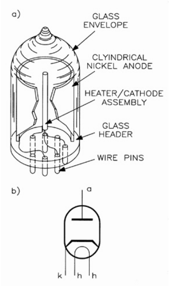
The Diode Valve

The diode valve is so called because it has just two electrodes – the cathode and the anode.



(a) Construction of a modern diode valve (indirectly heated type), (b) circuit symbol for a diode valve.

These correspond to the two electrodes of the original diode valve mentioned above, the cathode being the electrode that is heated and emits electrons, and the anode being the electrode that collects the electrons (notice also that these terms have passed forward into semiconductor phraseology - cathode, anode, emitter, collector!).

electrostatic field and the alternating voltage across the filament cause an alternating component of plate current that may be objectionable in amplifiers in which several tubes are used in succession. This difficulty led to the development of the indirectly heated, or *heater-type*, cathode. In addition to the unipotential emitting surface and freedom from large stray fields, the heater-type cathode has the advantage that a single source of power may be used to heat a number of cathodes between which a difference of potential must exist.

Indirectly heated cathodes used in receiving tubes consist of an oxide-coated cylindrical sleeve, usually of nickel, within which is some form of heater. The most common types of heaters are illustrated in Fig. 2-8. The 5Z4 and 25A6 heater coils are helically wound. That of the 6K7 type of cathode is wound in a reverse helix. After being wound and formed, the coils are coated with a refractory insulating material and inserted into the sleeve. The heater of the 25L6 type of cathode is covered with a refractory insulating coating of sufficient adherence to permit the wire to be bent into the desired shape after it has been coated. Because of the small magnetic field produced by the 6K7 type of heater, there is very little 60-cycle plate-current variation, or "hum," when the heater is operated on alternating current. The return type of helical heater exemplified by the 25A6 heater and the folded type of heater used in the 25L6 cathode make possible the use of enough wire for 25-volt operation. The advantage of the 25L6 construction is its low cost. More complicated cathode structures used in arc-discharge tubes will be discussed in Chap. 9.

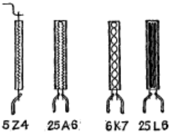


FIG. 2-8.—Structure of typical heater-type cathodes. (*Courtesy of Radio Corporation of America.*)

2-8. Effects of Gas upon Emission and Space Currents.—The deleterious effects of gas upon emitters of various types as the result of chemical action, absorption of thin layers of gas upon the surface, and positive-ion bombardment have already been mentioned. If the anode voltage is sufficiently high to produce ionization of the gas, other effects become apparent. If anode current is at first limited by space charge, the appearance of positive ions tends to neutralize the negative space charge surrounding the filament, thus increasing the anode current. If the voltage is high enough to give saturation current initially, then increase of current occurs because the electrons and ions produced by bombardment of neutral gas molecules by the emitted electrons add to the current. Unfortunately this increase of current is likely to be accompanied by a number of undesirable effects. Currents through ionized gases usually fluctuate, resulting in "noise" in tubes used for amplification. The relatively low velocity of positive and negative ions produces a lag in the response of current to changes of voltage. Variations of gas pressure resulting from changes of temperature or from the absorption or emission of gas from the walls and electrodes may cause the characteristics of the tube to vary. Finally, in a gassy tube, positive-ion current flows to an electrode to which a negative voltage is applied. When the anode current is controlled by means of a negative voltage applied to an electrode through a high resistance, the flow of positive-ion current through the resistance may cause an objectionable voltage drop and, under certain circumstances, may even result in damage to the tube (see Secs. 6-5, 9-17, and 10-16).

In the manufacture of high-vacuum tubes, many precautions are taken to ensure the removal of gas from walls and electrodes. The electrodes are thoroughly cleaned and are then heated for several minutes in an atmosphere of hydrogen, which removes oxygen and water vapor. After the tube is assembled and connected to the pumps, the electrodes are heated to about 800 or 1000°C by high-frequency induction in order to remove other occluded gases. Residual gas is removed by the use of *getters*, which are active chemical substances such as barium, magnesium, aluminum, and tantalum, having the property of combining with gases when they are vaporized. In glass tubes a small amount of the getter is mounted in such a position that it will be heated and vaporized or "flashed" during the inductive heating of the elements. By proper location of the getter, the vapor can be prevented from condensing in places where it might cause electrical leakage or undesirable primary or secondary emission. The effectiveness of the getter results not only from its chemical combination with gases during flashing, but also from subsequent absorption of gases by getter that has condensed on

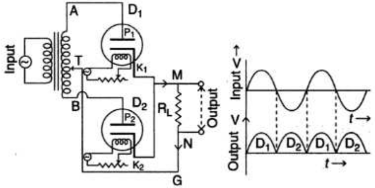
---

2. A rectifier is always followed by electronic circuits called filter circuits which allow only D.C. to pass through them and by pass the A.C. Thus a rectifier-filter combination gives a D.C. output.

Applications of Diode

The two main applications of diode are :

(a) As a rectifier (b) As a detector



(i) Circuit (ii) Input-Output waveforms

positive. Therefore, the second diode conducts but the first remains passive. Thus, the two diodes conduct alternately. But in both half cycles of A.C., the current in load resistance R_L flows in the same direction. So, we get continuous D.C. at output. For full-wave rectifier,

Note :

$$I_{D.C.} = \frac{2I_0}{\pi}$$

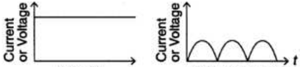
$$I_{rms} = \frac{I_0}{\sqrt{2}}$$

$$\eta_{max} = 81{\cdot}2\%$$

Ripple factor, $r = 0{\cdot}48$

The output of rectifier is fluctuating or pulsating. To make it smooth, filters are used.

Notes : 1. The output obtained from a half wave or full wave rectifier is not a pure D.C. but it is a pulsating D.C. (mixture of A.C. and D.C.)



(i) (D.C.) (ii) Pulsating D.C.

---

the walls of the tube. The action of the getter during flashing is increased by ionization of the gas by means of voltages applied between the electrodes or by the radio-frequency field of the induction heater. To ensure the removal of gas from the walls, tubes are baked during the process of manufacture. On machines that exhaust and seal the tubes separately, the bulbs are heated in ovens during exhaustion. On "Sealex" machines, the tubes are sealed and exhausted on the same machine, the heat from sealing being used to drive gases from the bulbs during exhaustion.

In tubes with metal envelopes, the shielding action of the shell makes it impossible to heat the electrodes and the getter by induction. The electrodes may be heated by radiation from the shell, which is heated by gas flames. Although the getter may be fastened to the inside of the shell and vaporized by heating the shell locally, another method has been developed that requires less critical control.[1] A short length of tantalum ribbon, which connects the shell to its terminal pin in the base, is coated with a mixture of barium and strontium carbonates. While the tube is on the pumps, the temperature of the tantalum wire is raised electrically to about 1100°C. This converts the carbonates into oxides. After the tube has been sealed off, the tantalum wire is heated to a temperature in excess of 1200°C. This causes the tantalum to reduce the oxides to pure metallic barium and strontium, which vaporize. Since the vapor moves in straight lines, it can be directed as desired by means of shields and by proper location of the tantalum wire. This type of getter is called *batalum* [See (11) in Fig. 3-11*b*].

2-9. Limitation of Anode Current by Space Charge.—The effect of space charge in limiting space current and the increase of anode current resulting from an accelerating anode potential have already been mentioned in connection with the theory of thermionic emission. Before proceeding to a discussion of the quantitative relation between anode current and anode potential in a two-element tube, it is of interest to discuss further the physical picture underlying the phenomenon. The behavior of the emitted thermionic electrons is complicated by their initial velocities. For this reason it is best first to formulate a theory on the assumption that the initial velocities are zero and then, when they are taken into consideration, to see in what manner the results should be altered. For the present, therefore, initial velocities will be assumed to be zero. It will be further assumed that both cathode and anode are homogeneous, constant-potential, parallel planes of large area, and hence that the electric field over the surface of the cathode may be assumed to be uniform.

---

[1] LEDERER, E. A., and WAMSLEY, D. H., *RCA Rev.*, **2**, 117 (1937). This article also discusses gettering methods used in glass tubes.

Electrons that leave the cathode constitute a space charge that exerts a retarding field at the cathode. The net field at the surface of the cathode is the difference between this retarding field and the accelerating field produced by the positive voltage of the anode. The number of electrons in the space, and hence the retarding component of field at the cathode, increases with the anode current. When the positive anode voltage is applied, the anode current builds up with great rapidity to such a value that the average retarding field at the cathode caused by the space charge is equal to the accelerating field caused by the anode voltage, making the average field zero at the cathode. Increase of emission then does not raise the anode current, as the additional emitted electrons merely reenter the cathode. If it were possible in some manner to increase the density of space charge by increasing the current beyond this equilibrium value, or if the anode voltage were reduced slightly, then the net field at the cathode would be a retarding one. For an instant, all emitted electrons would be prevented from moving away from the cathode, and the current and space-charge density would be automatically reduced to a value that would again make the average field at the cathode zero. An increase of anode voltage causes the accelerating field to exceed the retarding field. The number of electrons moving to the anode then increases until the retarding field again equals the accelerating field.

At first thought it may not seem plausible that there can be a steady flow of electrons to the anode when both the velocities of emitted electrons and the average electrostatic field are zero at the cathode. It is only the *time average* field, however, that is zero at any point on the cathode. The *instantaneous* field at any point may vary in a random manner between positive and negative values. Immediately after one or more electrons have entered some point of the anode, the net field at a corresponding

---

Operation

- A.C. input is applied the plate 'P' becomes positive and negative alternately.
- For the positive half cycle of input, the plate is positive with respect of cathode. So that diode conducts and plate current flows through the tube load R_L and secondary. So output occurs across load. R_L as shown in fig. (ii).

Important Points

- During – ve half cycle of A.C. input, →Plate is negative with respect to cathode. So the diode does not conduct, and no voltage appears across output.
- For half wave rectifier; (I_0 is peak value of current)
  - → Average value of current $I_{D.C.} = I_0/\pi$
  - → Root mean square value of current $I_{rms} = I_0/2$
  - → Maximum efficiency $\eta_{max} = 40{\cdot}6\%$
  - → Ripple factor $r = 1{\cdot}21$

(B) **Full wave rectifier**—It converts full A.C. into D.C. In this rectifier two diodes are used which conduct alternately. The output is obtained across the load resistance R_L. Here in first half cycle of A.C., plate of first diode remains positive and plate of second diode remains negative. Hence, the first diode conducts and the second does not. In second half cycle of A.C., plate of the first diode becomes negative and that of second diode becomes

Rectifier

Rectifier is a device which converts an A.C. into a D.C. The process is called **Rectification**. Rectifiers are of two types :

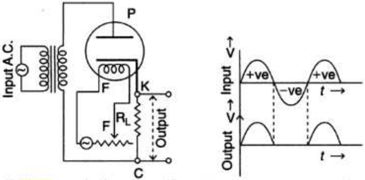
1. **Half wave rectifier**—Which conducts only during + ve half cycle of input A.C.

2. **Full wave rectifier**—Which conducts during full cycle of input A.C.

(A) **Half wave rectifier** (in half wave rectifier only one diode valve is used)

Circuit

- The input A.C. voltage to be rectified is applied to the primary of a transformer.
- The secondary of transformer is connected in series with load R_L between plate and cathode of diode (as shown in fig.).



(i) Diode as a half-wave rectifier (ii) Input and output waveforms

---

point of the cathode may be positive, causing one or more electrons to move away from the cathode. These electrons produce a retarding field behind them which prevents the departure of more electrons from that point until the entrance of other electrons into the anode again results in an accelerating field. Many electrons are entering and leaving the space at any instant, so that the field fluctuations are rapid and haphazard.

2-10. Child's Law.—The foregoing descriptive explanation shows that, if an ample supply of electrons is available at the cathode, the anode current in a diode varies with the voltage applied between the anode and cathode. A mathematical analysis of this phenomenon was first made by Child.[1] The equation relating the anode current and voltage is called *Child's law*. The general derivation for electrodes of any size and shape is too difficult to yield a useful equation, and so only the relatively simple cases such as those applying to plane parallel electrodes of large area and to long concentric cylinders are ordinarily considered. In deriving Child's law for plane parallel electrodes the following assumptions are made:

1. The cathode temperature is high enough at all points so that more electrons are emitted than are drawn to the anode; *i.e.*, the current is limited by space charge.
2. The cathode and anode are parallel plates whose area is large as compared to their spacing; *i.e.*, the electrostatic field is uniform over the surface of any plane parallel to the electrodes.
3. The surfaces of the anode and cathode are equipotential surfaces.
4. The space between the cathode and the anode is sufficiently free of gas so that electrons do not lose energy by collision with gas molecules in moving from the cathode to the anode.
5. Emitted electrons have zero initial velocity after emission.

Under these assumptions the following three equations may be written:

$$\frac{\partial^2 V}{\partial x^2} = 4\pi\rho \qquad (2\text{-}2)$$

$$\mathcal{E}V = \tfrac{1}{2}m_e v^2 \qquad (2\text{-}3)$$

$$\rho v A = i_b \qquad (2\text{-}4)$$

in which V is the potential, relative to the cathode, at a distance x from the cathode; ρ is the density of electron space charge at a distance x from the cathode; $\mathcal{E}$ and m_e are the charge and mass, respectively, of an electron; v is the velocity dx/dt of an electron at a distance x from the cathode; i_b is the anode current; and A is the area of the electrodes.

---

[1] CHILD, C. D., *Phys. Rev.*, **32**, 498 (1911).

Equation (2-2) combines in symbolic form the definitions of potential difference and electric field. It is a special form of Poisson's equation, one of the most important fundamental laws of electrostatics, and may be derived directly from Gauss's law[1] (see Sec. 1-10). Equation (2-3) states that the energy gained by an electron in moving from the cathode to a distance x from the cathode under the influence of the electric field appears entirely in the form of kinetic energy. Equation (2-4) is a symbolic formulation of the definition of the magnitude of an electric current as the rate of flow of charge.

In the solution of the simultaneous differential Eqs. (2-2), (2-3), and (2-4), the following boundary conditions must be applied: At the cathode, the potential V, the average electric field $\partial V/\partial x$, and the velocity v are zero. At the anode, where x is equal to the cathode-to-anode spacing d, the potential is equal to e_b, the applied anode voltage. Solution of the equations and substitution of numerical values of $\mathcal{E}$ and m_e give the following equation for the anode current of a diode:[2]

$$i_b = 2.34 \times 10^{-6} \frac{A e_b^{3/2}}{d^2} \quad \text{amp} \qquad (2\text{-}5)$$

By combining Eq. (2-5) with Eqs. (2-2), (2-3), and (2-4), theoretical expressions may be derived for density of space charge, electron velocity, electric field strength, and potential as functions of distance from the cathode. Curves derived from these are shown in Fig. 2-9.

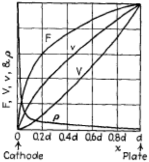


Fig. 2-9.—Variation of field strength F, potential V, electron velocity v, and space-charge density ρ with distance x from plane cathode. Zero initial velocity. Arbitrary units.

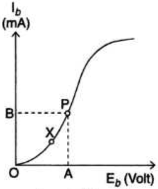
Child's law for concentric cylinders whose length is large as compared to their spacing is

---

[1] Page, L., and Adams, N. I., "Principles of Electricity," p. 83, D. Van Nostrand Company, Inc., New York, 1931.

[2] Page and Adams, *op. cit.*, p. 297.

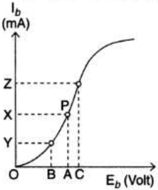


as D.C. plate resistance. The D.C. plate resistance R_p is given by

$$R_p = \frac{OA}{OB}$$

Note : Since plate characteristic curve is not a straight line—Therefore, D.C. plate resistance is variable. Hence, D.C. plate resistance may be calculated at the actual operating point.

(ii) **A. C. plate resistance**—The ratio of a small change in plate voltage across a diode to the resulting change in plate current is known as A.C. plate resistance.



$$r_p = \frac{\Delta V}{\Delta I}$$

Note : The A.C. plate resistance at operating point P can be found by considering small equal changes of plate voltage on either side of the operating point (*i.e.*, AB = A.C.)

$$\text{Change in plate voltage} = BC$$

$$\text{Change in plate current} = YZ$$

$$\therefore \text{ A.C. plate resistance at } p, \; r_p = \frac{BC}{YZ}$$

2. At $V_p = V_1$, almost all the electrons constituting space charge are collected by plate and space charge is eliminated. At this point rate of collection of electrons reaches its maximum value and it equals the rate of emission of electrons by cathode. Therefore, if plate voltage is further increased plate current becomes constant.
3. The only way to increase the plate current is to increase the rate of emission, *i.e.*, to increase the temperature of cathode. Since the plate current, in this region, may be limited by temperature of cathode, this is called **temperature limited region**. In this region plate current is independent of plate voltage and varies with temperature T of cathode as

$$I = cT^2 e^{-b/T} \qquad \ldots\text{(ii)}$$

where *c* and *b* are constant for cathode.

Equation (ii) is simplified form of Richardson equation for this case.

Plate resistance of diode—The plate current (I_p) varies as the plate voltage (V_p) is changed, therefore, a diode offers internal resistance which is known as its plate resistance.

Note : Mainly negative space charge is responsible for the plate resistance of diode. As it is a non-ohmic resistance its value is not constant and it differs at different operating points.

Types of Plate Resistance

(i) **D.C. plate resistance**—The ratio of total D.C. plate voltage across diode to the resulting current is known

---

$$i_b = 14.68 \times 10^{-6} \frac{h e_b^{3/2}}{br} \quad \text{amp} \qquad (2\text{-}6)$$

in which *r* is the radius of the anode, *h* is the length of the electrodes, and *b* is a factor whose value depends upon the ratio of the radius of the anode to that of the cathode. *b* has the approximate value $\frac{1}{4}$ for a ratio 2, $\frac{1}{2}$ for a ratio 3, and 0.9 for a ratio 8. If the plate diameter is large as compared to that of the cathode, Eq. (2-6) reduces to the approximate form

$$i_b = 14.7 \times 10^{-6} \frac{h e_b^{3/2}}{r} \quad \text{amp} \qquad (2\text{-}7)$$

Equations (2-5), (2-6), and (2-7) show the importance of close spacing between cathode and anode if large currents are desired at small anode voltages.

2-11. Deviations from Child's Law Observed in Practical Diodes.—Deviations from Child's law result from the failure of practical diodes to satisfy the assumptions made in its derivation. Since the temperature of the cathode is fixed by considerations of emission efficiency and life, there is always a saturation voltage above which the current is not limited by space charge but by filament emission. If other assumptions were satisfied, the saturation voltage would be quite definite and the current-voltage curve would be as shown by the dotted lines of Fig. 2-10. Because of variations in temperature, electron affinity, and field strength over the cathode surface, the anode voltage at which voltage saturation takes place is not the same for all points of the cathode. The curve of anode current *vs.* anode voltage therefore bends over gradually, as shown by the full line of Fig. 2-10. Above saturation the current is not entirely constant but

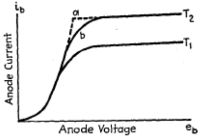


FIG. 2-10.—Curves of anode current *vs.* anode voltage at two values of emitter temperature.

continues to rise somewhat with anode voltage. This is explained by reduction of electron affinity with increase of external field (see Sec. 1-12), and lack of homogeneity of the surface of the emitter. The effect is particularly noticeable with oxide-coated cathodes.

The assumptions of uniform field and equipotential cathode are satisfied fairly closely in heater-type diodes with cylindrical plates. The voltage drop in filamentary cathodes may be shown to change Child's $\frac{3}{2}$-power law into a $\frac{5}{2}$-power law at anode voltages relative to the negative end of the filament that are less than the voltage of the positive end of the filament. This tends to make the lower part of the i_b-e_b curve steeper. The exact effect upon the curve of failure to satisfy the assumption of uniform field is complicated and impossible to predict completely.

2-12. Effect of Initial Velocities of Emitted Electrons.—Modified forms of Child's law which take into consideration the initial velocities of emitted electrons have been derived by Schottky, Langmuir, and others.[1] For the purpose of this book, a qualitative explanation of the effect of initial velocities is sufficient. Let it first be supposed that the electrons emerge with zero velocity. Under equilibrium conditions the space current and the space-charge density assume such values that the average field at the cathode is zero. The field and potential distributions in the interelectrode space are as shown in Fig. 2-9. Now let the emitted electrons suddenly have initial velocities that, for the sake of simplicity, are assumed to be the same for all electrons. Electrons that, without initial velocity, would have reentered the cathode now move toward the anode in spite of the fact that the average field is zero. As a result, the current and the space-charge density increase. The retarding field of the space charge now exceeds the accelerating field of the anode, giving a net retarding field at the cathode surface which slows up the electrons in the vicinity of the cathode. Equilibrium results when the retarding field in the vicinity of the cathode is sufficiently high so that the electrons are brought to rest in a plane a short distance *s* from the cathode. The average field in

[1] Schottky, W., *Physik. Z.*, **15**, 526 (1914); *Ann. Physik*, **44**, 1011 (1914). Langmuir, I., *Phys. Rev.*, **21**, 419 (1923). Davisson, C., *Phys. Rev.*, **25**, 808 (1925).

We note from fig. (i) that curves coincide at low voltage (in space charge limited region) but saturation current increases as shown by portion CD of characteristics.

(2) **Low voltage characteristics**—The plate current is practically zero at zero plate voltage (however, plate current is not exactly zero). If we measure plate current using a micro-ampere plate current of the order of few micro-ampere occurs. This is due to "the fact that even at zero plate voltage a few electrons may have sufficient K.E. to reach the plate and constitute a plate current of few micro-ampere." From the fig. (ii) the plate current becomes exactly zero at a particular negative value V_C of plate voltage, called **cut-off voltage.** The max. kinetic energy of emitted electron is related to V_C as :

$$K_{max} = e\,V_C$$

Important Points

1. If we increase plate voltage from zero volt to a value V_1 in steps, more and more electrons are attracted from space charge to plate (though at the same time same no. of electrons are emitted from cathode so that space charge is maintained) so plate current increases. As the plate current is limited by space charge, this region of curve is called **space charge limited region**. In this region, plate current is related to plate voltage by equation.

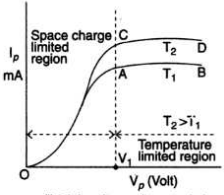
$$I_p = K \, . \, V_p^{3/2} \qquad \text{...(i)}$$

where K is a constant.

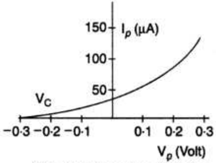
Equation (i) is known as **Child-Langmuir's law.**

V-I characteristics of Diode

(1) **High voltage characteristics**—Fig. (i) shows high voltage plate characteristics when plate current is measured in (mA). Keeping temperature of cathode constant, say (T_1) (*i.e.* filament current constant) when plate voltage increased from zero volt in steps and corresponding value of plate current i_p measured in m.A. the variation occurs as shown in curve OAB. If the cathode temperature is increased from T_1 to T_2.



(i) High voltage characteristics



(ii) Low voltage characteristics

---

this plane is zero, but instantaneous fluctuations allow just enough electrons to pass to give the required anode current. The behavior is similar to that which would obtain if the initial velocity were zero and the cathode were moved toward the anode by the distance s. Because of the random distribution of electron velocities the phenomenon is actually more complicated than this simplified picture indicates. The simple theory shows, however, that the effect of initial velocities is to increase the anode current corresponding to any anode voltage and is therefore equivalent to that of a small increase of anode voltage. Because the electrons emerge with velocities of the order of a volt or less, the effect is appreciable only for low anode voltages. The field and potential distributions throughout the interelectrode space are plotted in Fig. 2-11. That the potential must pass through a minimum where the field is zero follows from the fact that the field at any point may be expressed as the space derivative of the potential at that point.

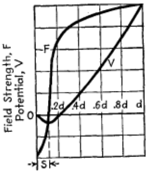

FIG. 2-11.—Variation of field strength and potential with distance from cathode for plane parallel electrodes of separation d. Initial velocities of emitted electrons considered.

The lower part of the i_b-e_b curve of Fig. 2-10 is raised slightly as the result of initial velocities of emitted electrons, and a small negative voltage must be applied in order to reduce the anode current to zero. Theoretical equations relating anode current and voltage at negative anode voltages have been derived by Schottky[1] and Davisson.[2] Because of their complicated form and because of failure to satisfy in practice the assumptions made in their derivation, these are seldom of great practical value. At negative anode voltages that are high enough to reduce the anode current to the order of 50 μa or less, the anode current of diodes with unipotential cathodes follows closely the empirical relation

$$i_b = k_1\epsilon^{k_2e_b} \qquad (2\text{-}8)$$

in which k_1 and k_2 are constants for a given tube. The current departs materially from this exponential law as the negative anode voltage is reduced in the vicinity of zero voltage, particularly at high cathode temperatures. Experimental curves corresponding to Eq. (2-8) were first obtained by Germer.[1]

---

[1] SCHOTTKY, *loc. cit.;* LANGMUIR, *loc. cit.*

[2] DAVISSON, *loc. cit.*

Unless the plate of a highly evacuated diode becomes hot enough to emit electrons, increase of negative anode voltage beyond the value that reduces the current to zero has no further effect upon the anode current. The fact that anode current flows in one direction only is employed in the application of diodes to detection and to power rectification, which will be discussed in Chaps. 7 and 11.

2-13. Relation of Richardson's and Child's Laws.—It should be noted that Richardson's equation and Child's law apply to two different conditions of operation of two-element tubes. Richardson's equation holds only under voltage saturation, whereas Child's law applies only under temperature saturation. In most applications, vacuum tubes are used in such a manner that temperature saturation prevails.

2-14. Shot Effect.—The random motion of electrons causes rapid variations of the number of electrons that pass from the cathode to the anode in unit time, and thus produces fluctuations of anode current. This phenomenon, which may be readily detected by the use of sufficient amplification, is called the *shot effect*. It is one of the factors that limit amplification by vacuum tubes (see Sec. 6-15).

Heating of the Plate.—The kinetic energy acquired by electrons in moving from the cathode to the plate is converted into heat when the electrons strike the plate. The average current that a vacuum tube can pass is limited by the temperature of the plate at which absorbed gas is driven out of the plate or electron emission takes place from the plate. The power that is converted into heat at the plate is equal to the time integral of the product of the plate current and plate voltage. Radiation of heat from the plate is increased by blackening its outer surface.

2-15. Classification of Tubes.—Electron tubes may be classified in a number of ways. These classifications include those based upon the process involved in the emission of electrons from the cathode, the degree of evacuation, the number of elec-

---

[1] Germer, L. H., *Phys. Rev.*, **25**, 795 (1925).

---

plate current. These electrons flow through the external circuit and finally return to the cathode, thus making up the supply of electrons lost by emission. On increasing plate potential more electron will gain sufficient kinetic energy so as to reach anode, hence the plate current increases.

Important Points to Note

- The current flows in the diode only when plate is made positive relative to cathode.
- No current can flow when plate is negative relative to cathode.
- Within a diode electrons can flow only from cathode to plate.
- Due to unidirectional conduction property the diode acts like a valve.
- The diode automatically starts conduction when the plate is positive or stops conduction when the plate is negative (due this property) the diode may act as a rectifier, converting A.C. into D.C.)

Characteristics of Diode

Characteristics of vacuum diode can be best studied by finding the relation between plate voltage and plate current for a given cathode temperature.

(1) **Anode (plate) at zero potential relative to cathode**—This situation is shown in fig. (i)—The emitted electrons do not have sufficient kinetic energy so as to reach the anode. However, a few electrons may reach the anode on account of their kinetic energy, constituting negligible current. The emitted electrons accumulate near the cathode and form a cloud of electrons. This is known as space charge. At a certain stage the number of electrons forming the space charge becomes constant for a given operating temperature. This space charge becomes a source of electrons that can be attracted to the plate, if it is at a positive potential.

(2) **Anode (plate) at negative potential relative to cathode**—This situation is shown in fig. (ii). The emitted electrons are repelled back due to retarding potential of anode. For a particular negative potential of anode plate current may be zero.

(3) **Anode (plate) at positive potential relative to cathode**—This situation is shown in fig. (iii). The electrons constituting the space charge are attracted to the plate. This flow of electrons from cathode to plate is known as

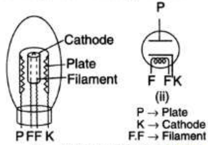
Vacuum Diode or Diode Valve

A vacuum diode consists of two electrodes : a cathode; and an anode enclosed in an evacuated glass tube. Its operation is based upon thermionic emission, it is also called thermionic diode.

Anode (or plate)—The anode is a hollow cylinder made of Ni or molybdenum and surrounds the cathode.

Cathode—A cathode may be directly heated or indirectly heated type. Usually an indirectly heated cathode is provided (except in high power application).

As shown in fig. (i) an indirectly heated cathode is in the form of nickel cylinder coated with oxides of barium or strontium. Inside the cathode, a heater filament of tungsten is inserted.



(i) Construction of diode
(ii) Symbol of diode

Fig. (ii) shows it symbol :

Operation of diode—When electric current is passed through the diode it emits a large number of electrons. These emitted electrons may be accelerated or retarded by applying positive or negative potential to anode relative to cathode.

the mutual conductance to decrease, which means that the amplification obtainable from the tube also decreases since amplification is proportional to mutual conductance, other things being equal. On the other hand, the plate resistance increases with increasing negative grid bias. As a check on the accuracy of measurement, the three curves should satisfy the relationship

$$g_m = \frac{\mu}{r_p}$$

within reasonable limits of accuracy, for any given value of grid bias.

If published average curves for the type of tube measured are available, it will be of interest to compare them to the curves determined experimentally. Exact duplication of the published curves is not to be expected, of course, because of slight variations in manufacture.

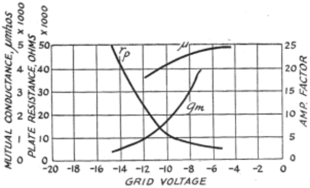


Fig 9.

trodes, and the type of application. Included in the first classification are the thermionic tube and the phototube. A *thermionic tube* is an electron tube in which the electron or ion emission is produced by the heating of an electrode. A *phototube* is an electron tube in which electron emission is produced directly by radiation falling upon an electrode. According to degree of evacuation, electron tubes are classified as high-vacuum tubes

and gas- or vapor-filled tubes A *high-vacuum tube* (*vacuum tube* or *pliotron*) is an electron tube evacuated to such a degree that its electrical characteristics are essentially unaffected by gaseous ionization. A *gas-filled* or *vapor-filled tube* (*gas tube*) is an electron tube in which the pressure of the gas or vapor is such as to affect appreciably the electrical characteristics of the tube. According to the number of electrodes, tubes are classified as *diodes, triodes, pentodes*, etc. For convenience or economy or for reduction of space or weight, two or more sets of elements may be enclosed in a single envelope. Thus, there are duplex (double) triodes, duplex-diode pentodes, triode pentodes, etc. The diverse classification of electron tubes according to application will be made in later chapters.

2-16. Construction of Tubes.—Tubes are made with both glass and metal envelopes.[1] The principal advantages of metal tubes lie in their greater mechanical strength and in the fact that the electrodes are permanently and completely shielded without the use of an external shield. Furthermore, they do not require on the inside of the envelope the conducting coating that must be used in glass tubes to prevent the wall from acquiring a positive charge as the result of secondary emission caused by the impact of electrons that pass around the plate. A disadvantage of metal tubes is that the shells become so hot in operation that they cannot be conveniently handled. This is of importance in the routine factory testing of radio receivers. Another minor disadvantage is the impossibility of determining visually whether the heater is in operation. Glass tubes appear to be somewhat more reliable. In rectifiers, particularly, metal

The values of amplification factor, µ, plate resistance, rp, and mutual conductance, gm, can be measured from these three sets of curves. The mutual conductance, ΔIpΔEg can be found from the curves of Fig. 6 since these curves show the relationship between grid voltage and plate current. The plate resistance, ΔIp/ΔEp, can be measured from the curves of Fig.: 7, which relate plate current to plate voltage for various values of grid bias, while the amplification factor ΔIpΔEg, can be taken from the curves of Fig. 8. The method of making these measurements is described in the introduction to this installment. Since these "constants" are a function of three variables a large number of graphs would be required to give their behavior even partially completely, but one special case is shown in Fig. 9. This graph shows the variation in µ, rp and gm as a function of grid bias when the plate voltage is held constant at 250 volts, the normal rated operating voltage for the tube, and is a plot of values measured at 250-volt points on each of the three sets of curves in Figs. 6, 7 and 8. It is plain that the amplification factor changes relatively little compared to the changes in the other two quantities. Increasing negative grid bias causes

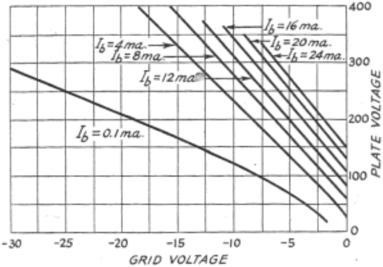

Fig. 8

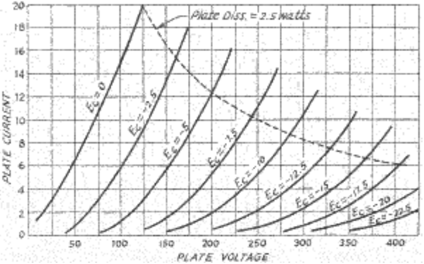

Fig. 7

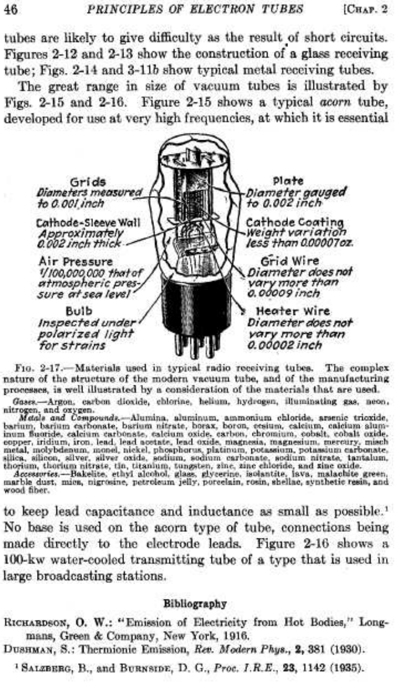
The "plate family," shown plotted from experimental data in Fig. 7, is obtained by holding the grid bias constant at selected values and measuring the plate current as the plate voltage is varied. These curves show the same general tendency to bend when the plate current is near cut-off, and to straighten out at higher values of plate current. The plate family is frequently more useful than the set of grid voltage-plate current curves represented by Fig. 6.

When the remaining quantity, plate current, is held constant while the grid voltage is varied (the plate voltage being adjusted for each value of grid bias to give the selected value of plate current) the set of curves shown in Fig. 8 results, again plotted from experimental data on a 6J5. These "constant current" curves show the relative effect of grid voltage and plate voltage on plate current. The curves are nearly straight lines for all except very small values of plate current, showing that the amplification factor is practically constant for a given plate-current value regardless of the plate and grid voltages. The fact that, with the exception of the curve for a plate current of 0.1 milliampere, the curves are very nearly parallel indicates that the amplification factor also is nearly independent of the plate current so long as the latter is not near the cut-off point.



46 PRINCIPLES OF ELECTRON TUBES [CHAP. 2

tubes are likely to give difficulty as the result of short circuits. Figures 2-12 and 2-13 show the construction of a glass receiving tube; Figs. 2-14 and 3-11*b* show typical metal receiving tubes.

enough points being taken at each plate voltage to permit smooth curves to be drawn. Notice that for each value of plate voltage the curve bends at the higher values of negative grid voltage (as the plate current decreases toward the cutoff point) but that the curvature decreases as the grid bias becomes less negative. The curves eventually straighten out and become practically parallel, and the distances between the 50-volt intervals also approach equality. The dashed line shows the value of plate current at which the plate dissipation (plate voltage multiplied by plate current) is equal to the maximum rated value for the tube; above this line the plate dissipation is exceeded.

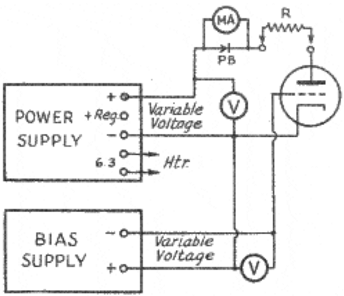

Fig. 5

The resistor R shown in Fig. 5 is not needed in this experiment, so the push-button may be connected directly to the plate.

Procedure: The object of the experiment is to determine the relationship between plate voltage, plate current and grid voltage of a small triode. One quantity is held constant throughout a run, the second is varied, and corresponding measurements of the third are made. A receiving triode such as the 6J5 is suitable. Three sets of characteristics can be taken; the first, with the plate voltage held fixed while the behavior of plate current with varying grid voltage is observed, is called the "grid voltage plate current" characteristic. When a series of such data is taken with several fixed values of plate voltage, a "family" of curves results. A typical grid-voltage plate-current family taken in this way on a 6J5 is shown in Fig. 6. The plate voltage was set at 50- volt intervals from 50 to 400 volts (the maximum output voltage of the power supply described in August QST),

Lecture 19 ANALYSIS OF RECTIFIER OPERATION

0. H. Schade

INTRODUCTION

The design of diodes for rectification of a-power requires unusual care even though their design is simple from the standpoint of the number of electrodes involved. The cathode must be capable of supplying the average current and peak current which will be encountered in ser-vice. The plate must operate at a safe temperature, which in turn depends on plate dissipation, the physical dimensions of the plate, and the thermionic and thermal emissivity of the plate material. Another factor to be considered is the purveyance of the diode, i.e., the steepness of its voltage-current characteristic. Purveyance affects both cathode— and plate-design because it controls current density and voltage gradient at the effective surfaces of both for a given cathode area. Then, too, there is the requirement for adequate insulation. Perveance and insulation requirements depend on the type of service in which the diode is to be used.

It is apparent that an analysis of diode-operating conditions in rectifier circuits is essential in order to arrive at optimum design specifications in each particular case, because the required data bear no simple relationship to the values of rectified current and voltage.

PRINCIPLES OF RECTIFICATION

1. General

Rectification is a process of synchronized switching. The basic rectifier circuit consists of one synchronized switch in series with a single-phase source of single frequency and a resistance load. The switch connection between load terminals and source is closed when source and load terminals have the same polarity, and is open during the time of opposite polarity. The load current consists of half-wave pulses. This simple circuit is unsuitable for most practical purposes, because it does not furnish a smooth load current.

The current may be smoothed by two methods:(a) by increasing the number of phases, and (b)by inserting reactive elements into the circuit. The phase number is limited to two for radio receivers. The circuit analysis which follows later en will treat single- and double-phase rectifier circuits with reactive circuit elements.

Switching in reactive circuits gives rise to “transients." Current and voltage can, there-fore, not be computed according to steady-state methods.

The diode functions as a self-timing electronic switch. It closes the circuit when the plate becomes positive with respect to cathode and opens the circuit at the instant when the plate current becomes zero.

The diode has an internal resistance which is a function of current. When analyzing rectifier circuits, it is convenient to treat the internal resistance of the diode rectifier as an element, separated from the "switch action" of the diode. Fig. 1 illustrates the three circuit elements so obtained. The diode characteristic is the geometric sum of these characteristics. The resistance r^ is effective only when the switch is closed, i.e., during the conduction period of the diode. The effective diode resistance must, therefore, be measured or evaluated

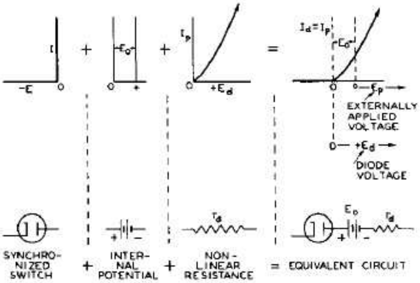

Fig 1

small fraction of a milliampere - it can be neglected in most applications of the tube. However, in flowing through an external load resistance of high value a volt or two may be developed across the load, which may need to be taken into account in some cases.

Triode Static Characteristics

Experiment 22

Apparatus: The set-up for this experiment is shown in Fig. 5. Insofar as the plate circuit of the triode is concerned. the arrangement is practically the same as that used for diode measurements, :Fig. 3, except that it is possible to measure plate voltage with the test instrument rather than the v.t. voltmeter. This is because larger plate voltage steps may be used so that a high range (500 volts or the nearest provided on the test instrument), which will have a resistance of a half megohm or so, will give sufficient accuracy for all measurement. The bias supply is incorporated in the

set-up to provide variable grid bias, and its voltage output also may be measured by the test instrument on the condition that the voltmeter resistance is 25,000 ohms or so (25-volt scale). Be sure that the positive output terminal of the bias supply is connected to the grounded side of the 115-volt line, using the lamp provided for checking as described in July QST. In using a single instrument in place of the three indicated, the push-button should be closed each time the plate voltage is measured so that the voltage will be that existing when plate current flows.

the behavior of the tube when an alternating voltage is applied is of more interest, in which case the a.c, plate resistance, or resistance effective to small changes in applied voltage, is important. The value of this plate resistance is found as described in the introduction to this installment.

When a load resistance is inserted in the plate circuit the linearity of the circuit consisting of the resistance and the tube is better than that of the tube alone. This improvement, which increases as the load resistance is increased, is because the load resistor tends to reduce the effect of variations in the resistance of the tube. For example, if the resistance of the tube varies between 1000 and 3000 ohms with a

certain range of applied voltage the resistance change is 2000 ohms, or an increase of 200%, using the smaller number as a base, If a 10,000-ohm resistor is connected in series, the minimum resistance becomes 11,000 ohms and the maximum resistance 13,000 ohms, so that the increase in resistance is now only 2000/11,000, or 18%. With 100,000 ohms in series, the increase is from 101,000 to 103,000 ohms, so that the percentage increase is now 2%. In the curves of Fig. 3 the addition of the load resistance makes all the points fall on a line which is practically straight except at the low voltage end where the tube resistance has its highest value. The higher the load resistance the less marked does this slight curvature become.

In taking data it will be observed that a small current flows in the plate circuit even at zero plate voltage.

This current is the result of the fact that some electrons are emitted from the cathode with sufficient velocity to reach the plate even though there is no positive charge on the plate to attract them. For complete cut-off of plate current

it would be necessary to make the plate a volt or two negative with respect to the cathode, thus repelling these high energy electrons from the plate. Since the current in any case is very small - a very

within conduction-time limits. Consider a switch in series with a fixed resistance and any number of other circuit elements connected to a battery of fixed voltage. The d-c current and rms current which flow in this circuit will depend on the time intervals during which the switch is closed and open; the resistance value is not obtainable from these current values and the battery voltage. The correct value is obtained only when the current and voltage drop in the resistance are measured during the time angle φ (Fig. 2) when the switch is closed.

The method of analysis of rectifier circuits to be discussed in this lecture is based on the principle that the non-linear effective resistance of the diode may be replaced analytically by an equivalent fixed resistance which will give a diode current equal to that obtained with the actual non-linear diode resistance. The correct value to be used for the equivalent fixed resistance depends upon whether we are analyzing for peak diode current, average diode current, or rms diode current. As will be seen later, the relations among these three equivalent resistances depend upon the circuit under consideration.

2. Definitions of Resistance Values

The instantaneous resistance (r^) of a diode is the ratio of the instantaneous plate voltage e^, to the instantaneous plate current, ip, at any point on the characteristic measured from the operating point (see Fig. 1). It is expressed by the equation

$$r_d = \frac{e_d}{i_p}$$

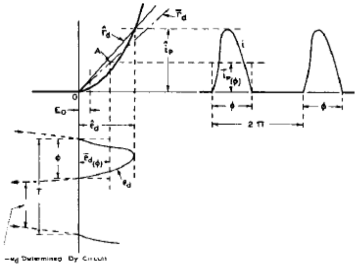

Fig 2

The operating point (0) of a diode is a fixed-point on the characteristic, marked by beginning and end of the conduction time. It is, there-fore, the cut-off point Id = 0 and Ed = 0, as shown in Fig. 1. The operating point is independent of the waveform and of the conduction time φ (see Fig.2).

The peak resistance (¾) is a specific value of the instantaneous resistance and is defined as

$$\hat{r}_d = \frac{\hat{e}_d}{\hat{i}_p} \quad \text{(See Fig.2)}$$

Peak voltage e<j and peak current ip are measured from the operating point 0.
The equivalent average resistance (rd) is de-fined on the basis of circuit performance as a resistance value determining the magnitude of the average current in the circuit. The value r^ is, therefore, the ratio of the average voltage drop β(}(φ) in the diode during

necessary to make provision for closing the plate circuit of the v.t.v.m. when the meter is being used elsewhere.

The observed data should be plotted in the fashion shown in Fig. 4, which gives characteristic curves taken on a 6H6. With no load the current is quite high, reaching 10 milliamperes with about 7.5 volts applied. Other types of tubes may give considerably different plate current values without load, but should approximate the load curves given since the current which flows at a given voltage is principally determined by the load resistance rather than the tube. As is to be expected, the current decreases, at a given applied voltage, as the load resistance is increased.

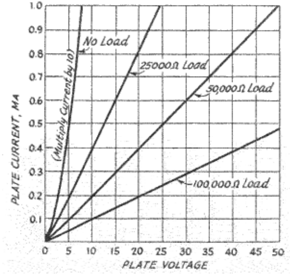

Fig 4

If the no-load curve is inspected carefully, it will be observed that it is not a straight line, particularly near the low-voltage end. The lamp in Exp. 10 was another example of a non-linear circuit, although for a different reason. In the present case, the nonlinearity arises from the fact that the number of electrons drawn to the plate is not strictly proportional to the voltage applied between plate and cathode, The d.c. resistance of the diode at any voltage is equal to that voltage divided by the current which it forces through the tube. In practice

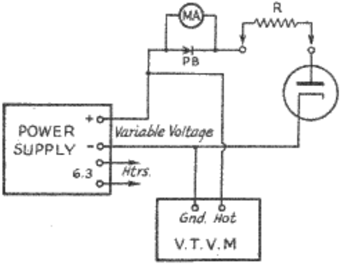

Fig 3.

Procedure: The object of the experiment is to plot characteristic curves, plate voltage vs. plate current for the tube alone (static characteristic) and with various values of load resistance in series with the plate circuit (dynamic characteristics). Starting at zero plate voltage, increase the plate voltage in small steps, taking plate current readings at each voltage step. With no load resistor in the circuit, take readings at intervals of voltage which will give current intervals of about 1 milliampere so that enough points will be secured to give a smooth curve when the points are plotted. In the case of the 6H6 tube, using one plate and cathode only, one-volt intervals are suitable. Proceed similarly when the load resistance is inserted in the circuit; in this case larger voltage intervals (5-volt steps, for instance) can be used

In using the single test set for all measurements. the pushbutton should be closed while the voltage measurement is being made so that the voltage can be adjusted to the proper value with plate current flowing. If the plate circuit is not closed at the time the voltage is adjusted, the voltage will drop when the milliammeter is connected in the plate circuit of the tube to measure plate current. It is not

conduction time to the average current ip(<p) during conduction time, or

$$\bar{r}_d = \frac{\bar{e}_{d(\varphi)}}{\bar{i}_{p(\varphi)}}$$

The curved diode characteristic is thus replaced by an equivalent linear characteristic having lie slope ?d and intersecting the average point A, as shown in Fig. 2. The coordinates ed(q>) and ip (φ) of the average point depend on the shape of voltage and current within the time angle φ.

The analysis of rectifier circuits shows that the shape of the current pulse in actual circuits varies considerably between different circuit types. The equivalent rms resistance (|r^I) is de-fined as the resistance in which the power loss Pd is equal to the plate dissipation of the diode when the same value of rms current II^I flows in the resistance as in the diode circuit. It is expressed by the equation:

$$|r_d| = \frac{P_d}{|I_d|^2}$$

3. Measurement of Equivalent Diode Resistances The equivalent resistance values of diodes can be measured by direct substitution under actual operating conditions. The circuit arrangement is shown in Fig. 3. Because the diode under test must be replaced as a whole by an adjustable resistance of known value, a second switch (a mercury-vapor diode identified in the figure as the ideal diode) with negligible resistance must be inserted in order to preserve the switch-action in the circuit.

Fig. 3 - Half-wave circuit for measuring (d)\> rd, and |rd|.

When a measurement is being made, the resistor Rd is varied until the particular voltage or cur-rent under observation remains unchanged for both positions of the switch S. We observe (1)that it is impossible to find one single value of 1¾ which will duplicate conditions of the actual tube circuit, i.e., give the same values of peak, average, and rms current in the circuit;(2) that the ratio of these three "equivalent" resistance values of the diode varies for different combinations of circuit elements; and (3)that equivalent average or rms substitution resistances may have different values when the average cr rms current in the diode circuit is adjusted to the same value in different types of rectifier circuits. The "peak resistance" value obtained for a given peak current is found to be substantially independent of the type of circuit.

$$\hat{r}_d = \bar{r}_d = |r_d|$$

Diode Characteristics

A Course in Radio Fundamentals
Lessons in Radio Theory for the Amateur
By George Grammer, W1DF
http://www.rfcafe.com/references/qst/radio-fundamentals-vacuum-tubes-sep-1942-qst.htm

Experiment 21

Apparatus: This experiment uses the plate power supply, tube board, test set, vacuum-tube voltmeter, and three 1- watt resistors, 25,000, 50,000 and 100,000 ohms. The circuit arrangement is shown in Fig. 3. Measurements must be made of the voltage applied to the tube and the current flowing in its plate-cathode circuit; the single test instrument can be used for both purposes by being shifted back and forth for each pair of readings. However, the small current consumed by the instrument when used as a voltmeter will cause the actual output voltage to be lower when the voltage is being measured than when the instrument is shifted to read plate current. Unless a separate voltmeter which can be left permanently in the circuit is available, it is advisable to use the v.t. voltmeter, thus avoiding the loading effect. The test instrument is therefore shifted between the plate circuit of the tube being tested and the plate circuit of the voltmeter tube.

The tube to be tested may be a 6H6, the diode section of a combination diode-amplifier tube, or simply a small triode such as the 6J5 with the grid and plate connected together to act as a single plate.

Λ. Waveforms and Equivalent Resistance Ratios for Practical Circuit Calculations

The form of the current pulse in practical rectifier circuits is determined by the power factor of the load circuit and the phase number. Practical circuits may be divided into two main groups: (a) circuits with choke-input filter; and(b) circuits with condenser-input filter. The current pulse in choke-input circuits has a rectangular form on which is superimposed one vapor diodes.

Table I

CONDUCTION TIME ANGLE φ	WAVE SHAPE	$\frac{\bar{i}_{p_\varphi}}{\hat{i}_p}$	$\frac{\lvert i_p\rvert_\varphi}{\hat{i}_p}$	3/2-POWER RECTIFIER CHARACTERISTIC			RECTANGULAR CHARACTERISTIC		
				$\frac{\bar{e}_{d_\varphi}}{\hat{e}_d}$	$\frac{\bar{r}_d}{\hat{r}_d}$	$\frac{\lvert\bar{r}_d\rvert}{\hat{r}_d}$	$\frac{\bar{e}_{d_\varphi}}{\hat{e}_d}$	$\frac{\bar{r}_d}{\hat{r}_d}$	$\frac{\lvert\bar{r}_d\rvert}{\hat{r}_d}$
CONDENSER-INPUT CIRCUITS									
≦ 20°		0.500	0.577	0.593	1.185	1.120	1.0	2.00	1.500
90° & 180°		0.637	0.707	0.715	1.120	1.057	1.0	1.57	1.272
130°		0.725	0.780	0.787	1.085	1.030	1.0	1.38	1.190
CHOKE-INPUT CIRCUITS									
180°		1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0

In this table, the designation the rms value of the current i-ρΐφ represents the rms during the conduction time. It follows that the relation

$$\hat{r}_d = 0.88\ \bar{r}_d = 0.93\ |r_d|$$

is representative for the group of condenser-input circuits containing high-vacuum diodes, and holds within ± 5 per cent over the entire range of variation in wave shape. The actual error In circuit calculations is smaller, as the diode resistance is only part of the total series resistance in the circuit.

EMISSION AND SATURATION OFOXIDE-COATED CATHODES

1. Oxide-Coating Considerations

The normal operating range of diodes (including instantaneous peak values) is below the saturation potential because the plate dissipation rises rapidly to dangerous values if this potential is exceeded. Saturation is definitely recognized in diodes with tungsten or thoriated-tungsten cathodes as it does not depend on the time of measurement, provided the plate dissipation is not excessive. The characteristic of such diodes is single-valued even in the saturated range, i.e., the range in which the same value of current is obtained at a given voltage whether the voltage has been increased or decreased to the particular value.

Oxide-coated cathodes have single-valued characteristics up to saturation values only under certain conditions. The cathode coating has resistance and capacitance, both of which are a function of temperature, current, and the degree of "activation," and vary during the life of the tube. The conception of a "coating impedance” is essential in explaining many peculiar effects observed when testing and operating oxide-coated diodes in rectifier circuits and will be treated briefly.

The cathode coating is usually a mixture of carbonates (barium, strontium, calcium) which are "broken down" into oxides, metal atoms, and gases during the exhaust process. A highly emit-ting monatomic layer of barium on oxygen is formed on the surface of

If we substitute the values obtained in the Barkhausen equation we obtain

DSRi = 0.02*5.7*9.4 = 1.07 ~ 1.

Notes

Strictly speaking the anode voltage UA is always obtained from the applied voltage minus the difference between the electron work function voltages at the cathode phiC and the anode phiA:

UA = U – (phiA – phiC) .

Secondary phenomena caused by the Maxwellian velocity distribution of the electrons are also neglected.

The open-loop voltage gain μ = D^-1 is often quoted instead of the inverse amplification factor D.

When grid and anode are connected together, the greater part of the current flows through the grid.

B1 = 8.36 V^-1 (150 mA)
B2 = 9.84 V^-1 (140 mA)
B3 = 11.24 V^-1 (130 mA)

and hence the cathode temperatures T:

T1 = 1390 K (150 mA)
T2 = 1180 K (140 mA)
T3 = 1030 K (130 mA)

The most probable velocities at different cathode temperatures are then:

vp (T1) = 204 · 10^3 m s^-1
vp (T2) = 189 · 10^3 m s^-1
vp (T3) = 177 · 10^3 m s^-1

2. Fig. 6 shows the triode control characteristics measured. If we take working point A (UA, IA, UG) in the linear portion of the family characteristics we can determine all the characteristics of the tube. For A (100 V, 20 mA, 1 V) we obtain

S = 10 mA/V

for the “slope” S (gradient of the curve at point A).

The inverse amplification factor D is obtained by going from the 150 V to the 50 V characteristic through A and parallel to the UG-axis and reading off

– dUG/dUA , from which D = 0.018.

To obtain the tube resistance Ri, we go from the 50 V to the 150 V characteristic through A and parallel to the IA-axis and read off

dUA/dIA, from which Ri = 5.85 kohms.

the coating, which, when heated, supplies the electron cloud forming the space charge above the coating surface (see Fig. 4) ·The» coating itself consists of non-conducting oxide clumps or crystals (shown as shaded areas)interposed with metal atoms and ions (circles),which axe produced by high cathode temperature and electrolysis during the activation and aging process of the cathode.

The distances between these metal atoms or atom groups are very small. The current flow from the base material through the coating is effected by relay-emission from atom to atom or particle to particle under the influence of electrostatic potentials. The coating is not con-ducting when cold. Electronic conduction through the coating is high when many metal relay chains, not broken by insulating oxides, have been formed,

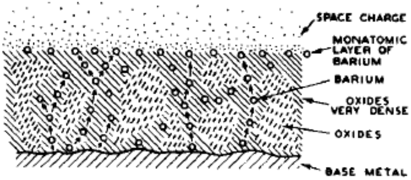

Fig. 4 - Structure of cathode coating.

and also when the electron emission is raised as a result of loosening the atomic structure by increased temperatures. Hence, the coating conductance may be represented by a large number of extremely close-spaced diodes in series-parallel arrangement, as shown in Fig. 4a

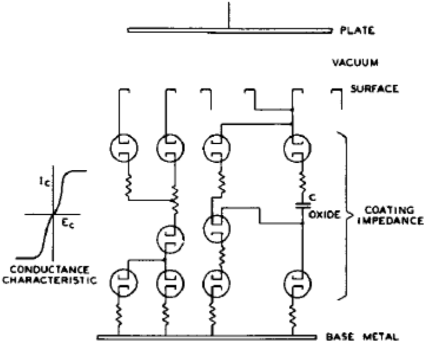

Fig. 4a - Representative diode network.

The coating activation is good when a fully emitting surface layer can be saturated without limitation of electron flow in the coating. This condition is indicated by a single-valued characteristic up to and beyond the saturation potential as shown in Fig. 5. In general, single-valued characteristics are obtained if the surface saturates before the coating conductance be-comes limited. (See temperature—limited conditions in Fig. 5).

The conductance of the coating may, however, limit the electron flow before the surface emission is saturated, and cause a peculiar voltage-current characteristic. Consider a high plate

where No is the total number of electrons and m (the restmass of the electron) is 9.11*10E-31 kg.

From this we obtain the most probable velocity

vp = sqrt4/pi * vp

and the mean velocity

vm = sqrt4/pi * vp

By fitting to exponential curves, using the expression

IA = A * e^B*UA

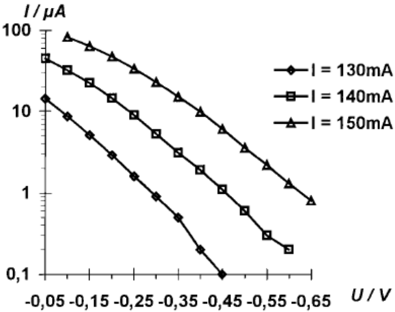

Fig. 5: Initial current of the diode at different heater currents.

we obtain from the measured values in Fig. 5 the exponents B, as follows:

The gradient of the IA/UG characteristic at working point A is called the “slope” S or “mutual conductance”:

$S = dIA/dUG$ at constant UA .

We obtain likewise the tube resistance Ri at working point A and at constant grid voltage:

$Ri = dUA/dIA$ at constant UG .

These three variables are interrelated by the Barkhausen equation (the “tube equation”):

$DSRi = 1$

1. If we plot the anode current against the (negative) and voltage semi-logarithmically in the initial current range of the diode we obtain a straight line of slope

$b = – e/kTc$ (cf. Fig. 5)

in accordance with

$\ln IA = \ln Io – |eUA/kTc|$,

where e = the electron charge = 1.60*10E-19 As, and k = the Boltzmann constant = 1.38*10E-23 VAsk^-1.

From this, we can calculate the cathode temperature

$Tc = – e/kB$.

For a Maxwellian distribution the electron velocites n are calculated in accordance with

$1/No\ dN/dv = 4/\sqrt{\pi}\ (m/2kT)^{3/2} * v^2 * \exp -mv^2/2kT$

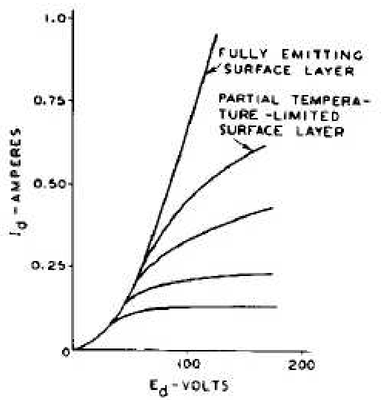

Fig. 5 - Single-valued saturation characteristic of diode with high coating conductance.

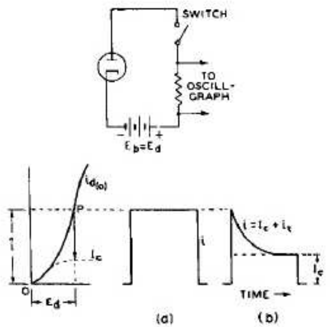
voltage suddenly applied over a periodic switch to a diode as in the circuit of Fig. 6. If the coating is not limiting, the current obtained is that at a point P on the corresponding diode characteristic. Hence, the current waveform in the circuit is as shown in Fig. 6a.



If the surface emission is assumed to be unchanged, but all free electrons have been moved. The oxide groups thus act like condensers in parallel to the coating resistance but with the peculiarity that their charge may be limited by hypothetical series diodes.

The coating resistance is extremely low* below saturation, due to the small spacing and high gradient in the "coating-diodes" but becomes in-finite when the conduction current is saturated; hence, the charging current must flow in the plate circuit (external) of the diode. The total plate current is, therefore, the sum of the conduction current Ic and the "transient" electron displacement current. The "coating transient” decays to zero like normal transients at a rate depending on the actual shunt conductance value and the total series resistance in the circuit(Fig. 6b). The decay can be changed by adding external resistance in the plate circuit. When the surface emission is good, i.e., as long as the total vacuum-space plate current is space-charge limited, the current will rise initially to the value

---

The emitted electrons first form round the cathode an electron cloud from which slow-moving electrons rebound and can thus return to the cathode. If we apply a positive voltage to the anode, some electrons are drawn out and the cloud becomes less dense as the anode voltage increases. In this part of the curve (space-charge region) the equation:

$IA = P \cdot UA^{3/2}$,

applies, where P = the tube constant.

As the anode voltage is increased still further, in the end all the electrons emitted from the cathode are collected, the space charge disappears and the tube reaches saturation. Changing the anode voltage no longer brings about a corresponding change in the anode current.

If we insert another grid-like elektrode between cathode and anode we obtain a three-electrode valve, or triode. The anode current can be controlled by a voltage applied between the grid and the cathode. But as it is controlled also (but to a lesser extent) by the anode voltage UA, the two voltages combine to give a resultant control voltage

$Uc = UG + D \cdot UA$.

The so-called “inverse amplification factor” D is a constant at a given working point A and is defined by

$D = dUG/dUA$ at constant IA .

Since electron tubes generally work in the space-charge region, the anode current is essentially expressed by the space-charge formula

$IA = P\,(UG + D \cdot UA)^{3/2}$

Theory and evaluation

We distinguish three different regions in the current/voltage characteristic of a vacuum diode: the initial current, space charage and saturation regions.

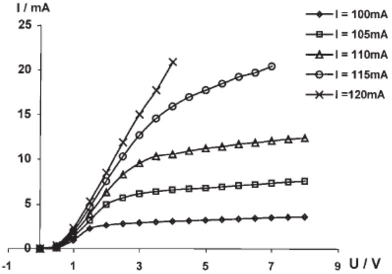


Fig. 4: Current/voltage characteristic of the diode for different heater currents.

A current still flows through the vacuum diode when the anode is negative with respect to the cathode $(UA < 0)$. This current, which is known as the “initial current”, bears the following relationship to the (negative) anode voltage:

$$IA = I0 \cdot \exp - |eUA/kT|.$$

The electrons contributing to this current still have, as the result of their Maxwellian velocity distribution, sufficient kinetic energy after they have left the cathode to surmount the anode field and reach the anode.

(point P) determined by the applied potential, but will then decay to the saturation value determined by the coating conductance.

The condition of oxide-coated cathodes can, therefore, not be judged alone by their capability of furnishing high peak currents, but the rate of change in current flow, and hence the current waveform, must also be carefully considered, because the diode characteristic may not be single-valued. Fig. 7 shows characteristics which are not single-valued. These were taken within 1/120 of a second (l/2 of a 60-cyclesine wave) with a cathode-ray curve tracer.

2. Current Overload and Sputter

The degree of activation is not stable during the life of the cathode. Coating conductance and surface emission change. Factors affecting the change are the coating substances, the evaporation of barium depending on the base material, and the operating conditions to which the cathode is subjected. This life history of the cathode is the basis on which current ratings are established. Rectifier tubes especially are subject to severe operating conditions. If a diode is operated with too high a current in a rectifier circuit and its surface emission is decreased to the saturation value, then the tube voltage drop will increase rapidly, and cause excessive plate dissipation and destruction of the tube. Should the coating conductance in this diode decrease to a value which limits the demanded current, power is dissipated in the now-saturated "coating-diodes," with the result that the coating voltage drop and coating temperature are raised. The temperature rise may cause reactivation but also may become cumulative and melt the coating mate—

* Its magnitude depends on the number of series diodes and, hence, on the barium content and thickness of the coating material.

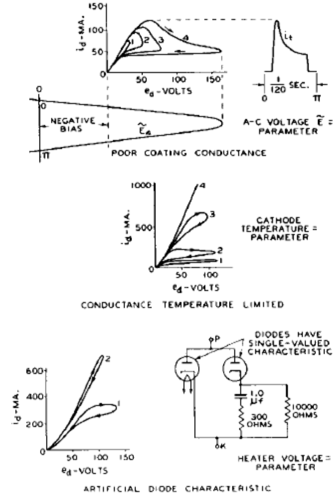

Fig. 7

Vapor or gas discharges may result from saturated coatings and cause breakdowns during the inverse voltage cycle. These breakdowns are known as "sputter," and destroy the cathode. Sputter of this type will occur more readily in diodes with long cylindrical electrodes and close spacing than in diodes with flat cathodes of narrow width and parallel—plane plates, because the activation gas can diffuse faster in the latter. A second type of sputter is caused by the in-tense electrostatic field to which projecting “high spots" on the

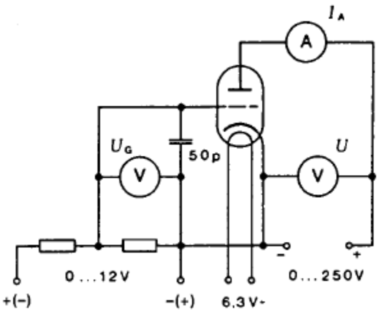

Fig. 3: Circuit for measuring the characteristic curves of a triode.

2. Construct the circuit shown in Fig. 3. As the tubes may oscillate in the VHF range if the wiring is not altogether satisfactory, connect a small capacitor between grid and cathode to short-circuit the high frequency.

Measure the anode current as a function of the grid voltage, both positive and negative, at various anode voltages (e. g. 50, 75, 100, 125, 150 V). Stop taking measurements as soon as the anode current exceeds 30 mA.

Because of the voltage drop across the internal resistance Ri of the ammeter, the anode voltage is represented by
$UA = U - IA \cdot Ri$

Plot the IA/UG-characteristics (control characteristics) on a graph.

Plot the initial current characteristics at different heater currents also. To do this, reverse the polarity on the voltage source and the voltmeter multimeter and measure the anode current with the microammeter (multimeter).

Because of the voltage drop across the microammeter (multimeter) the anode current UA is:

$UA = – (|U| + |IA \cdot Ri|)$

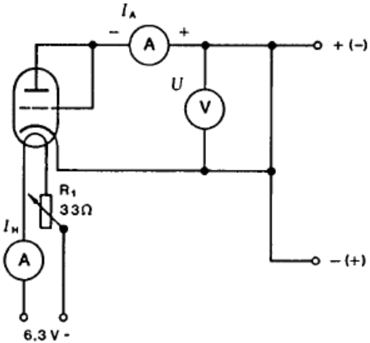

Fig. 2: Circuit for measuring the characteristics of a diode.

---

plate or cathode are subjected. These high spots are formed by loose carbon on the plate or large cathode—coating particles. The resulting current concentration causes these spots to vaporize with the result that an arc may be started.

3. Hot-Cathode Mercury-Vapor Diodes

The ionization potential Ej. of mercury vapor is a function of the gas pressure and temperature. It is approximately 10 volts in the RCA-83and similar tubes. A small electron current be-gins to flow at Ep = 0 (see Fig. 8), and causes ionization of the mercury vapor at Ep = Ej_. This action decreases the variational diode resistance Γρ to a very low value. The ionization becomes cumulative at a certain current value (rp = 0 at40 milliamperes in Fig. 8a), and causes a discontinuity in the characteristic. Hence, it is not single-valued within a certain voltage range. Beyond this range (see Fig. 8b), the slope (rp) of the characteristic becomes again positive until saturation of the emitter is reached.

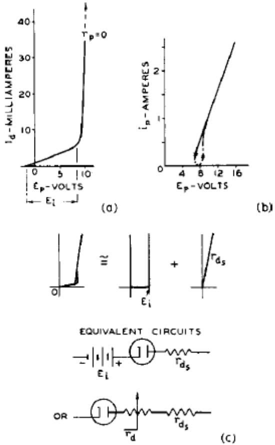

Fig. 8

For circuit analysis, the mercury-vapor diode may be replaced by a bucking battery having the voltage Ej_ and a fixed resistance,

$$r_{d_s} \cong \frac{\hat{e}_d - E_i}{\hat{i}}$$

as shown in Fig. 8c; or the diode characteristic may be replaced by an ideal rectangular characteristic and its equivalent resistance values and the series resistance rd^ as shown.

Characteristic curves of electron tubes (diode, triode)

PHYWE series of publications • Laboratory Experiments • Physics • PHYWE SYSTEME GMBH • 37070 Göttingen, Germany
http://www.nikhef.nl/~h73/kn1c/praktikum/phywe/LEP/Experim/4_1_10.pdf

Principle and task

The IA/UA-characteristic curve of a diode is recorded at different heater currents and the cathode temperature and electron velocity determined therefrom. Mutual conductance, inverse amplification factor and anode resistance are determined from the characteristic curve of a triode.

Problems

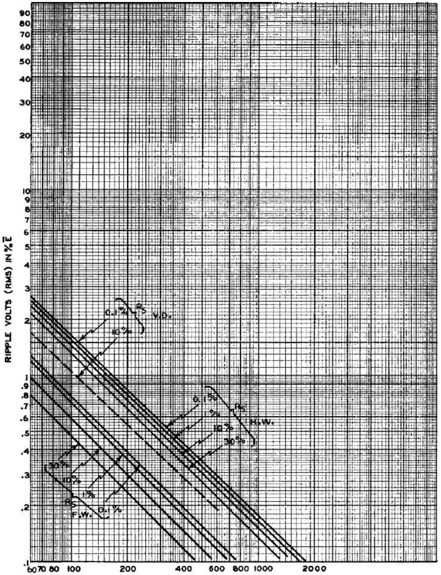
1. To measure the anode current of a diode as a function of the anode voltage at different heater currents and to plot it on a graph. To calculate the cathode temperatures and electron velocities from the initial current characteristics.

2. To record the anode current of a triode as a function of the grid voltage at different anode voltages. To determine the mutual conductance, inverse amplification factor and internal resistance of the tube at a working point in the linear portion of the characteristic.

Set-up and procedure

1. Construct the circuit shown in Fig. 2. Connecting the anode and the grid gives tube EC 92 (triode) the properties of a diode.
The heater current and thus the cathode temperature can be set with the potentiometer R1.

Measure the anode current IA as a function fo the anode voltage UA at different heater currents (150–110 mA) and plot the results on a graph. The voltage drop across the internal resistance Ri of the ammeter (multimeter) must be taken into account, so that UA = U–IA · Ri. Stop taking measurements
when IA becomes greater than 30 mA.



The first representation is advantageous when making approximate calculations, as the equivalent diode resistance is then the substantially fixed value rdg. The value rds is in the order of 4 ohms. The low series resistance and the small constant voltage drop Ei are distinct ad-vantages for choke-input filters, as they cause very good regulation; the low resistance, how-ever, will give rise to enormously high storting transients in condenser-input circuits, in case all other series resistances are also small. Mercury-vapor diodes as well as high-perveance (close-spaced), high-vacuum diodes having oxide cathodes should, therefore, be protected against transient-current overloads when they are started in low-resistance circuits to prevent destruction of the cathode coating. The destruction of the coating in mercury-vapor diodes is apparently caused by concentration of current to small sections cf the coating surface and not by heat dissipation in the coating.

CIRCUIT ANALYSIS

The rectifier diode is a switch operated in synchronism with the applied a-c frequency. The diode alternately opens and closes the circuit. This action causes a series of transients in re-active circuits. According to the decay time of the transients, fundamental rectifier circuits may be classified into two principal groups: (l)circuits with repeating transients in which the energy stored in reactive elements decreases to zero between conduction periods of the diode; and (2) circuits with chain transients in which(a) the magnetic energy stored in the inductance of the circuit remains above zero value, and (b)the electric energy stored in the capacitance of the circuit remains above zero value. The much used "choke-input" and "condenser-input" circuits fall under the second group.

The complete analysis of rectifier-circuit operation requires more time than this lecture provides. It is based on the fact that the total current in a circuit is the sum of all steady-state currents and transient currents within the time between two switching operations. We will analyze briefly the operation in two important circuits, i.e., the full—wave, choke-input circuit, and the condenser-input circuit.

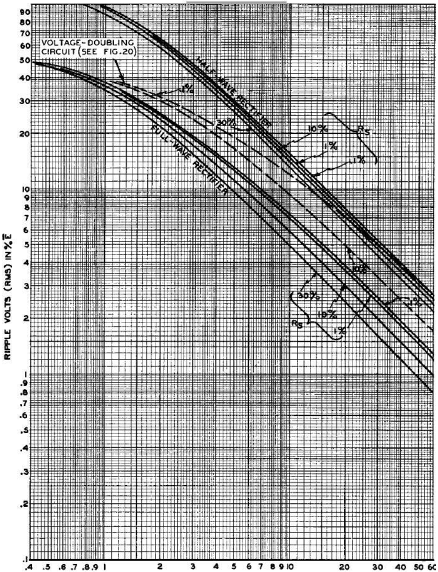
Fig. 9 - Full-wave choke-input circuit and its operation.

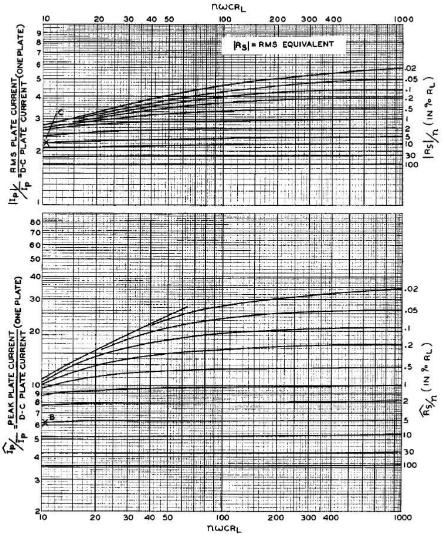
1. The Full-Wave Choke-Input Circuit

Circuit and operation are shown in Fig. 9. The construction is made by considering first one of the diodes shorted to obtain the phase relation of the a-c voltage e, and the steady-state current is, as shown. If we assume that the diode closes the circuit at the time e" = 0, a transient it with the initial value it0= -is(0) will flow in the circuit. The total current, i, is the sum of the currents is + 1¾. It starts, therefore, at zero and rises as shown until the second switching operation occurs at the commutation time t =η when the second diode receives a positive plate voltage. The total current, i,

RMS RIPPLE VOLTAGE OF CONDENSER INPUT LOAD CIRCUITS (lN ?°E) FOR VARIOUS VALUES OF Rs (GIVEN IN ?o R|_)
(MEASURED VALUES}



RELATIONS OF PEAK, AVERAGE, AND RMS DIODE CURRENT



after t = η is again the sum of currents xQ+ i-^, butte initial value if Q is increased by the value ï(π) still flowing in the circuit.

The current it0 increases, therefore, at every new switching time until the decay of the transient it(n) > during the time t = π, is numerically equal to the steady-state current rise 2Ïβ(0),as shown in Fig. 9* This leads to the equation for the final operating current at the n™ com-mutation time:

$$i_{n(\pi)} = - \tilde{i}_{s(o)} \frac{1 + \varepsilon^{-\frac{R}{2fL}}}{1 - \varepsilon^{-\frac{R}{2fL}}}$$

A broken line is shown connecting all commutation-current values. This line represents closely the average current I in the common circuit branch. The final average current ig, during the conduction time, and _the average current Iin the load resistance R, have the same value and are given by equation (7)_. The average plate current per diode is Ip =0.5I, since each diode conducts alternately, and passes a current pulse shown by the shaded area in Fig. 9. With the numerical values of the construction substituted in equation (7) and setting

$$\varepsilon^{-\frac{R}{2fL}} = 0.547$$

we obtain

$$i_{(n\pi)} = \bar{I} = 0.298 \text{ ampere.}$$

The described solution is illustrative in understanding starting and operating conditions of the choke-input circuit, but its accuracy is limited in cases of low power factor (large L or small R), since the decay terms in equation (7)become very small. The construction, however, shows the exact phase relations of current and voltage. The oscillogram in Fig. 10 was taken with the circuit values indicated in Fig. 9.

a. Critical Inductance — The analysis has shown that the transient currents in the particular case never decay to zero and are "chain transients.^ In practical circuits, the d-c load resistance R is shunted by a capacitance C. This does not affect the circuit performance, provided R does not increase beyond a critical value Rcr. Expressing this statement symbolically, we have

$$\bar{R} \leqq \bar{R}_{cr} = 1.5\ Z_{(2f)}$$

in which Z(2f) is the impedance of one branch circuit at double line-frequency. For large values of C,

$$Z_{(2f)} \cong 4\pi f L$$

$$\bar{R} \leqq 6\pi f L \quad \text{or} \quad L \geqq \frac{\bar{R}}{6\pi f}$$

$$L \geqq \frac{0.91\ |\tilde{E}|}{6\pi f\ \bar{I}}$$

where

$|\tilde{E}|$ = rms voltage of one-half the secondary winding

and

$\bar{I}$ = d-c load current.

The relation of equation (9) is characterized by the fact that the current i in the final operating condition (Fig. 9) has an a-c component which is so large that 1 becomes zero at one instant. Any further increase of this component caused by

discharged in series with the other condenser during the time of non-conduction of its associated diode. The analysis of operation is made according to the method discussed but will not be treated.

the reversed problem to determine the magnitude of the applied voltage necessary to give a certain average voltage output for a given load. The series-resistance value Rg includes the equivalent average resistance rd

of one diode and the power-transformer resistances as reflected into one secondary winding. The characteristics were plotted from accurately measured values as their complete calculation required too much time. The measurements were made cti circuits of negligible inductive reactance. Series resistance values were determined accurately by the method shown in Fig. 2. Table II gives a number of calculated values which show the accuracy of the curves to be approximately 5 per cent or bet-ter.

In compiling the data for the current-ratio characteristics in Fig. 21, it was found that the three rectifier-circuit types could be shown by single family after a "charge factor" η was added to the_ product of the circuit constants ωl and to Rg as shown in Table II. The factor η is unity for the half-wave circuit. For the full-wave circuit, η is 2 because the condenser C is charged twice during one cycle. For the voltage-doubling circuit, η is 1/2 because the two condensers require together twice the charge to deliver the same average current at double voltage. The values in the table indicate that the factor η is actually not a constant. The mean value of the current ratios does, however, not depart more than approximately 5 per cent from the true value, the error being a maximum in the steep portion of the curves and decreasing to zero at both ends. The upper section of Fig. 21 shows the ratio of rms current to average current per diode plate. This family is of special interest in the design of power transformers and for computation of diode plate dissipation.

Fig. 22 shows the rms value of the ripple voltage across R^ in per cent of the average voltage.

The voltage-doubling circuit shown with the other two condenser-input circuits in Fig. 17 maybe regarded in principle as a series connection of two half-wave rectifier circuits. Each con-denser is charged separately during conduction time of one diode, but is

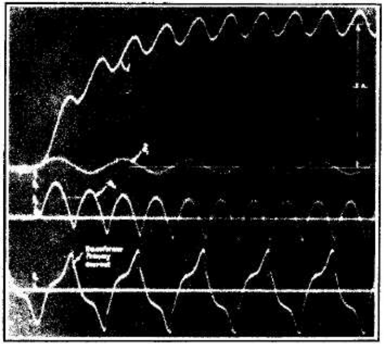

Fig. 10 - Oscillogram taken with circuit values in Fig. 9.

decreasing L still further will, therefore, open the diode circuit and hence interrupt chain-cur-rent operation. The circuit then becomes a type of condenser-input circuit and the output voltage E rises beyond the value given by the equivalent circuit for the chain-current operating range.

b-_Equivalent Circuit _for__ the Chain-^ur-rent_0^erating_Range — Commutation of the cur- rent in the chain-current range occurs at the instant when the supply voltage passes through zero. The voltage energizing the common branch of choke-input rectifier circuits has the form of a_ commutated sine wave for any load value R = Rcr· Since the circuit is never interrupted, currents and voltages may be considered steady-state components in a circuit energized by the equivalent commutated sine voltage as shown in Fig. 11a. The single generator in Fig. 11a may

Line voltage induced in one-half of the secondary winding (rms)	$\lvert\tilde{E}\rvert = 1.1\ \bar{E}$
Total average voltage	$\bar{E} = \begin{cases} 0.90\ \lvert\tilde{E}\rvert \\ 0.637\ \tilde{e}_{max} \end{cases}$
Voltage of frequency 2f (rms)	$\lvert\tilde{E}\rvert_{2f} = \begin{cases} 0.424\ \lvert\tilde{E}\rvert \\ 0.471\ \bar{E} \end{cases}$
Voltage of frequency 4f (rms)	$\lvert\tilde{E}\rvert_{4f} = \begin{cases} 0.085\ \lvert\tilde{E}\rvert \\ 0.0945\ \bar{E} \end{cases}$
Total choke voltage (rms)	$\lvert E\rvert_L = \begin{cases} \sqrt{\lvert\tilde{E}\rvert^2 - \bar{E}^2} \\ 0.482\ \bar{E} \end{cases}$

The current components in the common circuit branch are calculated from the above volt-ages divided by the impedance of one branch-circuit at the particular frequency. Because the current is commutated every half-cycle of the line frequency from one to the other branch-circuit, the average current in each diode circuit is one-half of the total average current; and rms values of currents or current components in each branch-circuit are obtained by multiplying the rms current values in the common circuit branch by 1/ /2. The peak current in each diode circuit has the same value as in the common circuit branch.

Average load current $\bar{I} = \dfrac{\bar{E}}{R_s + R_L}$

Average plate current (per diode) $\bar{I}_p = 0.5\ \bar{I}$

Double-frequency current (rms) in common circuit branch $|\tilde{I}|_{2f} = \dfrac{|\tilde{E}|_{2f}}{Z_{(2f)}}$

Total current (rms) in common circuit branch $|I|_L = \sqrt{\bar{I}^2 + |I|^2_{2f}}$

Rms diode current or rms current per transformer winding $|I|_d = \dfrac{|I|_L}{\sqrt{2}}$

Peak diode current $\hat{i}_d = \bar{I} + (|\tilde{I}|_{2f} \times \sqrt{2})$

The total power dissipated in diode and load circuits of the practical secondary circuit shown in Fig. 11c is the sum of the power losses in the circuit resistances. In equation form, it is

Total Power = Series-Resistance Loss
+ Choke-Core Loss
+ D-C Power in Load

The plate dissipation per diode is given by:

$$P_d = 0.5\ |I|^2_L \times |r_d|$$

$$P_d = 0.5\ |I|^2_L \times \frac{\bar{e}_d}{\bar{I}}$$

CENTER-TAPPED A-C VOLTAGE SOURCE

The regulation of choke-input circuits is determined by the_ total series resistance Rg, since the voltage E in the circuit is constant in the useful working range for an energizing-c voltage of constant value._ Thus, the regulation curve has the slope Rg (see Fig. 12),which includes the diode resistance.

The curve is correct for constant voltage e and beyond the critical-current value. In practical circuits, the voltage source e has a certain equivalent resistance, which must be added to r2. The equivalent internal resistance of the rectifier circuit as a d-c supply source is the slope of the regulation curve at the current value under consideration. This value should be used for steady-output conditions only, since the reactance in the load circuit cause transients at the instant of sudden load changes.

2. The Condenser-Input Circuit

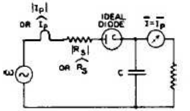
In rectifier circuits with shunt-condenser-input loads, the condenser is alternately charged and discharged. In the final state of operation, charge and discharge are balanced. The graphic analysis of such circuits is comparatively simple and readily followed. Formulas for the calculation of specific circuit conditions are easily derived from the constructions.

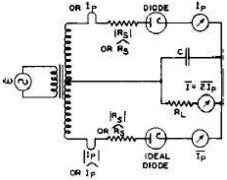
a._Circuits. _Without_ Series Resistance_ —
The graphic analysis of a half-wave rectifier circuit without series resistance (Rs) is illustrated in Fig. 13· Steady-state voltage e and current is are constructed on the assumption that the diode is shorted. The steady-state condenser voltage e'c coincides with e" because Rg = 0.
The diode timing is as follows: The diode opens the circuit at point 0 when the diode cur-rent becomes zero. The condenser voltage at this instant has the value

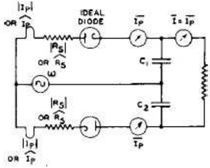
$$e_{C(o)} = \tilde{e}_{max} \sin \Theta$$

Since the condenser-discharge circuit consists of C and l, the condenser voltage decays exponentially as shown. At point C it has become equal to the energizing voltage e'. The diode be-comes conducting and closes the circuit. Because there is no potential difference between the steady-state voltages e and ec at this or any instant, the condenser does not receive a transient charge. The current, therefore, rises instantly to the steady-state value as shown on the i s curve and then decreases until it is zero at point 0.

(sine wave) for half-wave, full—wave, and voltage-doubling circuits. They permit the solution of







these transients analytically but the method is too involved to discuss in this lecture. The transients e-t and 1¾ in Fig. 15a prevent voltage and current from following the steady-state wave-forms. When Rg is large, they do not decay to zero within one cycle and, therefore, require additional steps in the graphic solution. The oscillogram shown In Fig. 16 checks the graphical construction of Fig. 15·

Fig. 16 — Oscillogram verifying graphical construction of Fig. 15·

c Generalized _operation__ Characteristics^{Steady-State^ Operation) — It has been shown that the conduction angle φ is a function of the circuit constants in condenser-input circuits. The section of the energizing voltage e utilized during conduction time has, therefore, no fixed value as in choke-input circuits where φ = 180°and where the voltage e during φ is a half-sine wave. It is, therefore, not possible to derive general equivalent circuit for condenser-input circuits which contains a voltage source of fixed wave shape and magnitude.

Steady-state conditions as well as transients are controlled by the circuit constants, which are contained in the product wl, The angle φ depends on the relative magnitudes of R^ and Rg and is, therefore, described in general is also the ratio s /^l^3^1011"1· General curve families may thus _be evaluated which show the dependent variables E, i, and I in terms of ratio versus the independent variable coCR^ various parameter values Rg/R^. The series resistance Rg includes the equivalent diode resistance which is evaluated by means of equation (6), because the current wave is periodic in the final operating state. The reasoning leading to equation(6) is not applicable to a single transient, as obtained for starting conditions of rectifier circuits.

Generalized characteristics have been evaluated for the three types of circuits shown in Fig. 17. The characteristics in Figs. 18, 19, and20 show the average voltage E across the load resistance Rl as a function of co CRt and Rg in per cent of the applied a-c peak voltage

The timing of the full-wave circuit in Fig.1Λ is quite similar. The time for the condenser discharge through l is reduced since e0 meets the positive half-cycle 6¾ and thus closes the circuit through D2· Point C in Fig. 14. is located at a higher value of e than in Fig. 13· The conduction angle φ is consequently reduced al-though C, R l, and Θ have the same values in both circuits. The average current in the full-wave circuit is, therefore, smaller than twice that of the half-wave circuit.

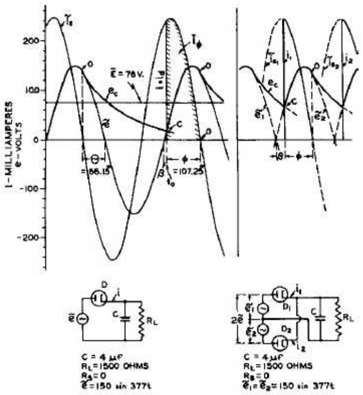


Fig. 13 (left) - Half-wave, condenser-input circuit without series resistance.

Fig. 14 (right) - Full-wave, condenser-input circuit without series resistance.

b. Circuits With_ Series _ Resistance —

In circuits with series resistance, the steady-state condenser voltage ec does not coincide with the supply voltage e, as illustrated in Figs. 15a and15b. Phase displacement and magnitudes of cur-rent and voltage under steady-state conditions are required for analysis of the circuit and are computed in the conventional manner. The parallel circuit C II Rj, is converted into an equivalent series circuit to determine the angles Θ and©' lay which Γ8 is leading e and ec, respectively. The steady—state condenser voltage Za in the parallel circuit equals the voltage across the equivalent circuit as shown by the vector diagram in Fig. 15b.

The diode opens the circuit at the instant id = 0. For circuit constants as in Fig. 15, the diode current id substantially equals Γ3 at the time of circuit interruption because the transient component i^' of the current has decayed to a negligible value. Point 0 is thus easily located. In circuits with large series resistance, however, id = 0 does not coincide with ïβ=0 due to slow decay of the transient. In both cases the condenser voltage each (0) equals the voltage (o) at the time 0, because id = 0 and consequently there is no potential difference on Rg. The condenser voltage decays exponentially ai Rj, from its Initial value at 0, as discussed for circuits with Rg = 0, and meets the supply voltage e" against point C. At this instant (tQ), the diode closes the circuit. Current and voltage, however, do not rise to their steady-state values as in circuits with Rg = 0, because the steady-state volt-age e"c(o) differs from the line voltage e(0) by the amount e"c(0) = ^s(o)x%· This demanded potential change on the capacitance causes transients. It is possible to determine the value of

JC Bose patents radio wave detector, September 30, 1901

Jessica MacNeil -September 30, 2017

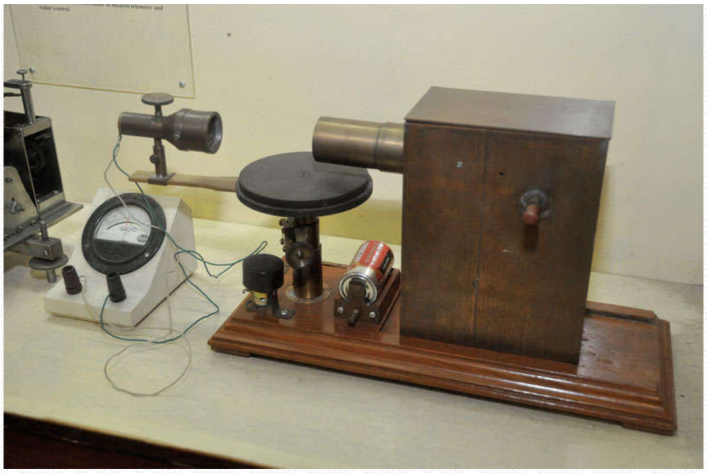
1 Comments

Share G+ Tweet Like 18

James Clerk Maxwell's **equations** predicted the existence of electromagnetic waves of diverse wavelengths in the 1860s, and in 1888 Oliver Lodge and Heinrich Hertz verified it, along wires and in free space. After reading about their experiments, JC Bose, a professor of physics at Presidency College in Calcutta, India, reduced the waves to about 5mm to study them.

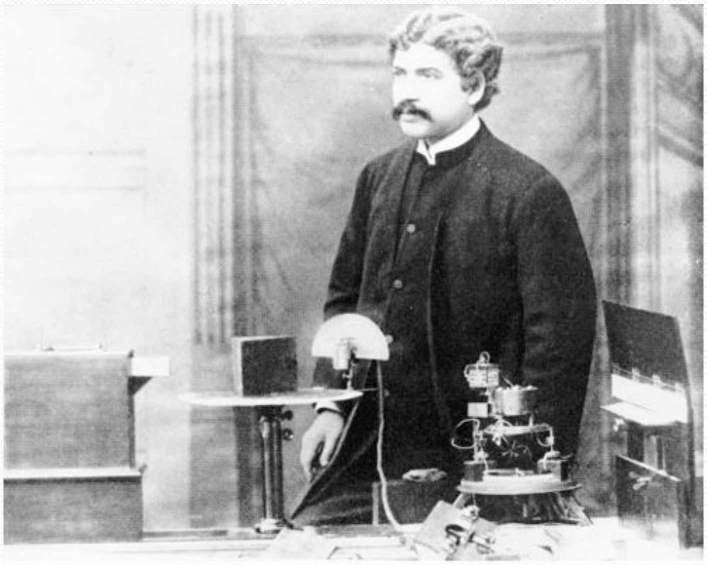
He developed the use of galena (lead sulfide) crystals contacted by a metal point for detecting millimeter electromagnetic waves, and filed patent 755840, for a "**Detector for electrical disturbances**" in 1901. It was the first device to use a semiconductor junction to detect radio waves.

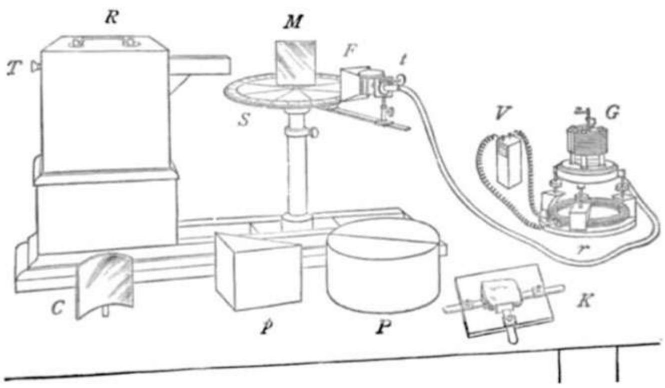
Bose created a portable device to study the optical properties of short waves, which incorporated the earliest waveguide and horn antenna. It would be more than 30 years before more research and analysis was done with the now widely-used horn antennas. His use of dielectric lenses, polarizers, prisms, and semiconductors at frequencies as high as 60 GHz, were also well ahead of his time.



Bose's 60-GHz microwave apparatus at the Bose Institute in Kolkata, India.
Source: Wikipedia user Gangulybiswarup

In a 1895 demonstration, he used electromagnetic waves to ignite gunpowder and ring a bell from a distance, reported to be nearly a mile. In 1897 Bose presented his microwave experiments at the Royal Institution in London (see the photo and diagram below).





R, radiator ; S, spectrometer-circle ; M, plane mirror ; C, cylindrical mirror ; p, totally reflecting prism ; P, semi-cylinders ; K, crystal-holder ; F, collecting funnel attached to the spiral spring receiver ; t, tangent screw, by which the receiver is rotated ; V, voltaic cell ; r, circular rheostat ; G, galvanometer.

He founded the Bose Institute in 1917 in Calcutta where some of his original instruments and devices are displayed. Bose spent much of his later career studying the effects of electromagnetic radiation on plants.

Much of Bose's component technology would eventually be used to develop microwave radio transmission. For his pioneering work in quasi-optic millimeter wave research, IEEE has called him the father of radio science. According to a 1997 *Microwave Symposium Digest* publication, "He developed an elegant millimeter wave spark transmitter, self recovering coherer detector, wire grid polarizer, cylindrical diffraction grating, dielectric lens and prism, rectangular waveguide, horn antenna and microwave absorber, for the studies of reflection, refraction, absorption and polarization of millimeter waves and its application to wireless remote control for firing a gun."

Jiri Polivka

J.C.Bose was really a wonderful genius! He was ahead of time with most of his ideas.
The sad part is that he worked in India, then a British colony. This fact caused that his wonderful work was "out of sight" in Europe nd the U.S. Then most of his ideas if ever found were stolen and copied. Others gained money while he used his modest wealth to establish the first college in India where math and physics were taught.

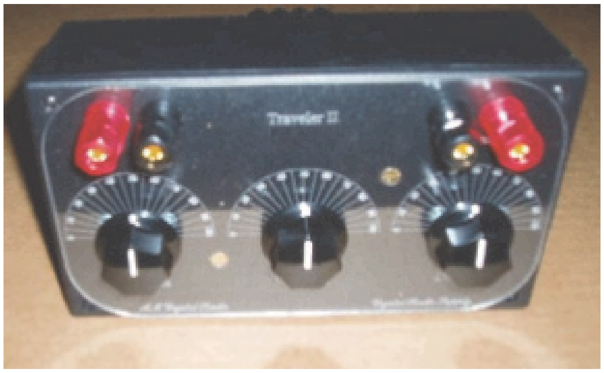
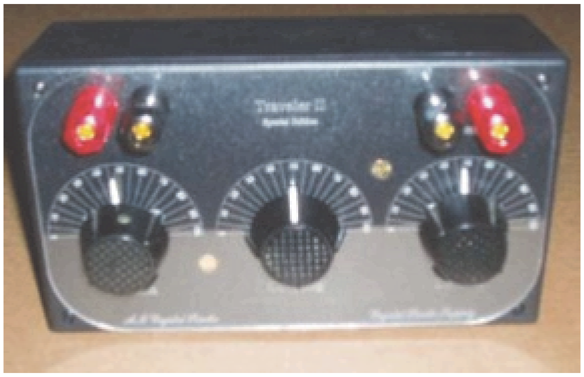
Introducing the Traveler II AM Band Crystal Radio

Traveler II



Traveler II
Special Edition



The Traveler II and the Traveler II SE are electronically the same radio. The only mechanical differences between the two sets are:

1. The Special Edition model uses an 8:1 planetary drive capacitor for the detector tuner, whereas the Traveler II uses a direct drive unit.

2. The Special Edition model uses a 6:1 dual-gang planetary drive capacitor for the antenna tuner, whereas the Traveler II uses a direct drive dual-gang unit

3. The Special Edition unit uses dial pointers and more expensive new old stock (NOS) knobs to take advantage of the additional band spread of the planetary drive capacitors.

Both Sets have the following features:

1. For portability, they are built in a tough ABS box that measures approximately 7-7/8" x 4-1/4" x 2-1/2". An assembled unit weighs approximately 1 pound and 10 ounces.

2. A cast acrylic dial plate that is reverse engraved (engraved on the back side of the dial plate so that there is no ink to wear off.

3. The high quality plated binding posts will accept many ways of making connections, including holes that will accept pins from the old-style magnetic headphones.

4. The 1/4" phone jack automatically switches the audio output from the binding post circuit, containing a 47 K resistor, to the phone jack when the headphones are plugged in. The binding posts work great for very high impedance headphones, such as the included ceramic earphone, while the phone jack can be used for lower impedance headphones or even a speaker – for those extra strong signals.

5. These sets use high Q ferrite Litz coils that are wound with 175/46 Litz wire and have a quality factor of 620 @ 790 KHz

6. The Traveler uses the very popular Tuggle front-end circuit that is valued for its fine selectivity.

7. Variable inductive coupling is provided, a feature seldom found on a receiver of this size.

8. Crystal Radio Supply's exclusive 2:1 reduction gear box provides a full 180 degrees of variable coupling for a 90 degree change in coil orientation. It is made from high quality Delrin gears and a marine-grade HDPE housing with all-brass hardware and a spring-temper bronze brake. This provides precise tuning as well as resetting of your inductive coupling when you return to a station.

Care of the Front Panel

The Front Panel on your Traveler II Crystal Radio Set is made from High Quality "Cast Acrylic". This grade of Acrylic is superior over other grades of acrylic and will still look beautiful after many years of service if the following simple precautions are observed:

1. Do not use paper towels to clean your front panel as this may cause scratches.

2. Use a soft cotton fabric such as that from a cotton T-shirt.

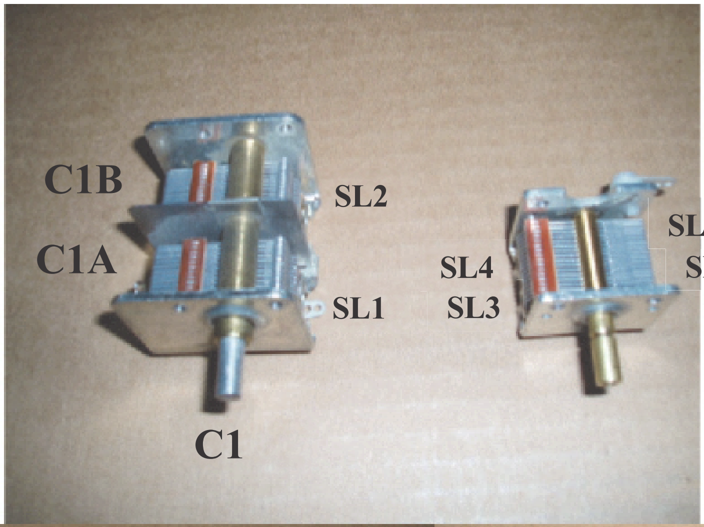
3. To remove fingerprints and smudges, clean your panel with isopropyl alcohol (rubbing alcohol) that can be found at most pharmacies.

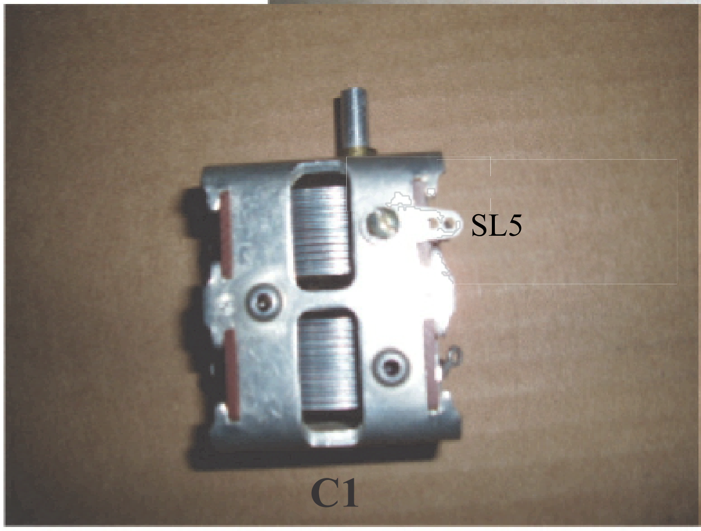
4. Do not use detergents.

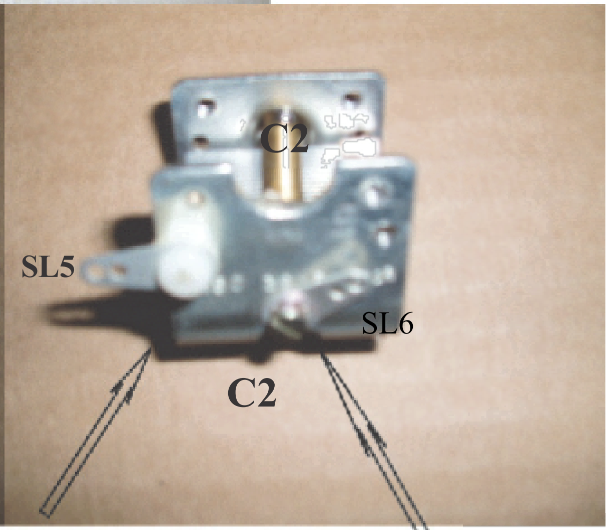
5. Do not touch the front of your panel; only handle it by the edges.

Assembly Instructions for the Traveler II Crystal Radio

Capacitor identification and preparation



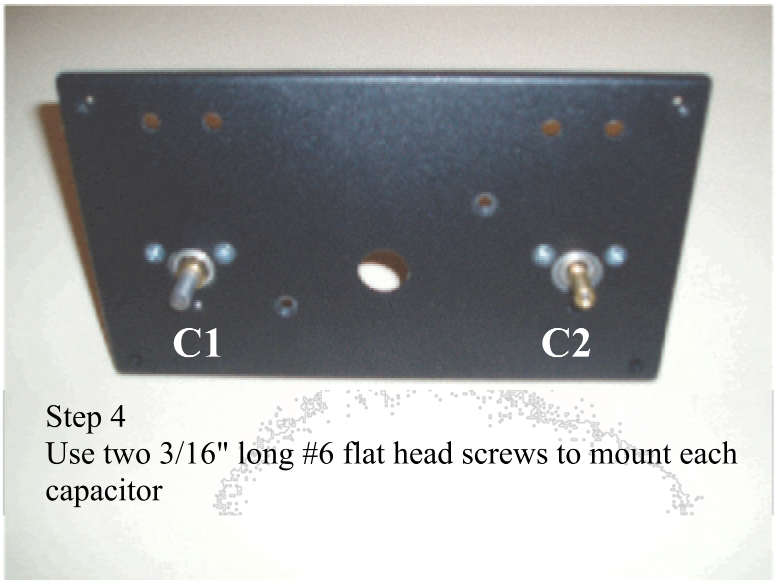




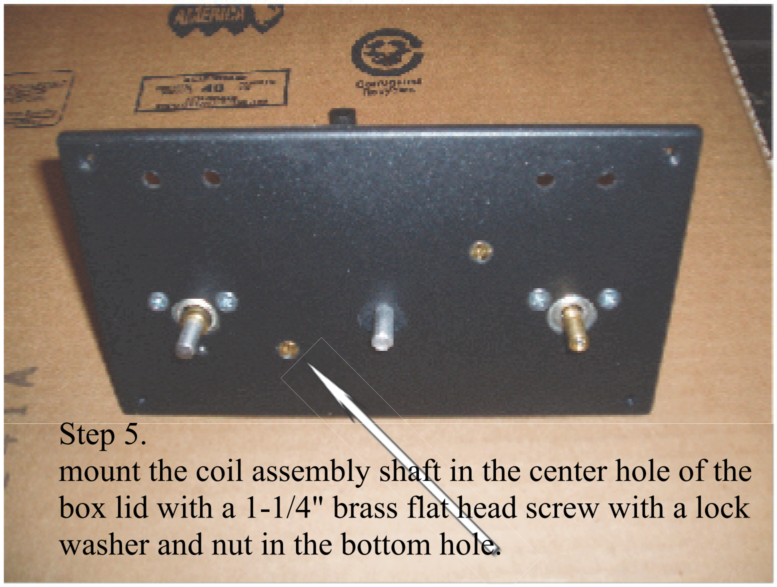
Step 1.
On the bottom of C1, install a #6 solder lug using a #6 fillister head screw. Fillister head screws are the ones with the thick round heads.

Step 2.
On the back of C2, mount a #6 solder lug on top of a 1/4" long nylon spacer using a 3/8" long #6 nylon screw.

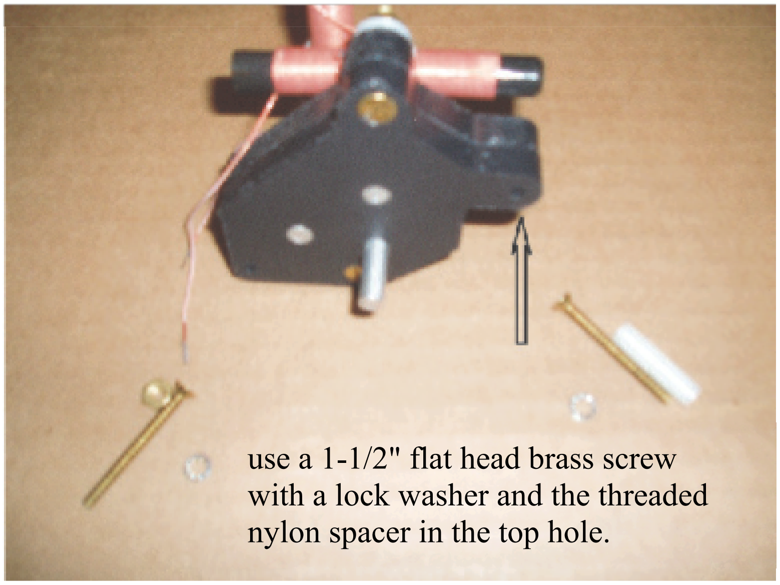
Step 3.
In the bottom center hole on the back of C2, install a #6 solder lug using a #6 fillister head screw. Bend the solder lug up slightly as shown.



Step 4
Use two 3/16" long #6 flat head screws to mount each capacitor



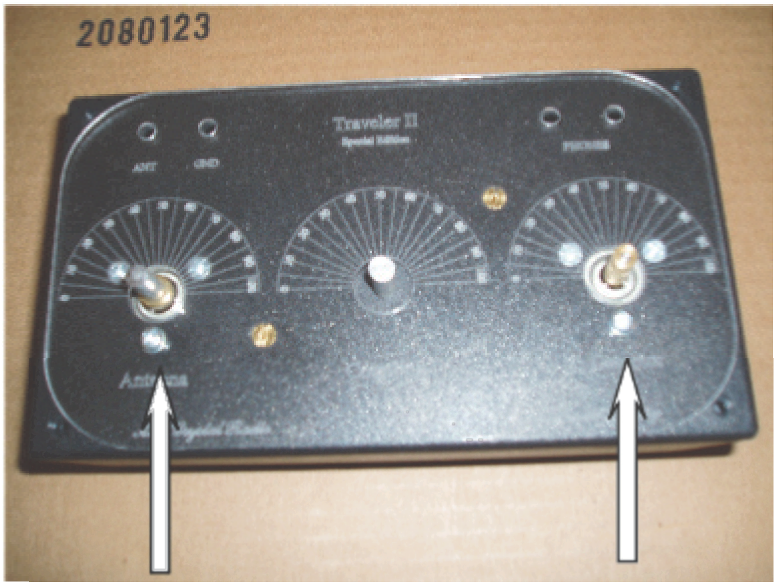
Step 5.
mount the coil assembly shaft in the center hole of the box lid with a 1-1/4" brass flat head screw with a lock washer and nut in the bottom hole.



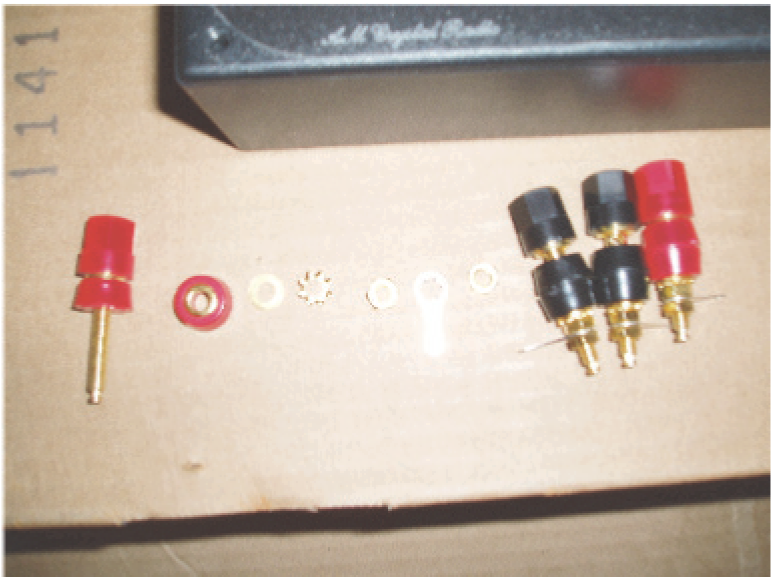
use a 1-1/2" flat head brass screw with a lock washer and the threaded nylon spacer in the top hole.

In the steps below, when handling the dial plate do not touch the face. Only handle by the edges

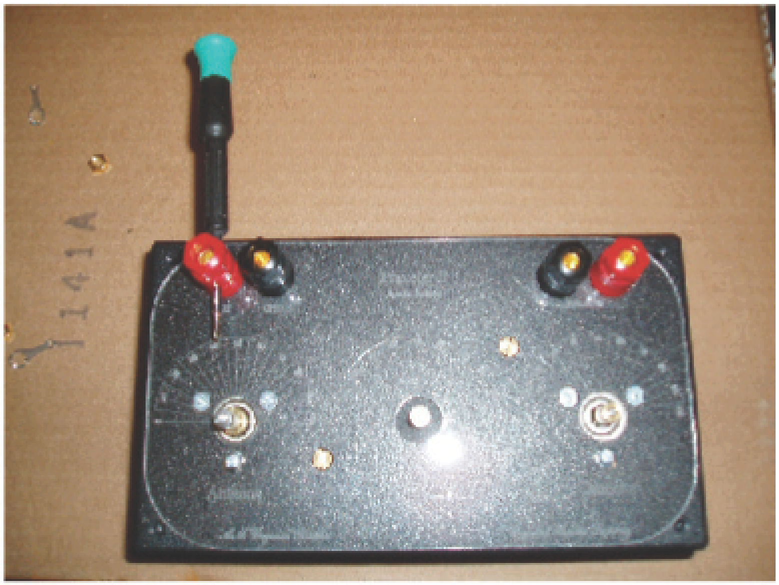
Set the lid assembly on top of the box while you perform the next step.



Step 6.
Place the dial plate on the box lid as shown and start two 1/4" #6 round head screws in the bottom capacitor holes. These screws will secure the bottom of your dial plate to the box lid. Leave these screws loose for now; do not tighten.

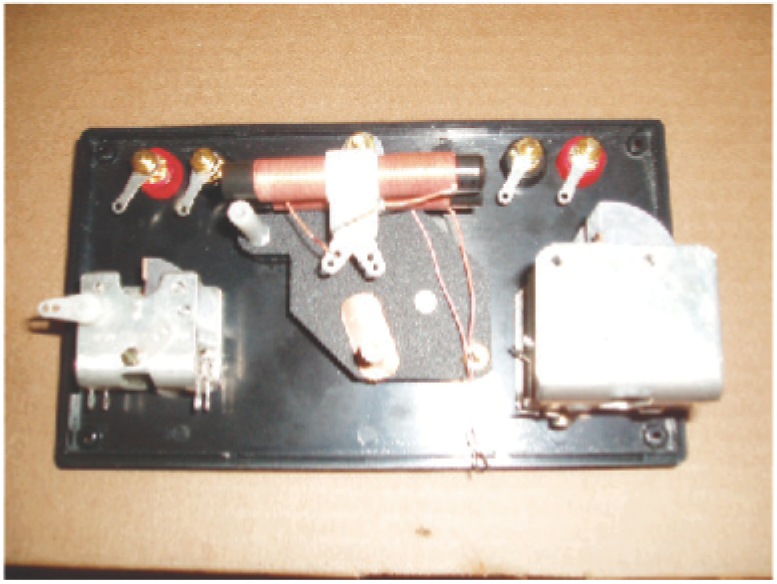


Step 7.
Install the binding posts as shown on page 1. Observe the dissembled binding posts above. The large section goes on the top side of the lid and all the other parts are installed on the bottom of the lid in the order shown from left to right. Do not install the last two parts on each binding post until after the next step. (The solder lug and one of the nuts.)



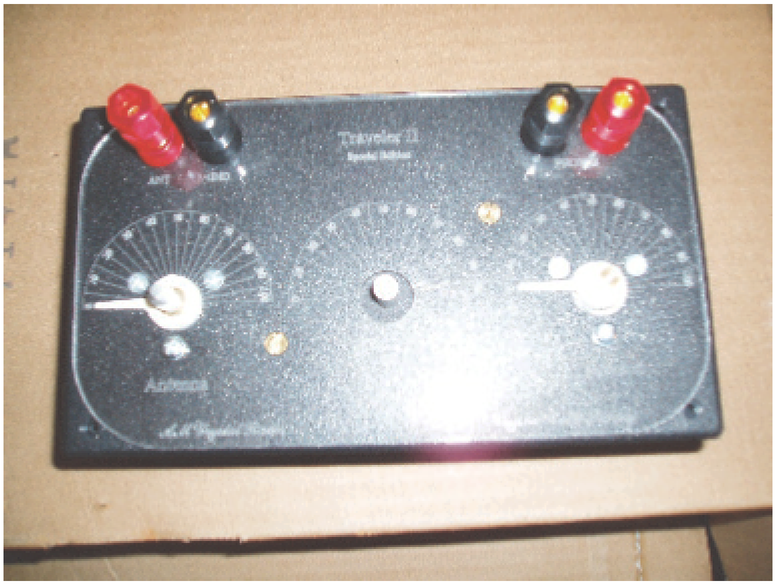
Step 8.
As shown above insert a small screwdriver thru the holes in the binding posts and hold them in the above vertical alignment while you tighten the nut on the bottom of each binding post.

You can also tighten the bottom capacitor screws at this time. Be careful and do not over-tighten as you may damage the dial plate.



Step 9.
Now install a #10 solder lug and brass nut on each binding post and tighten them down with the solder lugs pointed in the directions shown above.

Installation of knobs and pointers.



Step 10.
Make sure the two coils are parallel to each other then install the "Coupling" knob with the line pointed at the “100” mark on the dial.

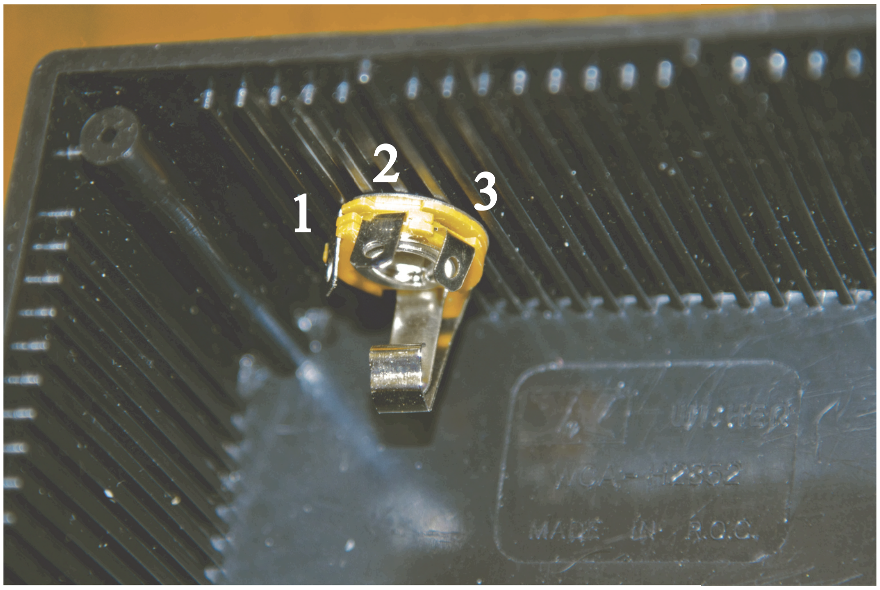
Step 11.
Fully close the tuning capacitors C1 and C2 and for the Traveler II SE, install the dial pointers as shown, pointed at the zero mark on the dial plate. (If you have the Traveler II, instead of the dial pointers, install the knobs with the white line aligned to the zero marks.)

Do not over tighten the dial pointers. Only tighten them enough to keep them from slipping.

Once the dial pointers are installed, Traveler II SE owners can install their tuning knobs. (These knobs have no white mark.)

The knobs and binding post will help protect the dial panel during the remainder of the assembly process. However, it is a good idea to lay the assembly on a soft cloth such as a cotton T-shirt.

If you do use a cloth under the assembly, be careful and do not let it catch fire from soldering.



Step 12.

Install the phone jack in the ABS box as shown with the long part of the phone jack on the bottom. Secure with the hardware provided.

Step 13.

Prepare two lengths of #24 gauge TEST LEAD wire by cutting each to the length of 3-1/4" and by removing 1/4" of insulation from each end.

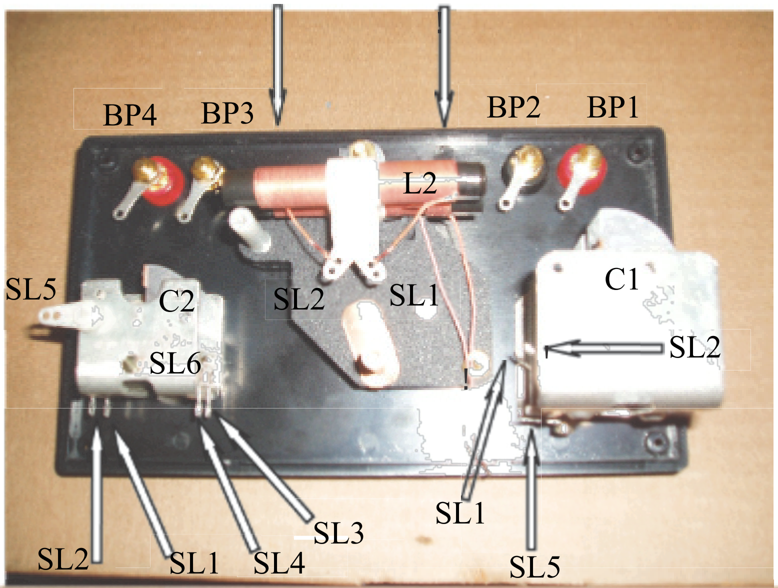
Prepare the following lengths of #26 gauge solid-strand hookup wire by cutting to the desired length and by removing 1/4" of insulation from each end.

2 wires	4" long
1 wire	4-1/2" long
2 wires	6" long
1 wire	6-1/2" long

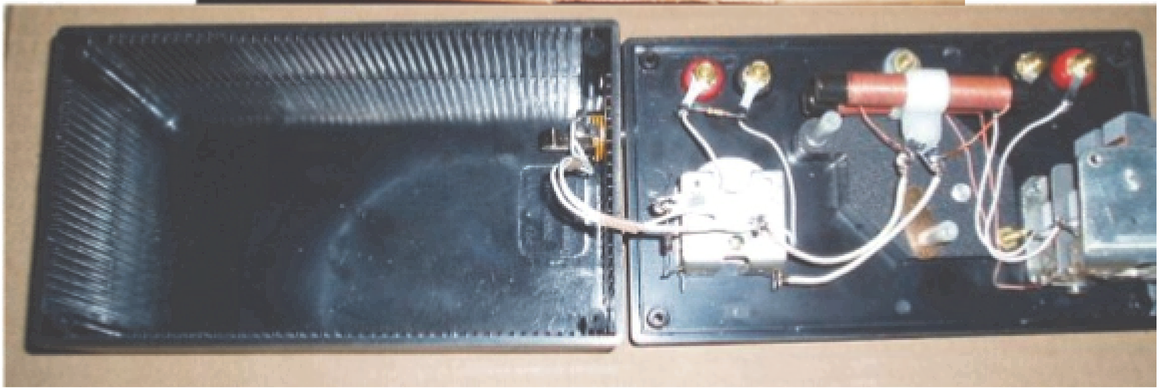
This end of the coils have lead #2

This end of the coils have lead #1

The top coil is L2
The bottom coil is L1



Refer to page 6 for capacitors solder lug locations



Step 14. Check off when each number is finished.

Do not bend the soldered ends of the wires of coils L1 and L2, as they are brittle and may break. Just place them in the solder lug holes and allow the solder to hold them in place.

1. Make sure lead #1 of coil L2 is attached to the top hole of SL1 that is mounted on the coil tuning shaft.

2. Make sure lead #2 of coil L2 is attached to the top hole of SL2 that is mounted on the coil tuning shaft.

3. Connect one end of a 3-1/4" long Test Lead Wire to SL4 of capacitor C2 and the other end to SL1 on the coil tuning shaft. Solder both ends including coil lead #1 from coil L2.

4. Connect one end of a 3-1/4" Test Lead wire to SL6 on the back of capacitor C2. Do not solder. Connect the other end of this wire to SL2 that is mounted on the coil tuning shaft and solder this connection along with the coil lead #2 from coil L2.

5. Connect coil lead #1 from coil L1 to solder lug #5 of capacitor C1 and solder.

6. Connect coil lead #2 from coil L1 to solder lug SL2 on capacitor C1, but do not solder at this time.

7. Connect a 4" solid strand hookup wire to SL1 of capacitor C1 and connect the other end to the solder lug on binding post #2 and solder and solder both ends.

8. Connect one end of a 4-1/2" long hookup wire to SL2 of C1 and solder two wires. Connect the other end to the solder Lug on binding #1 and solder.

9. Connect one end of a 4" hookup wire to SL6 of C2 and the other end to the solder lug of binding post #3. Do not solder at this time.

10. Connect one end of the 47 K resistor to the solder lug on binding post #3 and solder. Connect other end to the solder lug on binding post #4. Do not solder.

11. Connect one end of a 6-1/2" hookup wire to the solder lug of binding post #4 and solder two wires. Connect the end to solder lug #3 of the phone jack and solder.

12. Connect one end of a 6" hookup wire to solder lug #6 of C2 and solder three wires. Connect the other end to solder lug #1 on the phone jack and solder.

13. Connect one end of a 6" hookup wire to solder lug #2 on the phone jack and solder. Connect the other end to the outside hole of SL5 on C2. Do not solder.

14. Connect the banded end of the 1N34A diode to the bent up solder lug SL2 of C2 and the other end to the inside hole in SL5 and solder both ends.

Congratulations! You have just finished wiring up your crystal radio. Just mount the lid on the box with the four black screws and you are done and ready to fire it up. You will be amazed at its accurate tuning of the full broadcast band and its outstanding ability to separate adjacent stations using various degrees of coupling and fine-tuning of the antenna and detector capacitors.

Basic Tuning Procedures

!

To tune across the band, set the coupling at about 50 and set both capacitors at zero.

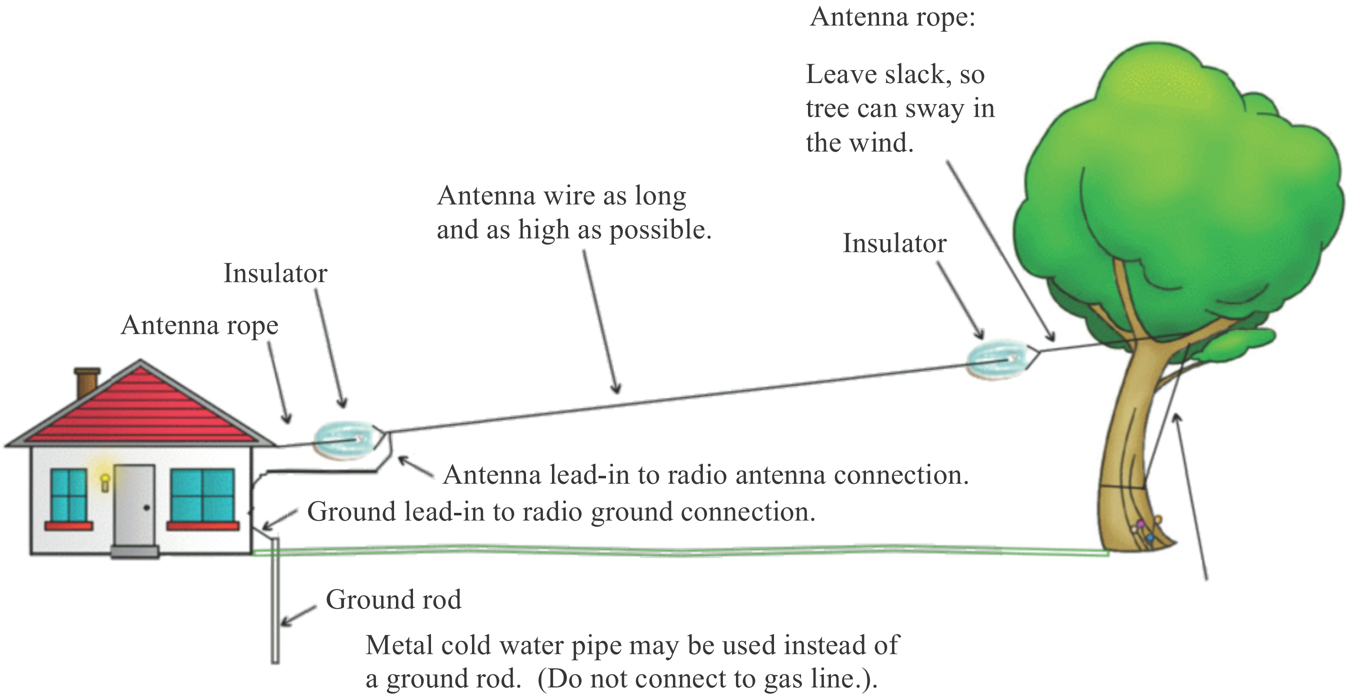
Slowly rotate both capacitors simultaneously keeping both pointers at approximately the same place on the dial. When a station is found, adjust both the capacitors and the inductive coupling for best reception.

The less coupling, the better the selectivity. Just take your time and you will master the tuning quickly and will be amazed at the stations that you can dig out of nowhere.

The Traveler II is a quality hi-performance crystal radio. However, without a good outdoor antenna and ground system you will never realize it's full potential. The ceramic earphone that came with the Traveler II is very sensitive. However they are cheap little things and do not last very long. So if you intend to use them, spares are recommended.

It is recommended that you purchase a pair of high-impedance headphones so that you can use both ears. A unit with an impedance of 2000 ohms or more is recommended. Normally headphones of the magnetic type can be purchased used or NOS.

Typical Antenna Installation



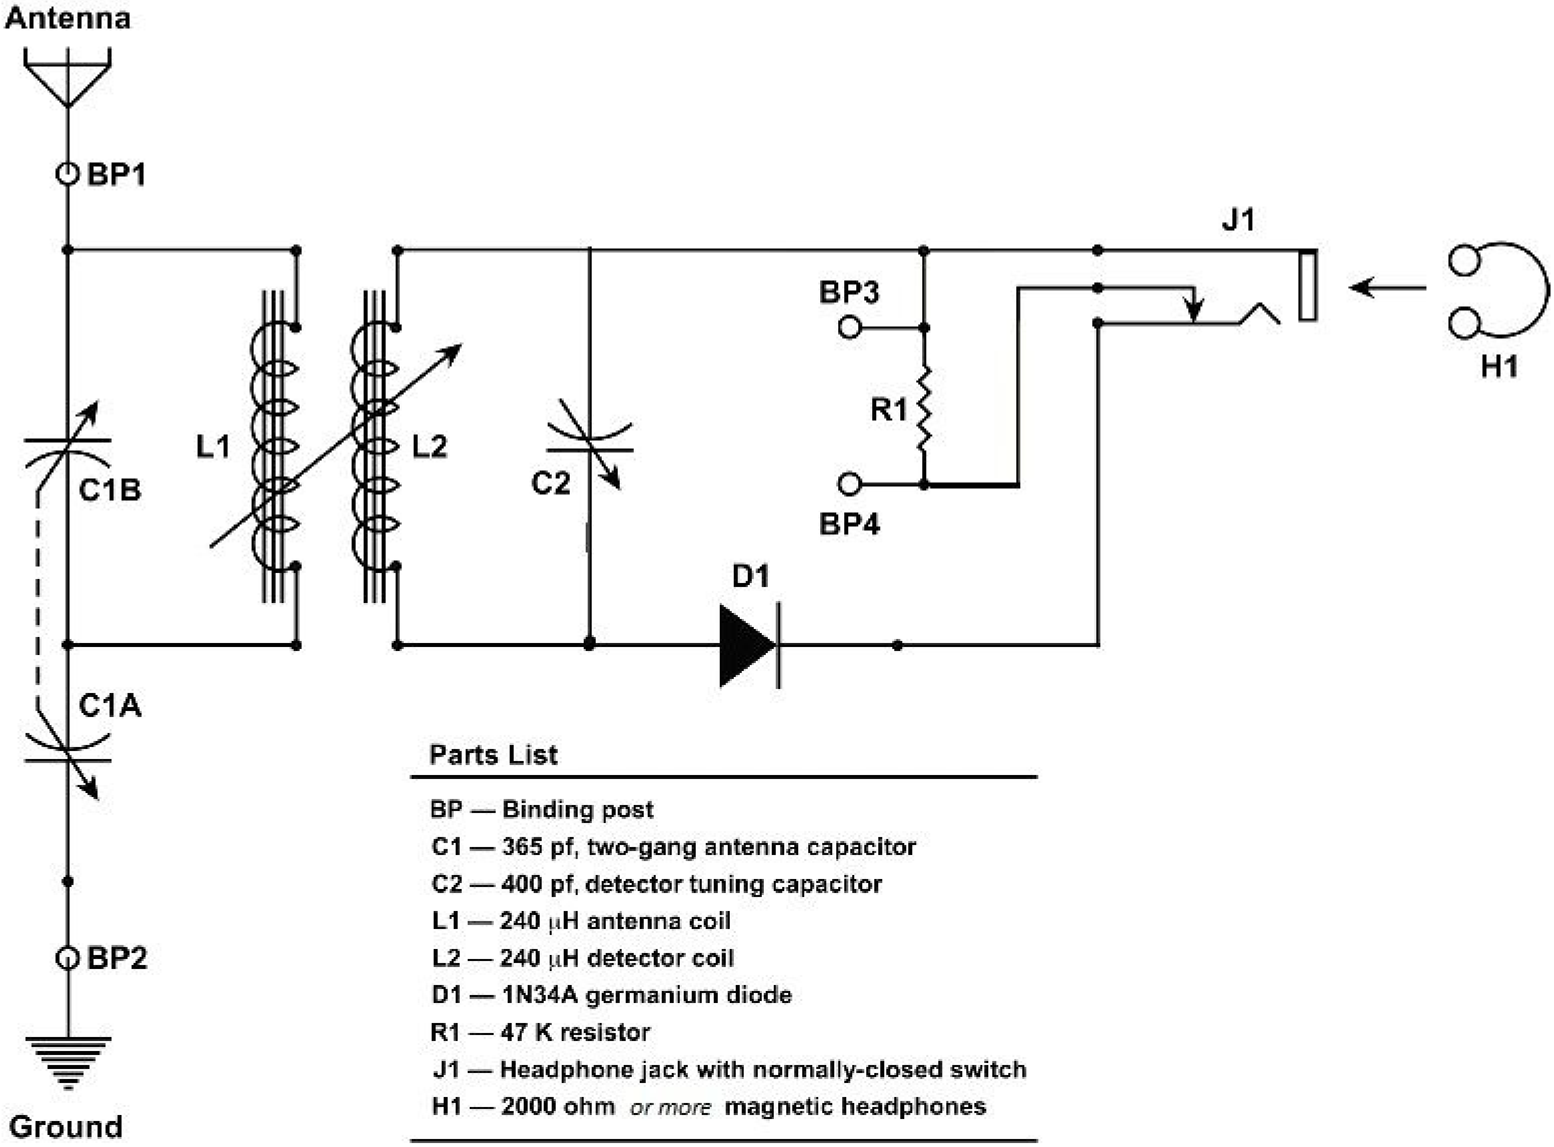
Antenna rope:
Leave slack, so tree can sway in the wind.
Antenna wire as long and as high as possible.
Insulator
Insulator
Antenna rope
Antenna lead-in to radio antenna connection.
Ground lead-in to radio ground connection.
Ground rod
Metal cold water pipe may be used instead of a ground rod. (Do not connect to gas line.).

For safety purposes, a lightning arrestor must be installed in the lead-in wire. If not, remove the lead-in wire from the house when not in use or at least during thunderstorms.

To increase your antenna's length, you can extend it to additional insulated supports – it need not run in a straight line. The length of your antenna greatly affects the performance of your set. A 100 ft or more antenna is considered very good. However, everyone does not have room for a long antenna. In most cases, you just put up the best antenna you can and that is the performance that you get. If you can only get up a short antenna, you can help match it to the radio by adding a coil of wire to the lead-in wire.

!

Traveler II & Traveler II SE Schematic



Parts List

BP — Binding post
C1 — 365 pf, two-gang antenna capacitor
C2 — 400 pf, detector tuning capacitor
L1 — 240 μH antenna coil
L2 — 240 μH detector coil
D1 — 1N34A germanium diode
R1 — 47 K resistor
J1 — Headphone jack with normally-closed switch
H1 — 2000 ohm *or more* magnetic headphones

Hi-impedance headphones, such as the included ceramic earphone, can be connected across BP3 and BP4 where R1 provides better sound quality. This resistor can be omitted or altered in value to optimize performance with other headphones.

A note before getting into the crystal radio story.

After I experimented with the Heathkit CR1 crystal radio and built the radio described below, I got out my old regenerative radio I made in 1958 and was once again astounded by how much better it performed than even the CR1. I have now come to the conclusion that anybody who wants to build an ultra-simple radio really should consider my Armstrong "Crystal" Radio first.

Recently added to my website

If you are looking to build a little radio that is as simple and as easy to build as a basic crystal radio, but performs many, many times better than even the best and most complex crystal radio, I highly recommend building my Armstrong "Crystal" Radio. There is a link to the Armstrong Radio project at the very bottom of the following crystal radio story. Please scroll down for the link, but I invite you to look over the pictures and headings to see if there isn't something that might interest you.

If you are determined to build a tiny crystal radio with no amplification or are just interested in reading about my crystal radio and how I built it for its entertainment and especially for its educational value, please read on.

A miniature, but selective and high performance
CRYSTAL RADIO KIT

The description of a project intended for advanced science students and hobbyists and containing personal and controversial opinions and thoughts that you can skip

by John Fuhring

My tiny, but selective and sensitive crystal radio.

Introduction

Not long ago I rebuilt and put into operation a Heathkit CR1 crystal radio. I hadn't built a crystal radio since I put together my first radio when I was 10 years old, nor had I used a crystal set since I was 13. During the period of the mid to late 1950s, I owned at least three crystal radios of varying performance. With the Heathkit, I now had a crystal radio that performed far better than any of the radios that I remember using as a kid and once again I was struck by the magic of building and operating such an utterly simple and basic radio receiver. Suddenly it occurred to me that it might be fun to try my hand at designing and building my own crystal set from scratch. Besides that, a former grammar school teacher I'm friends with suggested to me that school aged kids would have a lot of fun learning about radio theory if they could build a working crystal radio and he asked me to come up with such a radio.. Of course, this strongly reminded me of how, in 1955, my aunt gave me crystal radio kit to build and how that experience lead to my lifelong interest in radio and my career in electronics. The memories flooded back and awoke in me that desire I think we all have and that is to pass along to others those things that have helped us.

Well, I have given a lot of thought to crystal radios lately and I have concluded that the ultra-simple, very poorly performing crystal radios that most teachers have their classes construct are just not worth building. Rather than try to force kids who are just not interested in how their technological world actually works -- and after all, most of us only want to use technology, not design or even understand it -- I think that building a crystal set should be limited to only those students who show a genuine interest in this sort of thing. In my opinion, the only students who should build something like this are the kids I call a school's "the scientific elite" (but who others would call "the nerds"). I think that building a crystal radio should be done as an individual science project, but not as a class project. However, and this is most important, any radio anybody builds should be worth building and should at least approach the performance of the Heathkit CR1.

It soon became my goal to design a low cost, but good performing little radio that would not only be easy and practical to build, but would be something a young person would be proud of and want to keep and use. Of course, this applies to adults too, even old geezers like me. So, the following paragraphs will describe the little radio I have come up with. Please be aware that because the little radio is very compact, it requires some very careful, precision soldering using a dangerously hot soldering iron. Additionally, winding 7 feet of wire on each of two toroid forms is tedious and requires manual dexterity and skill. Because of these difficulties, I am very much of the opinion that this little radio is not a project for very young (under 12) kids. You must use your own judgment regarding whether or not this project is practical for you or your student(s) to build.

Design considerations for a simple but good performing crystal radio

Before I begin the technical phase of this article, please note that I performed several experiments with different kinds of wire and different detectors before I finalized the design that I will be presenting. What I'm presenting here is how and with what materials and components I think a builder should use for optimum performance.

Here then are my design criteria:

Any crystal radio worth building should have good selectivity. That means that you should be able to hear a station without the audio of an adjacent station in there too. Of course, the selectivity of any crystal radio is such that, if you listen closely, you will always hear a powerful nearby station in with your station, but that unwanted signal should be very faint.

Any crystal radio worth building should have good sensitivity. That means that you should be able to hear even relatively distant and weak stations. Of course, crystal radios have no amplification and depend entirely on capturing enough radio energy to operate the earphone to produce sound waves. The radio must have efficient tuning coils, tuning condensers and a efficient detector so that the tiny amounts of energy that is picked up by the antenna is not wasted or lost in the radio any more than absolutely necessary. If the radio is designed properly with low-loss components, the human ear, with its amazing ability to hear even very low energy sound waves, will do the rest.

Any crystal radio worth building should be in a pleasing enclosure or chassis that makes mounting the components easy, makes connecting to the antenna and ground easy, makes it easy to plug in the earphones and makes operating the tuning controls convenient. When the project is complete, the builder should have a radio that looks like a radio and something (s)he is proud of and proud to show to others.

Certainly, the Heathkit CR1 fits these criteria extremely well and I think that the little radio I will present on this page fits the criteria well too. In some respects, if I may say so myself, my radio fits some of them even better than the CR1.

An update as of June 21, 2017

After exchanging some email with a reader, I have revisited my little project and have rethought some things. I then went in and made some simple modifications and I am extremely pleased with the results. The modifications work so well, I am redrawing the schematics and the improved version of this radio is what I will present.

Building the radio

List of parts:

1) Two each, T80-15 toroid cores. **
2) Two each, dual section 335 X 335 PF variable tuning capacitors (670 PF total each). ***

3) Two each, knob and shaft extension for the above tuning capacitors.
4) Four each, 2.5 X 5 MM countersink screws to mount the tuning capacitors.
5) One 1N34A diode.
6) One piezoelectric earphone (or high Z magnetic earphones) with a miniature phone plug.
7) One panel mount miniature phone jack (to match item 6 above).
8) One, panel mount RCA type jack.
9) One RCA type plug with item 10 wire leads soldered to it to match item 8 above.
10) Two each, 6" 20 Ga. colored (red & black) insulated wire leads for the antenna and ground. (Use black for ground)
11) Two each, small alligator clips. Solder to the end of the above insulated wires for antenna and ground connections.
12) Two pieces of 40/46 litz wire each 7 feet long. No. 30 (or larger) magnet wire can be used but not recommended.
13) One 6" section No. 24 ga magnet wire for the interconnecting link. Litz wire can be used, but stiffer wire may be preferred.
14) One 24,000 ohm (24K) resistor. A 1/4 or 1/8 watt resistor is recommended to more easily fit in the limited space.
15) One L1 coil made of 6 turns of litz wire wrapped around a wooden match stick. Cut off unused wood.
16) One 12 coil made of 12 turns of litz wire wrapped around a wooden match stick. Cut off unused wood.
17) A single pole double pole miniature switch.
18) A small tube of RTV type adhesive. Do not use an adhesive that becomes hard because you may want to change coils.
19) Metal or plastic box to mount the components.
20) Antenna 60 + feet or as long as practical and mounted as high up as practical.

** Use only toroids made with the -15 material. Other cores will greatly complicate winding and/or degrade performance. Smaller cores may be used, but the number of turns will have to be adjusted.
*** You can use smaller values for finer tuning. For large chassis projects, conventional 360 PF air variable condensers are excellent and will probably give you higher 'Q' and lower signal losses. Ganging the two sections of the miniature condensers as I have done gives a greater tuning and antenna trim range. Since the tuning of a crystal radio is so broad, condensers ganged this way are still easy to adjust for maximum signal and minimum interference from stations off to the side.

Total cost of parts will be about $25 -$30.

Notes

I originally wound the coils with No. 30 magnet wire, but was dissatisfied with the selectivity and sensitivity. I had never used the stuff before, but I knew that a special kind of "woven" multi-strand wire worked best for radio coils operating at broadcast frequencies. Of course, I'm talking about litz (German for woven) wire that reduces something called the "skin effect." Because of the magnetic field that is generated by AC flowing in a conductor, electron flow is forced out to the "skin" or outermost part of the conductor. This is an undesirable feature of conductors carrying AC current but at 60 Hz it is hardly noticeable. The skin effect gets worse the higher in frequency you go and at radio frequencies, it is really bad causing high resistance in coils and ruining their 'Q' or "quality factor." Litz wire, because it is made of several wires woven together, noticeably increases a coil's 'Q' and allows it to tune much sharper. Litz wire also reduces a coil's resistive losses, thereby allowing the radio to pick up faint signals. I rewound both coils with litz wire and as expected, noticed a big improvement in both selectivity and sensitivity.

Next I experimented with detector diodes to see which kind gave the better sensitivity. Originally the radio used a BAT-46 Schottky diode for its detector. I even experimented with biasing the Schottky for additional sensitivity, but in the end, I replaced the Schottky detector with an ordinary 1N34A point contact diode. In my radio with its particular configuration, the old technology 1N34A diode gives superior performance.

I further experimented with with the the radio's selectivity by varying the coupling between the two toroid coils. With toroids, it is impossible to get a coupling lighter than a single turn unless you put a coil, a capacitor or a resistor in series with the coupling loop. To get the maximum selectivity out of one of these radios, it is necessary to have fairly light coupling between the antenna and the tuning toroid coils so at first I tried a resistor and it worked - sort of. When I put a little coil of Litz wire (wrapped around a bit of wooden match stick) in series with a single linking coil, I noticed a profound improvement to the overall selectivity of the set, but not much loss of sensitivity. A second coil was put in with twice as many turns on its matchstick and one or the other is selected by a little toggle switch. When this "larger" coil is selected, it very noticeably improves selectivity over the smaller coil, but it does cut down a little on the radio's sensitivity.

The station (detector) tuning coil is tapped 30 turns from the top so that 2,000 ohm magnetic headphones can be used without loss of selectivity.

In my radio's present configuration, its selectivity now matches the Heathkit CR1, but although very good, it isn't quite as sensitive.

Suggest layout and building instructions.

All measurements are in inches.

Steps in building the radio

First, shop around and pick out a suitable chassis box to put the radio in. A small box such as shown above will accommodate the miniature tuning condensers and the jacks for the earphone and antenna/ground RCA jack, however the parts will be crowded as shown in the pictures. A larger box will make assembly and soldering somewhat easier. A plastic box will make drilling and mounting the components extremely easy. A small wooden box that could be lacquered and polished might be very handsome.

The two capacitor extension shafts should be filed down for an overall length of 0.4 inches with the mounting screw cut to 0.48 inches. You can leave them their original length, but the knobs won't be flush with the panel.

This radio uses two T80-15 toroid cores that are each wound with 7 feet of 40/46 litz wire. Three turns on each side form a coupling link between the toroids. The station tuner coil is tapped 30 turns from the top. At what will be the top of this coil and with an inch of wire sticking out, square knot tie the wire to the toroid (to hold it in place) and then begin winding the coil while counting each turn. At 30 turns, stop winding and create a tap. Tapping is accomplished by simply twisting the wire for about a half inch. Carefully start winding again and continue to wind until all the wire is used up (about 70 more turns). When finished winding, the twisted wire at the tap and the wires at the ends of the coils are heated with a soldering iron until the insulation melts and then "tin" the wires with hot solder.

Note that the diagram that accompanies the tuning condensers shows which of the long metal tabs are connected to the stator (ground) and the rotor sides of the units. These condensers have 4 trimmers built into them, but we will not use any trimmers so ignore (or cut off) their tabs.

With the photos and schematic as a guide, perform the following:

1) For the antenna tuning condenser, bend the rotor tabs over at a 90 degree angle and solder them together.
2) For the station tuning condenser, bend the rotor tabs over at a 90 degree angle and solder them together.
3) Extend the ground tabs (stators) of the two condensers until they touch and then solder them together. This is the ground bus.
4) Solder short pieces of bare wire from the outer shells of the RCA and phono jacks to this bus.
5) Trim the leads to fit and solder one side of the 24K resistor to this bus.
6) Place the other lead of the 24K resistor into the mounting hole of the ungrounded side of the phone jack.
7) Trim the leads of the detector diode to fit and place one lead in the same hole of the phone jack with the 24K resistor.

8) Solder the detector diode and 24K resistor leads from steps 6&7 to the phone jack.
9) Place the station tuning coil on top of the station tuning condenser and perform the following:
10) Solder the top of the station tuning coil to the station tuning condenser's rotor tabs.
11) Solder the bottom of the station tuning coil to the ground bus.
12) Place the antenna tuning coin on top of the antenna tuning condenser and perform the following:
13) Solder the top of the antenna coil to the ungrounded lug of the RCA jack.
14) Solder the bottom of the antenna coil to the rotors of the antenna tuning condenser.
15) Glue the two toroids to the tops of their tuning condensers as shown. Use a silicone rubber adhesive and allow it to set.
16) L1 With a 4 inch section of litz. wire, wind 6 turns on a wooden match stick and glue them down. Leave one end with a long pig-tail and the other end a little shorter. Trim off the excess wood.
17) L2 With a 4 inch section of litz. wire, wind 12 turns on a wooden match stick and glue them down. Leave one end with a long pig-tail and the other end a little shorter. Trim off the excess wood.
18) Solder the short end of L1 to the "wide" terminal of the switch. No stripping is necessary with litz wire.
19) Solder the short end of L2 to the "wide" terminal of the switch. No stripping is necessary with litz wire.
20) Thread the two L1 and L2 long wires through both toroids as shown and bring them out together to the center terminal of the switch. Twist them together and solder them on. Remove excess wire.
18) Solder the other side of the detector diode to the tap of the station tuning coil as shown.
19) Solder two 3-6 inch pigtail leads on to the RCA plug for the antenna (red) and ground (black) and solder alligator clips to their ends.
20) Connect the alligator clips to a long wire antenna and suitable ground, plug in the earphone and tune to a local station. Recheck wiring if you fail to detect a station.

Refer to the schematic diagram and the photos below to make sure you have wired everything correctly. Remember that a schematic diagram is not exactly as a radio is wired, but is electrically correct and actual wiring must make all the connections (and no others) as shown. As long as the leads are kept short and if all the connections are made properly and there are no shorts to other parts of the circuit, the radio will work It is up to you to figure out the best routing and lead lengths for all the connections shown in the schematic. Keep in mind that external connections such as to the earphone, the antenna and the ground go to the earphone jack and the antenna jack respectively. If you are not familiar with schematic diagrams and how to wire something up using such a diagram, this is an excellent project for you to start learning how this is done.

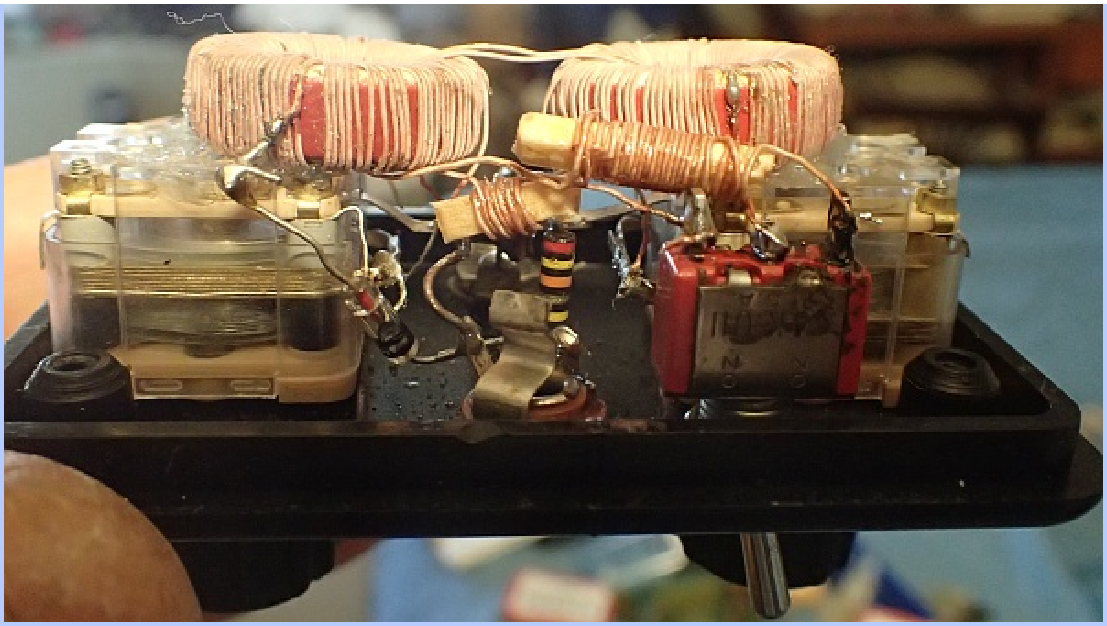
Finally, the RCA jack and the phono jack normally uses the outside shell connected to ground so that when they are bolted to a metal panel, they are at the right potential. If you are using an insulated panel to mount these jacks, it doesn't matter if the outside shell is grounded, but I recommended that you connect it this way. You may notice that the detector diode is shown in the schematic as "forward biased," however, it makes no difference (in this case only) which way you connect the diode.

Tools you will need

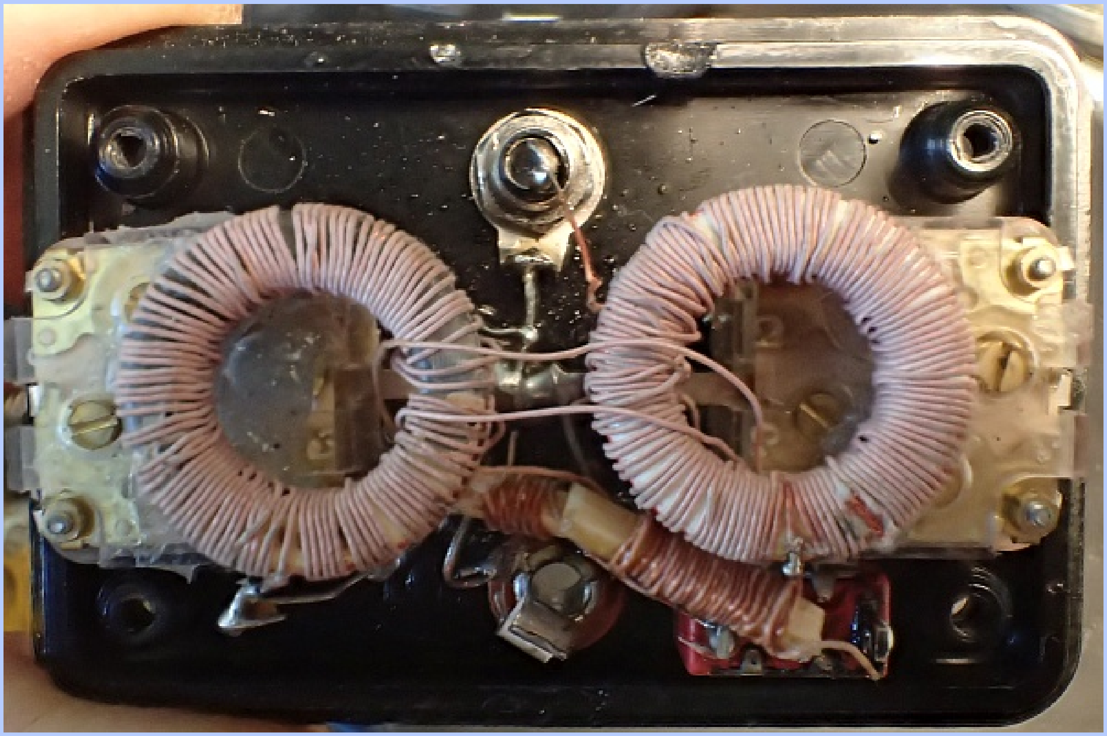
1) A low wattage soldering iron. A temperature controlled soldering station is ideal, but an ordinary iron will work fine.
2) A very fine needle nose plier or (better yet) a fine hemostat.
3) A small wire cutter.
4) Drill, bits and countersinking tool for cutting holes in the panel.
5) Screwdrivers to fit the various screws.
6) Pliers or wrenches for tightening the jack's mounting nuts.

Do not over-tighten screws or nuts.

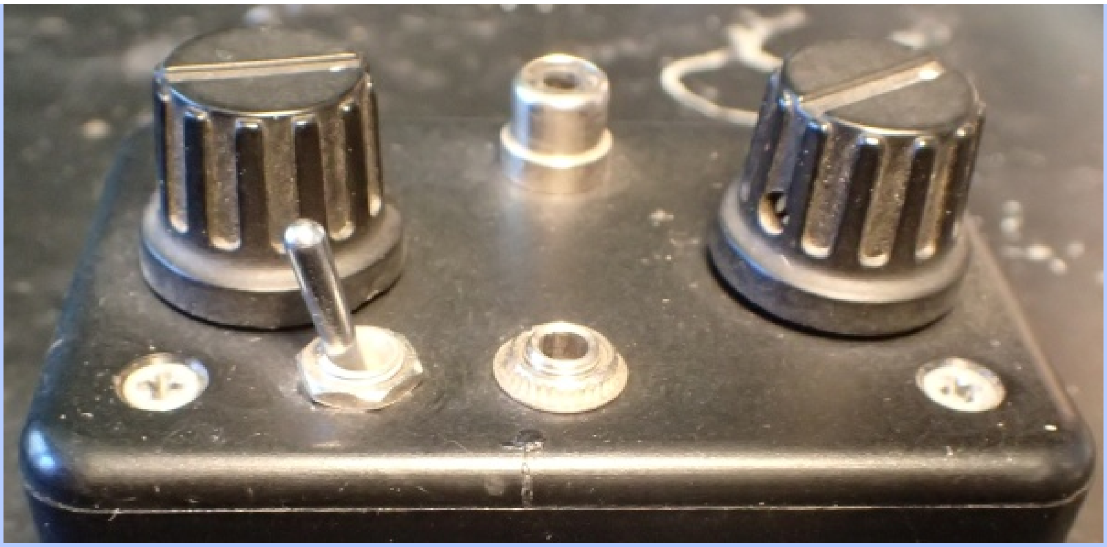
Photos of the completed project in its tiny box



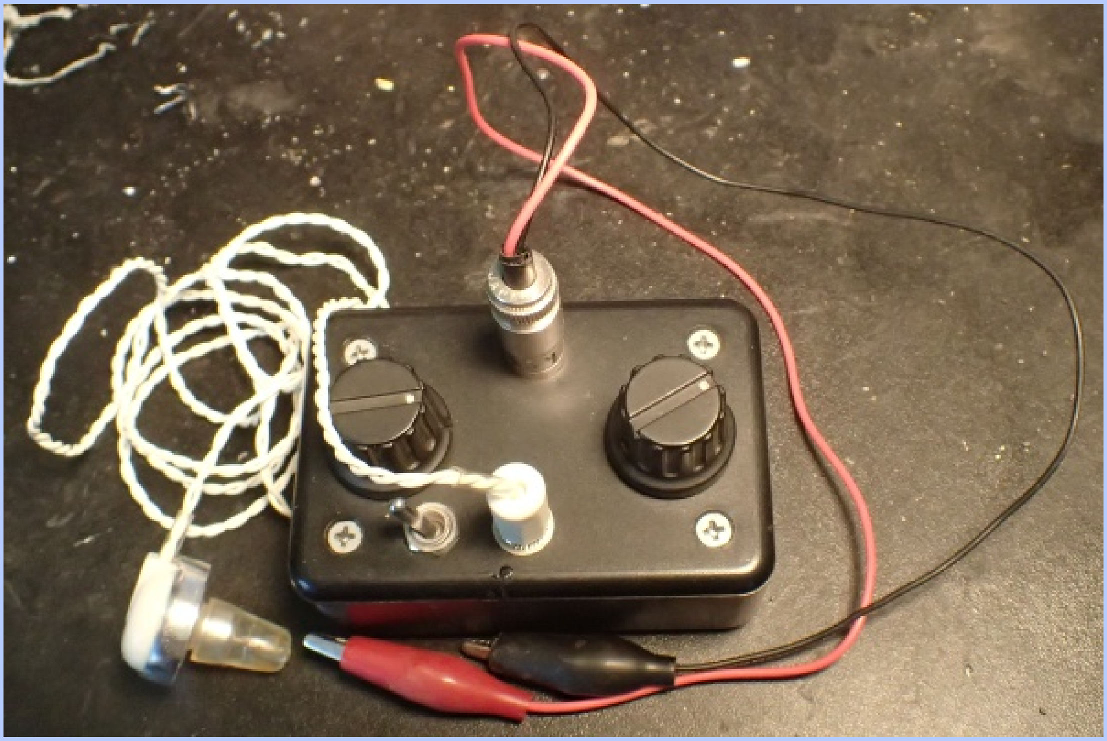
Plastic lid with all components mounted. The toroids are mounted with a drop of RTV.
Silicone rubber mounts the toroids quite securely, but allows for future changes.
Miniature tuning condensers have dual sections, each 335 PF and are ganged for 670 PF.
The long ground tabs of the two condensers are soldered together and make a very convenient ground bus that the other components can attach to.
Also shown here are L1 and L2 which are turns of litz wire wrapped on match sticks.
This little radio will tune to the LF band below the broadcast band, but I doubt you will find anything down there to listen to.



Looking down with the phone jack at the center bottom and the RCA antenna jack on the top.
Notice a ground bus runs in the center connecting the two condensers and that the other components are soldered to it.



The front panel. Antenna tuning on the left, station tuning on the right.
The toggle switch controls wide or narrow selectivity tuning.



The completed project with a RCA plug attaching the antenna and ground.
I think you will agree that this is a very neat little package.
The tiny size belies its rather excellent performance.

selectivity switch was installed.

The way this radio works is as basic as it is possible to get

and here's how it all works:

The setting:
Imagine that there is a radio station 10 miles away and that it that is broadcasting radio waves at 1,400 KHz.
Imagine that our radio station is broadcasting hundreds of watts of energy into space and that if we could capture just a tiny amount of this energy, it would be possible to hear what was being broadcasted.
Imagine that we have a crystal radio like the one above connected to a long wire antenna.

(1) The passing radio wave from our station induces a tiny high frequency voltage on our antenna wire. The antenna is connected to the antenna coil (coil on the left of the diagram) with its antenna tuning capacitor to the left and below it.
.

(2) When the antenna capacitor is tuned just right so that the inductance of the coil is matched by the capacitance of the tuning capacitor, a tiny current from the antenna flows in the antenna coil to produce an oscillating (or varying) magnetic field inside the toroid core on the left. By carefully adjusting the antenna tuning capacitor, this oscillating magnetic field will be right in tune with 1,400 KHz and 1,400 KHz only. This is important because it helps separate our 1,400 KHz signal from all the others on the AM band.
.

(3) The oscillating magnetic field created by currents in the antenna coil causes a voltage to be developed in the turns of the link coil through the principle of mutual inductance. The oscillating voltage in the link creates a oscillating magnetic field in the right side core the core that has the station tuning coil wound on it. The link isolates the two circuits so that unwanted signals are not coupled between them.
.

(4) The 1,400 KHz signal that has been coupled to the station tuning coil is contained in a "tank circuit" that is made up of the station tuning coil and the station tuning capacitor (shown to the coil's right).
.

(5) By carefully adjusting the station tuning capacitor so that its capacitance exactly matches the coil's inductance, a so-called tank circuit is formed. This tank circuit "resonates" or "tunes in" the 1,400 KHz signal and that means that it further separates our 1,400 KHz signal from all the other nearby signals. We now have just the radio signal we want, but we need to do more because it is impossible for our ears to hear radio frequency signals.
.

(6) To "detect" the presence of the radio frequency signal that is resonating in the tank circuit, the station tuning coil is wired to one side of the 1N34 detector diode.

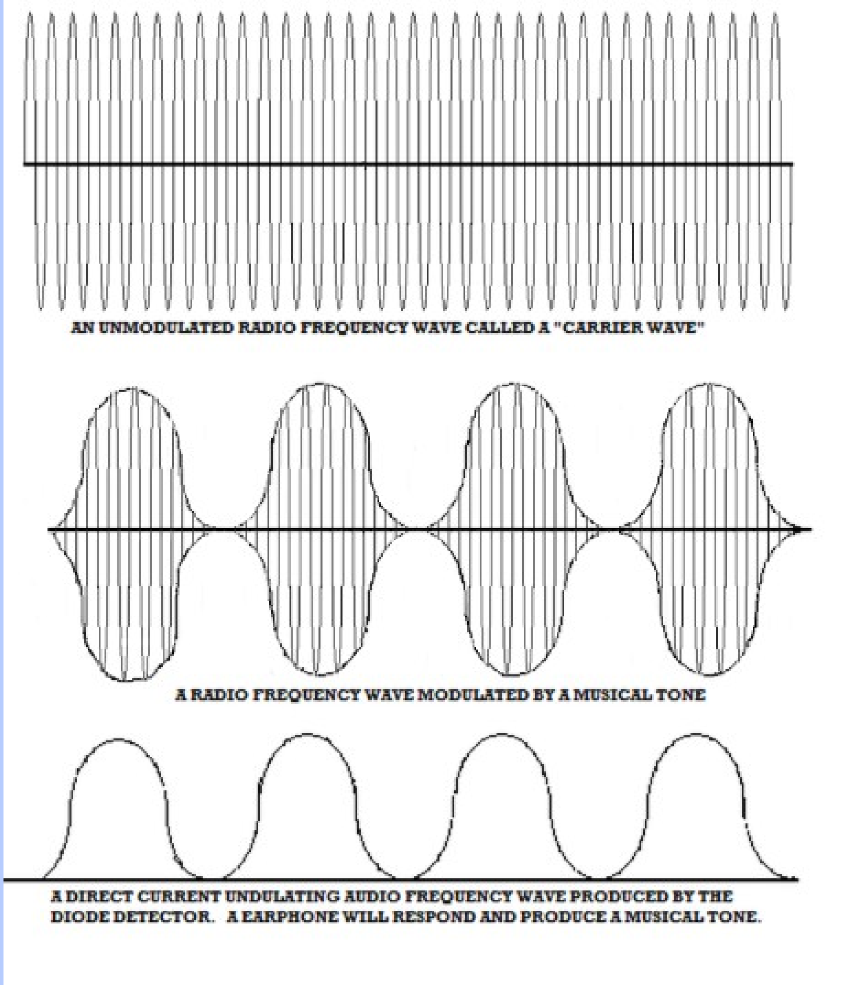
.

(7) The 1N34 diode chops off the negative part of the radio frequency wave. The detector needs to do that or the negative part of the wave would cancel out the positive part of the wave and nothing would be heard.

.

(8) When the diode detector chops off part of the radio frequency signal, direct current audio frequency undulations are all that are left over from the original radio wave. These direct current audio frequency undulations correspond to the sound being transmitted by the station and when the wires of a very sensitive earphone are connected to the detector, these undulations of direct current cause the mechanism inside the earphone to vibrate in step with the undulations and it is those vibrations that we hear as sound.

Here is a graphical representation of what's going on when a radio frequency signal is detected (turned into sound):



AN UNMODULATED RADIO FREQUENCY WAVE CALLED A "CARRIER WAVE"

A RADIO FREQUENCY WAVE MODULATED BY A MUSICAL TONE

A DIRECT CURRENT UNDULATING AUDIO FREQUENCY WAVE PRODUCED BY THE DIODE DETECTOR. A EARPHONE WILL RESPOND AND PRODUCE A MUSICAL TONE.

Graphs of the various waveforms seen at the tuner stage (top two) and at the detector stage. Unmodulated carrier waves are also called "continuous waves" and can't be heard by a crystal detector except as a kind of a very faint humming noise and a quiet spot on the tuning dial. AM radio stations try to avoid sending out unmodulated carrier waves (called "dead air") and so this waveform is rarely seen. More common is the waveform showing lower frequency sound waves superimposed on the carrier wave.

The thick black line is where the voltage is zero as a carrier wave crosses from positive to negative. As shown here, the negative going parts of the wave are stopped by the detector diode so that positive to zero to positive undulations remain. If you reverse the diode, the direct current undulations will be negative to zero to negative, but the same musical tone will be heard in the earphone.

Crystal radios use only one half of a radio frequency's wave because full wave rectification is unnecessarily complicated and results in reducing the selectivity with little or no increase in sensitivity.

The importance of a good antenna and ground system

These radios are not connected to your house's AC power and they use no batteries. A crystal radio has no amplifying circuits and yet they output sound and sound is energy. Where do they get the energy to make sound? Do they somehow use mysterious and occult "free energy from space" or something goofy like that? The energy needed to run these radios doesn't cost you anything directly, but it isn't free or mysterious. The energy is from a tiny fraction left over from the hundreds of watts of radio frequency energy a station broadcasts out to space. The vast, vast majority of the energy a broadcast station radiates out of its antenna system is lost, but a tiny fraction of it may be picked up by an antenna at somebody's house.

Antennas for listening to AM stations can range from tiny "loop" antennas that are extremely inefficient, but good enough for amplified radios, all the way to elaborate "long wire" systems dozens and dozens of feet long and high up in the air. The general rule was discovered by Marconi over a hundred years ago that the longer and higher the antenna, the better it is at capturing some of that energy that is passing by. To capture enough passing energy so that it can be processed by the crystal radio's components and then come out as sound energy strong enough to vibrate the mechanism inside the earphone, the antenna needs to be as long and as high as is practical. Practical is what you have room for and how high you can safely go. Practical antennas can be strung between poles located at the ends of a roof or from the house out to a distant tree or pole. It is true that antennas longer than 60-100 feet and higher than 25 feet do capture more energy, but things soon get very difficult and for very little extra gain at distances and heights beyond what is practical.

In addition to a really good long wire antenna (as long as is practical as mentioned), this radio must have a good ground. Right now, I am using my house's wiring as a ground and it seems to work well. Water pipes, when available to connect to, are supposed to work even better. When using house wiring, it would be a deadly mistake to connect to anything but the AC ground, so be careful.

Tuning this radio for maximum sensitivity and selectivity

The trick to tuning this radio is to first locate a strong local station of known frequency and tune it in with both the antenna tuner and the station tuning controls. Both controls should be used to peak the signal for maximum loudness. Once you have an idea where on the dial your station is located, move both controls to about where you guess the weaker station you want to listen to might be. Once there, slowly and carefully adjust the station tuning until you hear something and then peak it up with the antenna tuning control. You may have to go back and forth a few times to get maximum volume with minimum interference from nearby and stronger stations.

The best time of the day to have fun with these kinds of radios

During the daytime and during the summer months, about all that can be received with a little set like this, at least around here, is the trash in English that the local broadcasters pander to and a couple of Mexican language and music stations, but in the evening, electrified layers way up high in the outer fringes of the atmosphere allow radio waves to be bent back down to earth so that interesting stations worth listening to, but which are 200 to 300 (sometimes even more) miles away may be heard loudly and clearly. This long distance "refraction" or bending of the radio waves back to earth (a process called "skip") makes it possible to hear these distant stations, but it isn't like listening to the station next door. This "skipping" of radio waves off electrically charged layers in the upper atmosphere makes these signals subject to all kinds of things including interference from even more distant stations, fading in and out, some strange sounding distortions and sometimes there is even an echo effect. These so-called "propagation effects" can be annoying, but if you just wait a few seconds or minute or so, the signal generally returns.

I think that listening for yourself, to hear what Nature is doing to these signals way up in the sky, is part of what makes listening to the Broadcast Band at night so interesting. There is a certain randomness to this skip that is explained to some degree by solar astronomy and physics. Scientists and engineers all over the world closely monitor our local star and measure it for electrical and magnetic activity. Reports and prediction tables are compiled by various scientific agencies and all this stuff is available on the Internet. When you can test these predictions for yourself by listening for "skip," you are participating in a scientific observation in your own little way.

Building and operating a crystal radio gives insights into science and technology

Listening to far distant stations with a crystal radio like this one shows you how ships like the Titanic could communicate with other ships and to shore stations hundreds of miles away with nothing more than crystal radio receivers. Speaking of the Titanic, two thirds of all the people on her died and only about 700 were rescued, but without early radios, very much like this crystal set, everybody would have died. In the 100 years since the Titanic disaster, just imagine how radio has connected ships, airplanes, space missions and your cellphone with the rest of the world.

If you make one of these radios and actually put it to use, you will see how, with a good antenna and good sharp tuning circuits, individual radio signals can be picked out from the mass of signals out there and a station you might want to listen to can be heard from a long way off under the right conditions. For me, this is a very wonderful thing, especially when I consider that these radios do not amplify their signals, but use the tiny amounts of electrical energy that is picked up by the antenna to make sound. Such is the extreme sensitivity of human hearing and the amazing efficiency of the circuits, the detector crystal and the earphone, that microwatts of power, originally coming from a station hundreds of miles away and landing on my antenna wire, can be heard clearly.

How far we have come

When you think about it, it seems that such basic radio technology represented by this little crystal radio is quite old, but in fact, the first Fleming Valve and crystal radios were invented just a little over 100 years ago. When my mother was a girl, people were building crystal sets so that they could listen to the wonderful new radio broadcasts from the big cities. In a relatively short span of time, the time since my grand parents were young in the 1890s to my parent's time, to this very moment, consider just how far we have come with radio, television, GPS, cell phones, satellite broadcasting, wireless Internet, interplanetary missions to space and so much other allied radio technology.

A totally irrelevant comment

I know that the following is irrelevant to this article, but I'd just like to say that compared to the one tube (valve) Armstrong regenerative radio I built in 1958 while in the 8th grade (and without any adult help or supervision and the story of which is found elsewhere on my website), both the Heathkit and this little crystal radio really suck. It is no wonder that the crystal radio was quickly superseded by valve radios (starting about 1919 and using Armstrong's designs) even though the early vacuum tubes (valves) were extremely expensive, ate up expensive batteries and quickly burned out. Yes, even by 1920 the crystal radio was technically obsolete and their owners started to become just a tiny fraction of the listening public that they are today. Nevertheless, crystal radios did not completely disappear. They have remained popular all these years and years and years because these little radios are easy and cheap to build and they have provided endless hours of fun and precious education to uncounted numbers of people over the decades.

Why you might want to have second thoughts about building this radio

(These are my personal opinions that you are not obliged to agree with and you may skip down if you wish)

There is something that should be considered when thinking about having your young people build any kind of AM radio and what I'm referring to is the unpleasant realization that, in many places in the U.S., there is absolutely nothing on AM radio that is (in my opinion) good for young, developing minds to listen to. Many local broadcasters pander to the most disgusting right-wing propaganda and Fundamentalist religious crap. Anyway, it is my opinion that persons wishing to direct young people into building a simple AM radio should carefully monitor their local AM broadcasting for the kind of trash I'm taking about. If the local airwaves are full of this trash, they must ask themselves: would building this kind of a project likely help or harm their young people? I think building an AM radio can have the potential to do more harm than good if your area is dominated (as mine is) with this sort of trash broadcasting. Now, on the other hand, if you actually WANT your kids to be exposed to religious or political propaganda before before their minds are sufficiently developed to resist brainwashing, then ignore this warning.

Of course, this applies to adults wishing to build one of these radios too. Is it really worth the expense and especially the effort to build a crystal radio when there is nothing to listen to? I did it strictly for the technical challenge, but certainly not to listen to local entertainment.

All this aside, if you decide build this radio or (better yet) my Armstrong "crystal" radio, I think you will have a lot of fun and will learn a lot. Just remember that for about the same money you can get a MP3 player with an FM radio and 8 gigs of memory. While the MP3 player is a better deal, listening to it won't teach you anything about electronics. However, the horrible trash that's on AM radio has a well deserved reputation for making its listeners stupid and crass while listening to classical music through your MP3 player just might make you smarter and highly cultured, but it's your choice.

Other considerations

Finally, there are some serious downsides to building this radio you should be aware of. One downside is the extreme tediousness of winding the toroid coils. Let's face it, few of us have toroid winding machines and putting 100 turns (about 7 feet of wire) on one of these cores is time consuming and boring with many a tangled wire. Mounting the tiny components wasn't all that difficult because the plastic box lid was very easy to drill, but it was fine work and time consuming. The most serious downside is the very fine and very careful soldering that must be done to connect up all the very tiny parts. If I would have chosen a larger box to put everything in, the soldering wouldn't have have required so much patience and expertise, but it would still be, in my opinion, beyond the skill of most middle school (and younger) kids to do except under the most close and individual supervision especially when you consider that the young person would be handling a hot soldering iron that could burn him/her badly if mishandled.

A final word

I have to admit that with the exception of the Heathkit CR1 radio, this is the best crystal radio I have ever made or used and I'd say the project was a success. I'm sure that people will tell me that there are some ultra high performance crystal radios out there that have very sophisticated low loss coils, high quality tuning capacitors and superior detectors with that could outperform this and the CR1, but I have no desire to go to the trouble to try to build them.

By the way, if you build a crystal radio based on what has been presented here, please drop me a line and describe it to me and, if you can, attach some pictures. I'd sure appreciate it if you would tell me how much you like the radio and how it performs for you. You can write me directly at my geojohn.org mail address. Be sure to look over my story of the Armstrong "Crystal" Radio before you decide to build this or any crystal radio.
Good luck.

The End

Having arrived this far, obviously you have a superior attention span and reading ability that far exceeds that of the majority of web users. I highly value the opinion of people such as yourself, so I ask you to briefly tell me:

Did you enjoy this article or were you disappointed?

Please visit my guest book and tell me before you leave my website.

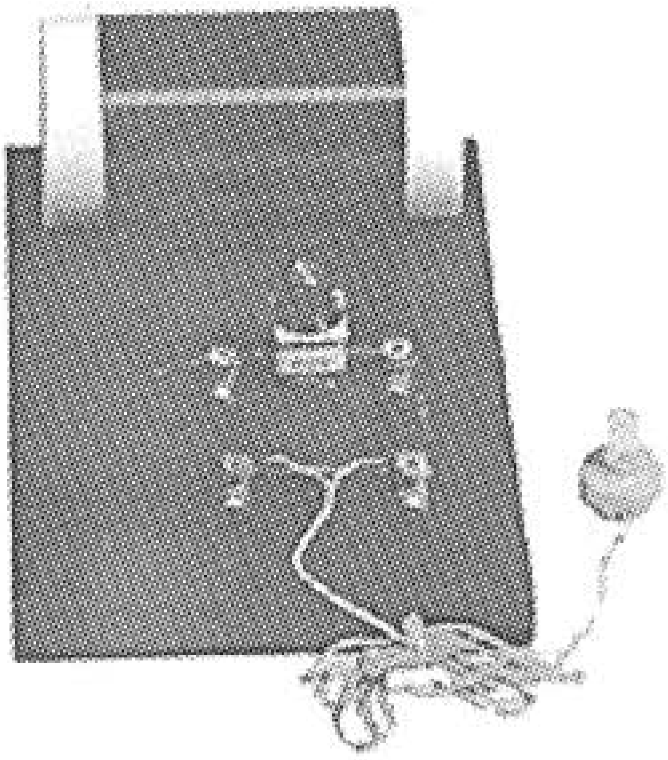
Or you can **contact me by E-mail** directly if you have any questions or comments.

If you liked this article, perhaps you would like to read about the radio my radio is based on.

The high performance Heathkit CR1 crystal radio

Crystal Radio Kit

model VEC-121K



Relive the experience of early radio pioneers. Wire up the earliest radio circuit and listen to the magic of radio that needs no power. This is a lot more than just a nostalgic novelty -- this little baby really works!

- **No soldering needed! Great educational project for kids!**
- **You wind your own inductor and wire up the earliest radio circuit just like the early radio pioneers.**
- **This humble crystal radio set uses a crystal diode detector designed nearly 50 years ago -- you'll get performance that our earliest radio pioneers would envy.**
- **Put up an antenna, connect a ground, and you'll be amazed at the stations you'll pull in and hear.**
- **Includes all hardware and parts needed to build a working crystal radio set plus wire for an antenna and a sensitive earphone.**

Simple: No soldering. Requires a small screwdriver, wire-strippers, cutters. You wind your own coil. Doesn't require test equipment for final adjustment of tuning.

VECTRONICS

High-performance electronic kits . . . fun to build and use!

IMPORTANT WARRANTY INFORMATION! PLEASE READ

Return Policy on Kits When *Not* Purchased Directly From Vectronics: Before continuing any further with your VEC kit check with your Dealer about their return policy. If your Dealer allows returns, your kit must be returned *before* you begin construction.

Return Policy on Kits When Purchased Directly From Vectronics: Your VEC kit may be returned to the factory *in its pre-assembled condition only*. The reason for this stipulation is, once you begin installing and soldering parts, you essentially take over the role of the device's manufacturer. From this point on, neither Vectronics nor its dealers can reasonably be held accountable for the quality or the outcome of your work. Because of this, Vectronics cannot accept return of any kit-in-progress or completed work as a warranty item for any reason whatsoever. If you are a new or inexperienced kit builder, we urge you to read the manual carefully and determine whether or not you're ready to take on the job. If you wish to change your mind and return your kit, you may--but you must do it *before* you begin construction, and within ten (10) working days of the time it arrives.

Vectronics Warrants: Your kit contains each item specified in the parts list.

Missing Parts: If you determine, during your pre-construction inventory, that any part is missing, please contact Vectronics and we'll send the missing item to you free of charge. However, *before* you contact Vectronics, *please look carefully* to confirm you haven't misread the marking on one of the other items provided with the kit. Also, make certain an alternative part hasn't been substituted for the item you're missing. If a specific part is no longer available, or if Engineering has determined that an alternative component is more suitable, Vectronics reserves the right to make substitutions at any time. In most cases, these changes will be clearly noted in an addendum to the manual.

Defective Parts: Today's electronic parts are physically and electrically resilient, and defective components are rare. However, if you discover an item during your pre-construction inventory that's obviously broken or unserviceable, we'll replace it. Just return the part to Vectronics at the address below accompanied with an explanation. Upon receipt, we'll test it. If it's defective and appears unused, we'll ship you a new one right away at no charge.

Missing or Defective Parts After You Begin Assembly: Parts and materials lost or damaged *after construction begins* are not covered under the terms of this warranty. However, most parts supplied with VEC kits are relatively inexpensive and Vectronics can replace them for a reasonable charge. Simply contact the factory with a complete description. We'll process your order quickly and get you back on track.

Factory Repair After You Begin Assembly: *Kits-in progress and completed kits are specifically excluded from coverage by the Vectronics warranty.* However, as a service to customers, technicians are available to evaluate and repair malfunctioning kits for a minimum service fee of $18.00 (½ hour rate) plus $7.00 shipping and handling (prices subject to change). To qualify for repair service, your kit must be fully completed, unmodified, and the printed circuit board assembled using rosin-core solder. In the event your repair will require more than an hour to fix (or $36.00, subject to change), our technicians will contact you in advance by telephone before performing the work. Defective units should be shipped prepaid to:

Vectronics
300 Industrial Park Road
Starkville, MS 39759

When shipping, pack your kit well and include the minimum payment plus shipping and handling charges ($25.00 total). No work can be performed without pre-payment. Also, provide a valid UPS return address and a day time phone number where you may be reached.

INTRODUCTION

Relive those bygone days of radio--a time almost 90 years ago, when early radio pioneers experimented with crystal radio receivers! Wind your own "inductor" coil, wire up the earliest radio circuit; and, there's no soldering needed! Everything is assembled on a pine "breadboard", just like great, great granddad did when he was a youngster. Learn about basic radio theory. Put up an antenna (wire included), connect a ground, and experience the magic of a radio that needs no power. A special high-sensitivity earphone allows you to hear AM Broadcast signals from many miles away; this little baby really performs. The VEC-121K is a fascinating project for youngsters of all ages!

The VEC-121K features a modern "fixed detector", eliminating the need for frequent and frustrating catwhisker adjustments. A large, Hi-Q antenna coil, and a modern miniature Hi-Q tuning capacitor, are used for best sensitivity and selectivity. The high-impedance parallel-resonant tuning circuit allows a short receiving antenna to deliver maximum signal to the set.

TOOLS AND SUPPLIES

Having the right tool to do a job always makes things go better. There is no soldering required, and only a few basic hand tools are needed to assemble your VEC-121K crystal radio set.

This is a list of the tools you will need:

SAFETY EYEGLASSES or GOGGLES! Working with wires, tools and radio parts is a lot of fun, but please, *safety first*! Your local hardware store carries inexpensive safety goggles. Before you are going to be cutting or working with wires, hammering, handling any chemicals, or using any tools, put on your safety eye wear first!

1. **Phillips screwdriver.** There are eight Phillips head screws included in the kit, and we will use this tool when it is time to mount parts on the wood board. Try to find a screwdriver with a *shaft* (the distance between the tip and start of the handle) that is at least 3" long.
2. **Long-nose pliers.** These pliers have a long and tapered nose and are used by electricians. The long slender nose makes it easy to hold or bend a wire that is being worked on.
3. **Wire cutters.** These special pliers have sharp cutters to cut wires. Some long-nose pliers styles feature built-in wire cutters. Wire cutters are sometimes called "nippy cutters" or "diagonal wire cutters"—depending on how they're made.

4. **Ruler or tape measure.** A small 12" ruler or flexible tape measure will do.
5. **Small penknife.** A penknife, or small Exacto™ knife, is needed to scrape off wire insulation. If you aren't old enough to use a knife, a small section of sandpaper will do.
6. **Small Hammer.** It will be used with a finishing nail to mark where the screw holes are placed on the pine board.
7. **Small-Screwdriver or Hex-Tool**. Size to fit the set screw in the tuning knob--depending on which type of knob is supplied with your kit.

Radio Shack carries many inexpensive small hand tools for electronics work.

Here are some items that will come handy:

1. **Masking tape.**
2. **Cyanoacrylate adhesive.** This is the fancy name for contact cement, which is sold as "Super Glue™" or "Crazy Glue™". You'll use the contact cement to hold the coil windings in place. These adhesives are very strong, and can instantly glue your fingers together if you are not careful! If you are not old enough to work with contact cements, have someone who is older help you when gluing is directed in the instructions. The glues used to assemble plastic model airplanes are safer to work with and may also be used instead of super glue. However, they will require a longer time to dry. Always have an adult advise and supervise your use of any chemicals!

WOODWORKING AND FINISHING (OPTIONAL)

Perhaps this is your first kit building experience, or your first homemade receiver project. If so, your VEC-121K crystal receiver will be a source of pride for many years to come. Before assembling this kit, you might wish to consider sanding and staining the pine board—this will bring out the beauty of the wood, and make your project look as if it was done by an "*old pro*". Many early radios were built in what was called "breadboard" fashion. The radio parts were laid out on a small section of wood board.

Early radio parts were very expensive, even a simple crystal radio set could cost a week's pay! Most experimenters had to improvise. Often an old breadboard (used to roll out bread dough) was used as a base to mount radio parts. If you were well-to-do, your "breadboard" was probably a fine piece of mahogany or walnut board!

Sanding: Before applying a stain finish, carefully sand the pine board using 200 grit sandpaper. When sanding the surfaces, always sand in the direction of the grain to avoid scratching the wood. The two board edges that expose the end grains of the wood will be rather rough to the touch, and will require some extra sanding to produce a smooth even surface. You may have to use a 150 grit in the beginning on the end grains. Sanding is best done outdoors. Wear a disposable paper dust mask while sanding.

Finishing: Your local hardware store stocks small cans of woodworker stains. Either a walnut or mahogany wood stain finish is a good choice. Both oil-based and water-based stains are available. We suggest using a water-based stain for this project—it is easier to work with and easier to clean up afterwards. You will need a clean cloth, or *staining cloth*, to apply the stain. Follow the manufacturer's directions very carefully, and read the safety information on the label. Use disposable latex gloves when handling stain. If you're too young to safely work with wood stains, ask an adult for assistance with this portion of the project. *Always handle any chemicals with great care!*

Important Note: Once the stain is dry to the touch, the assembly work may begin. Before attaching the tuning capacitor with the double-sided adhesive tape, the board should be allowed to dry for a few days. This will allow the stain to fully *cure,* or dry, so it does not interfere with the tape adhesive.

BEFORE YOU START BUILDING

Your work area: Use a good workbench with good lighting so you can see what you are doing. At times we will need to set items aside to allow glue to dry; or you will need to stop working on your project for other activities. Your work area should be in a place where your project does not interfere with others.

Keep your work area clean and free of clutter. Kit parts should be kept in the box until you need to use them. When you are finished for the day, return the tools to their proper place. Put unused kit parts back in the box so you will not lose them. If you are old enough to use glues and wood stains, you may have younger brothers and sisters who aren't! Keep chemicals out of the reach of younger children.

Following directions: Kits are built in "steps". These steps follow a logical order, that means following the instructions will make your kit building experience easier and ensures that your project will work *first time* when finished.

You will notice a check box ☐ as each instruction gives you a simple task, or direction, to follow. When the task is finished, make a small check mark in the box to show that part has been completed. This will allow you to keep track of where you left off when returning from a break.

For example, a direction may read:

☐ Tighten the screw until snug, this will make a good electrical connection between the Fahnstock clip and wire.

When finished following the directions, "check off" that the step has been done.

☑ Tighten the screw until snug, this will make a good electrical connection between the Fahnstock clip and wire.

Don't rush!

Have you ever noticed that when you try to rush doing something, it never turns out right? Don't try to build the crystal set receiver in one day! The time spent building a kit is most of the fun. We will be "breaking down" the kit assembly into several phases. For example, the first phase is preparing the "breadboard". The next kit phase involves winding the coil.

Working with wire:

Unspooling: Your kit includes a 100-foot roll of 18 AWG enamel-coated wire. This wire is used to wind the tuning coil, for your receiver's antenna, and is also to be used for making connections between the radio components. Do not remove the wire tie from the roll of wire until you are ready to use it. There is a right and wrong way to remove wire from the spool! Never allow the wire to uncoil, like a Slinky™ toy! Doing so will cause the wire to twist and make kinks when you try to use it. Instead, hold the spool of wire in both hands, and carefully unroll the wire from the spool. Re-tape the unused portion when finished.

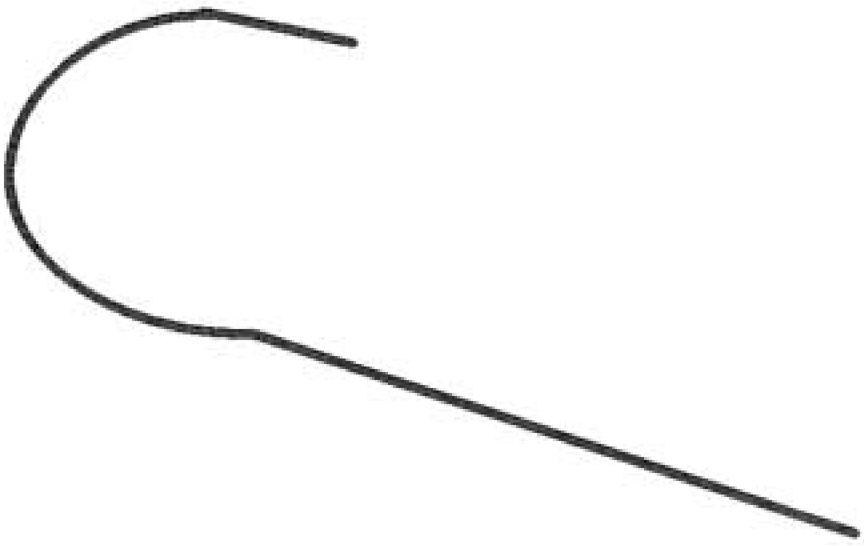
Removing insulation: Electrical connections are made by removing the insulation from the enamel wire. When you need to make an electrical connection, you will be instructed to remove the wire insulation. We will tell you where the insulation should be removed, and how much to remove. This can be done by using a small piece of 150 grit sandpaper. Fold the sandpaper in half so the "sandy" sides face together. Place the wire into the sandpaper fold, and slide the sandpaper back-and-forth over the wire while applying a gentle pressure. Turn the sandpaper every so often to fully remove all of the insulation. Gently scraping the insulation with a small penknife will also work. Lay the wire on a piece of scrap board, and draw the knife blade over the insulation to scrape it away. *Always scrape in a direction away from your body!*

All of the insulation must be removed to make a good electrical connection. The bare area of the copper wire should be bright and shiny when you are finished.

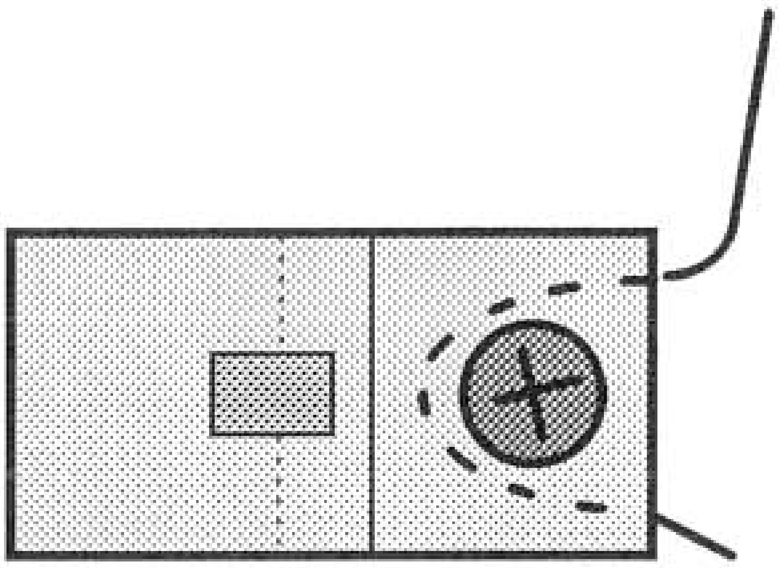
Making connections:

The directions will tell you to make one of two types of connections: *"End"* connections or *"through"* connections.

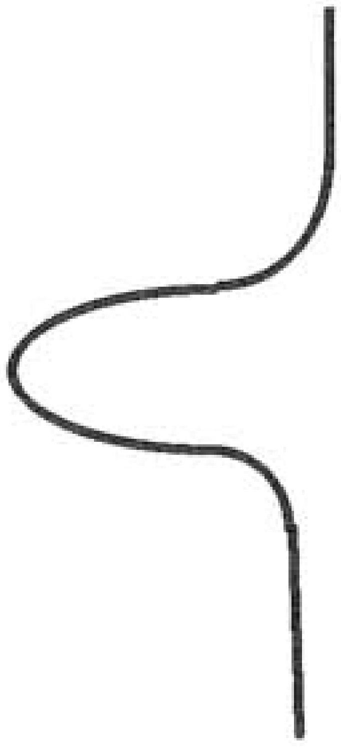
End Connections: End connections are made when the end of a wire is connected. To make an end connection, you will have to remove about 1" of insulation from the wire and form the end into a "fishhook" shape, as shown below.



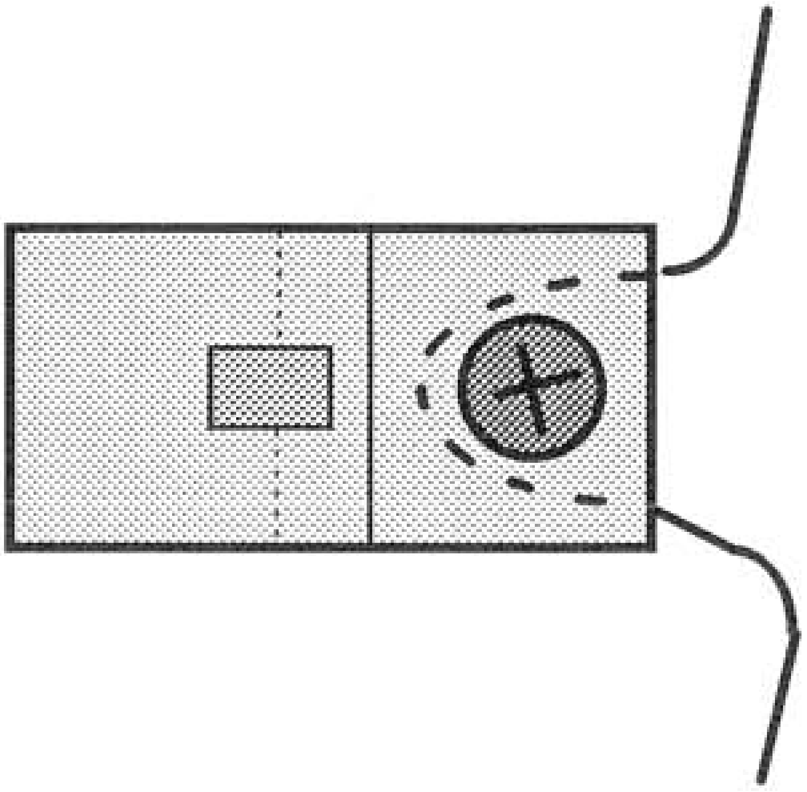
In the following drawing, a wire end connection is used to make an electrical connection to one of the Fahnstock clips mounted on the pine board. Note we show the wire as a "dotted line" where it passes *under* the Fahnstock clip. When the Phillips screw is tightened, a good electrical connection is made. The drawing shows how the wire hook is placed between the Fahnstock clip and board.



Through connections are used when the wire goes to a electrical connection at a Fahnstock clip, and then continues on to make one or more connections to other points. The directions will tell where to make a through connection on a wire, and how much insulation needs to be removed.



The wire insulation is removed where shown in the directions, and made into a half loop as shown above.



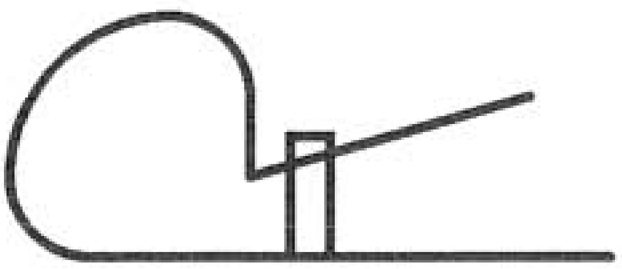
The above drawing shows a through connection being made to a Fahnstock clip. The dotted line shows where the wire runs under the clip body.

PARTS LIST

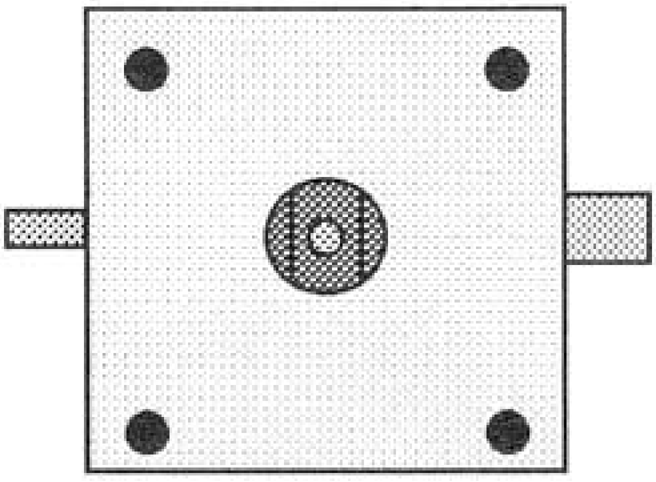
You are just about ready to begin your kit building adventure! But first, let's take a few minutes to make sure everything needed is present and accounted for. If any parts are missing or damaged, you'll need to refer to the directions given in the Vectronics kit warranty section of the manual.

☑	Qty	Part Description
☐	8	Phillips head screws
☐	1	5 inch length of white 2-1/2" diameter PVC plastic pipe
☐	1	100 foot spool of 18 AWG enamel coated wire.
☐	6	Fahnstock clips.
☐	1	Tuning capacitor shaft extension
☐	1	Tuning capacitor
☐	1	Tuning knob
☐	1	Double-sided foam tape
☐	1	Earphone
☐	1	Pine board , 3/4" high by 5-1/4" deep by 6" wide
☐	1	Insulated stranded wire, 7 feet long
☐	1	27K resistor (red-violet-orange-gold)
☐	1	1N34A germanium diode

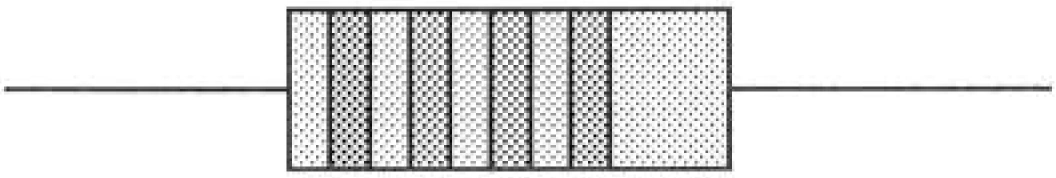
Fahnstock clips



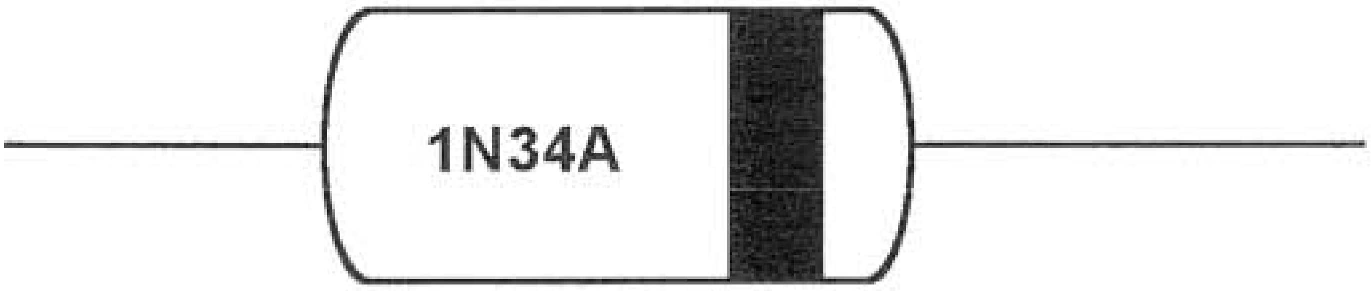
Tuning capacitor.



Resistor:



Germanium diode:



STEP-BY-STEP CONSTRUCTION

Before starting any construction, please read the Vectronics warranty. Kits that have been started *cannot* be returned for credit. Make sure this kit is within your skill level before starting assembly!

Phase 1: Breadboard preparation

☐ Find the pine board. Look it over carefully, and select which side you wish to use for mounting the parts. Chose the side that has the fewest imperfections, and has the nicest looking grain pattern.

☐ Locate the drawing that shows the screw hole pattern for the pine board.

☐ Place the screw hole pattern guide over the board, be sure the board edges line up with the outline on the drawing. Use masking tape to hold the pattern to the board.

☐ Using a finishing nail and small hammer, make a small punch mark at each of the eight screw hole locations. These marks will show you where the screw holes are located on the board. *Don't drive the nail into wood!* We need only make small indentations, about 1/8", to mark the screw locations, and to provide pilot holes for the wood screws.

☐ Remove the paper pattern guide.

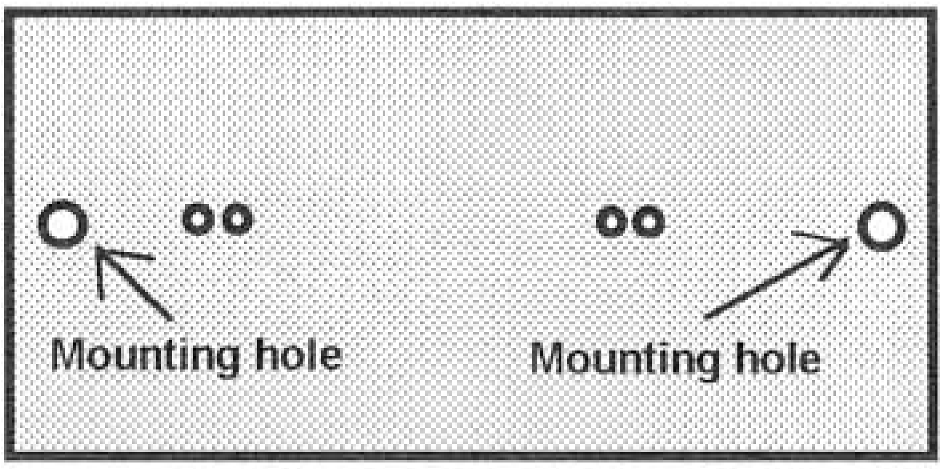
☐ Find one of the eight Phillips head screws and a Phillips head screwdriver.

☐ At each of the eight screw hole locations marked by the finishing nail, screw the Phillips head screw fully into the board, stopping when its head reaches the board surface. Make sure the screw remains perfectly straight, and not tilted, when doing each of the eight holes.

☐ Return the screw to the parts bag.

☐ Find the 5-inch length of PVC pipe. The tuning coil will be wound on this section of plastic pipe. It is called a *coil form*.

☐ There are six holes drilled through the pipe, look for the two outer, and larger sized, mounting holes.



☐ Now, make sure that the two screw pilot holes on the pine board for mounting the coil form are correct. Refer to the drawings in the manual that show the placement for the Fahnstock clips and coil form. Temporarily mount the coil in its proper location using two Phillips head screws. You do not need to fully tighten the screws, we are just checking to see that things fit properly.

Important Note: You will need to use a screwdriver with a long shaft (about three inches) for these two screws because of the large diameter of the coil form.

☐ If the coil form mounting holes align properly with the breadboard's mounting holes, you may remove the coil and return the screws to the parts bag. If things don't match up just right, you will have to mark the correct position for the breadboard pilot hole with a pencil, and remove the coil. Make a new pilot hole by using the hammer and finishing nail to make a small indentation to start the screw. Run a screw into the pilot hole until the head reaches the board surface. Remove the screw and return it to the parts bag.

This completes Phase 1. There should be eight screw holes in the pine breadboard at this point. If so, the mounting holes have been properly located, marked, and the screw holes are ready for parts installation!

If you haven't already done so, this is an excellent time to stain the board (if you are planning to do so).

We are ready to begin Phase 2.

Phase 2: Winding the tuning coil

This portion of the assembly involves winding about 66 turns of 18 AWG enamel coated copper wire over a 2½" area of the PVC plastic coil form. This will take time, patience, planning and practice! Here are a few suggestions to help you along.

You will be directed to unwind a length of wire from the 100-foot coil of enamel wire in several of the following steps. Always unspool the wire, never allow it to uncoil in Slinky™ toy fashion. The unspooled length of wire should be laid out in a straight line—*do not* allow it to simply pile onto the floor, or you will end up with a hopeless tangle of wire. After unwinding a length of wire, use two strips of masking tape to secure the remaining wire on the coil.

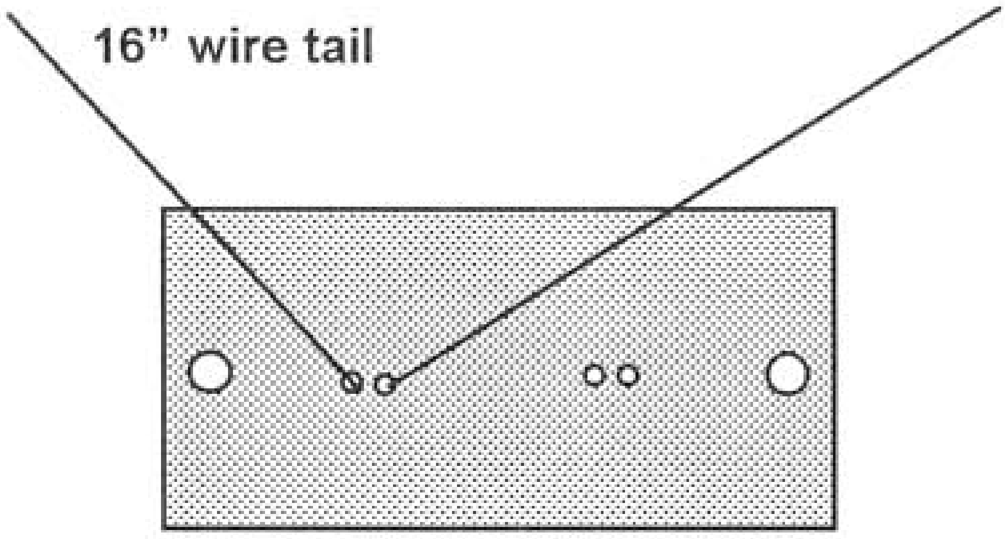
The winding on the coil should be smooth and even—with no gaps or kinks. If the copper wire kinks during handling, smooth it out as best you can before trying to wind it. We are going to wind a single-layer coil, this is called a *solenoid* winding. The winding is done in several steps. You will be instructed to stop winding after a certain amount of wire is wound. If you have a friend who is willing to help, ask him to give you a hand winding the coil. Four hands can be very helpful!

☐ Remove several 5-inch lengths of masking tape from the roll of tape. Keep them within arm's reach while winding the coil.

☐ Find the PVC coil form and the 100-foot hank of coil wire.

☐ Unspool about 15' of wire from the 100-foot coil of wire. Leave wire attached to the spool—*do not cut it!* Tape the remaining wire so it will not unwind and become tangled.

☐ First, secure the wire at the starting point of the winding. Insert about 16" of wire into the starting hole, and loop it back out of the adjacent wire hole and pull tightly. Either end of the form may be used as the starting point. This will secure the wire. The illustration below shows how to do this:



☐ Tuck the 16" wire tail back inside of the coil form, so it will be out of the way during winding.

☐ Hold the coil form in your left hand. The wire coming from the 100-foot coil should be between you and the form. Insert the middle and index finger of your left hand into the coil form. Place your left thumb over the wire at the starting hole.

☐ Use your right hand to help turn the PVC coil form while winding the coil. This takes a little practice, but you will quickly master the technique once you start.

☐ Wind several turns of wire by turning the form. Use your left hand thumb to guide the wire, and keep enough pressure on the wire with your thumb so that the windings are tight, even, and spaced together.

☐ After several turns are completed, examine your work. (Keep your thumb in place so the wire doesn't loosen on the coil form!) The wire windings should be even and spaced so the wire of each turn is firmly pressed against the next. The windings should be tight. There should be no gaps between the wire turns. You can squeeze the windings together to remove small gaps.

☐ The first several turns of the winding form the foundation for the rest of the windings. If you didn't quite get it right the first time, unwind the coil and try again.

☐ Once you are satisfied with your work, grab a piece of masking tape with your right hand, and tape across the windings to hold them securely. *Note:* Tape across and over the windings—the tape should follow the 5" width of the coil.

☐ Using its dispenser tip, put a small drop of contact adhesive on the winding at its beginning and end point. Smear any excess back over adjacent windings using the dispenser tip. Draw a very light bead of adhesive across the full width of the winding. Very little adhesive is needed for these tasks! Let the coil sit until the contact cement has fully cured! (You may use the glue sold for assembling plastic models for these tasks. Remember, it will take several hours for the glue to harden.)

☐ Now, finish winding the tuning coil. It takes about 3 feet of wire to do four full turns. It takes about 66 turns of wire to fully wind the coil over the 2.5" coil span; so you will use about 52 feet of wire for the entire winding. Don't bother trying to count turns as you go. A few extra or missing turns will not affect the performance of the crystal set. What is important is to have the winding cover the full 2.5" inch span, without gaps.

☐ Unspool another 20 feet of 18 AWG enamel coated wire. Remove the masking tape from the coil form. Continue winding until the 20 feet of wire is used. Tape the new windings to hold them in place.

☐ Again, inspect the new windings you have just completed. Are they tightly wound, and free of gaps between adjacent windings? Squeeze the newer windings towards the starting windings to close up any gaps. When you're satisfied, use masking tape to secure the turns, and then fix the windings in place using contact cement or model glue.

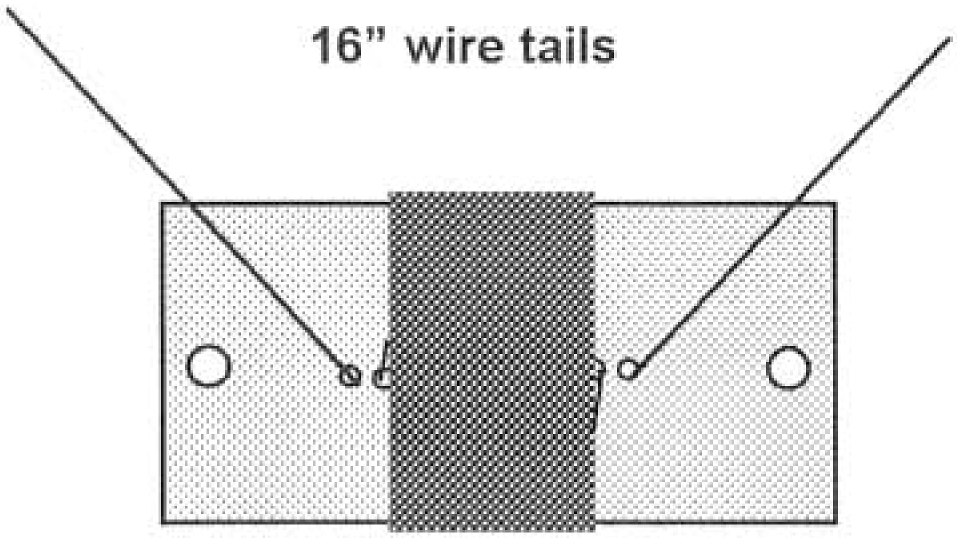
Important Note: As you continue adding windings, you will reach a point where your left hand fingers will no longer reach inside of the PVC coil form. At this point, you will need both hands on the form as you work, and you will be using both thumbs to guide the wire and keep the proper tension.

☐ Continue by unspooling 20 foot lengths of wire at time, winding the coil until you reach the "finish" point on the coil form. Securely tape the coil windings, and glue the new windings in place.

☐ At the end of the winding, mark off an additional 16" of wire, and cut the wire at this point.

☐ Insert the 16" inch wire tail into the "finish" wire hole in the PVC coil form. Bring the wire back out through the adjacent hole and pull with enough force so the wire is snug. Secure the end point of the winding with a very small drop of contact cement.

☐ Fish the wire end for the starting point of the winding out of the form. Your coil should now resemble the illustration below:



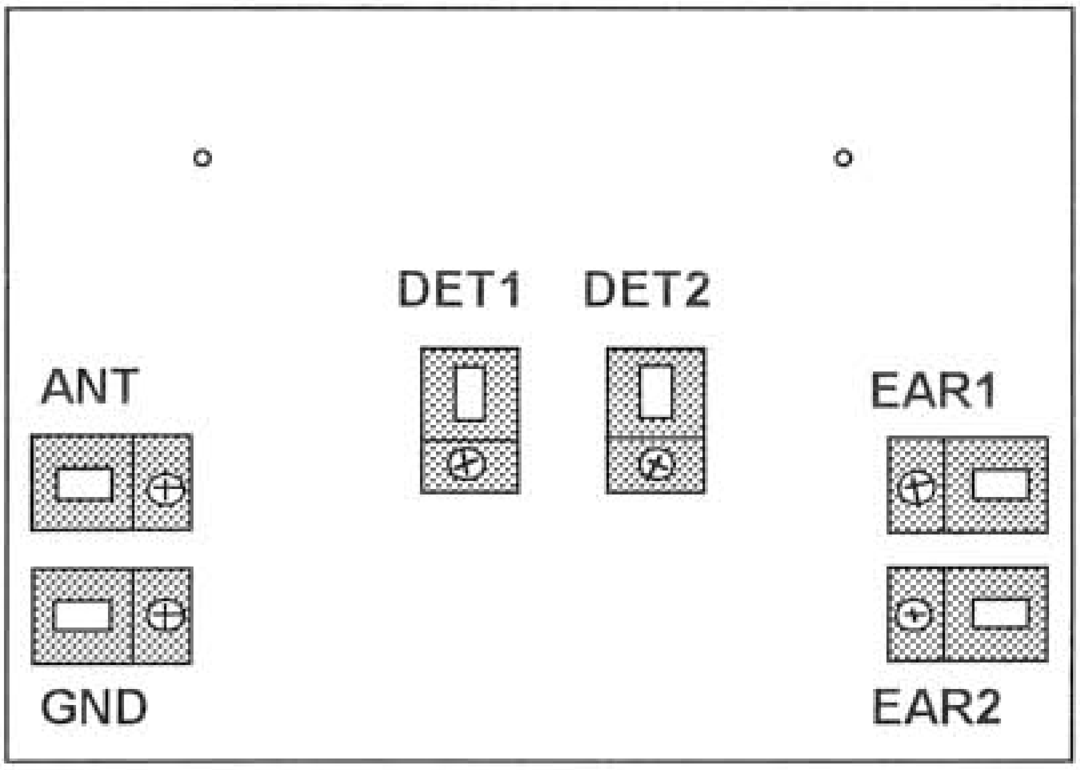
☐ Rewind any excess wire back onto the supply spool.

Congratulations! You have just wound an inductor that has about 217-uH of inductance! Put the coil aside for now, you'll be mounting it on the breadboard soon.

Phase 3: Mounting the parts

☐ Locate the six Fahnstock clips, and six of the eight Phillips screws supplied with the kit.

☐ Refer to the positioning guide below for the following steps.



In the following several steps, we will mount the six Fahnstock clips.

☐ Place a Fahnstock clip at the point shown as *GND* in the drawing. Align the clip so its rounded over edge faces the board edge.

☐ Secure the clip to the board using one of the Phillips head screws. Tighten the screw until snug, so it holds the clip firmly. *Do not over tighten.*

For the remaining steps, align the Fashnstock clips as shown in the drawing.

☐ Mount a second clip at the *ANT* position on the breadboard using a Phillips screw.

☐ Mount a clip using a Phillips screw at the *DET1* position on the breadboard.

☐ Mount a clip using a Phillips screw at the *DET2* position on the breadboard.

☐ Mount a clip using a Phillips screw at the *EAR2* position on the breadboard.

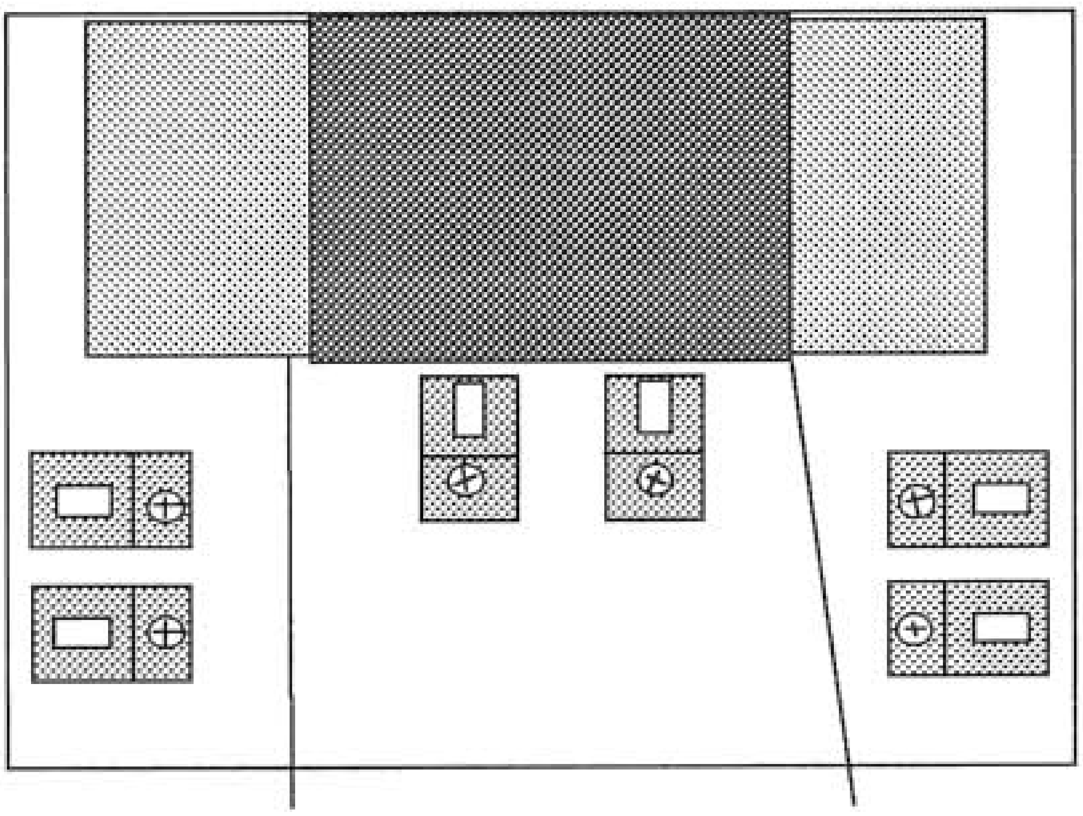
☐ Mount a clip using a Phillips screw at the *EAR1* position on the breadboard.

The six Fahnstock clips should all be mounted at this point.

☐ Find the coil and the remaining two Phillips head screws.

☐ Mount the coil to the board using the two Phillips head mounting screws. Before tightening the screws, make sure the two 16" coil lead wires are oriented towards the front of the breadboard. You may now tighten the screws so the coil is mounted snugly against the board. *NOTE: Over-tightening the screws may damage the coil form, or cause the screws to strip the pine board.*

Your crystal receiver should resemble the following drawing:

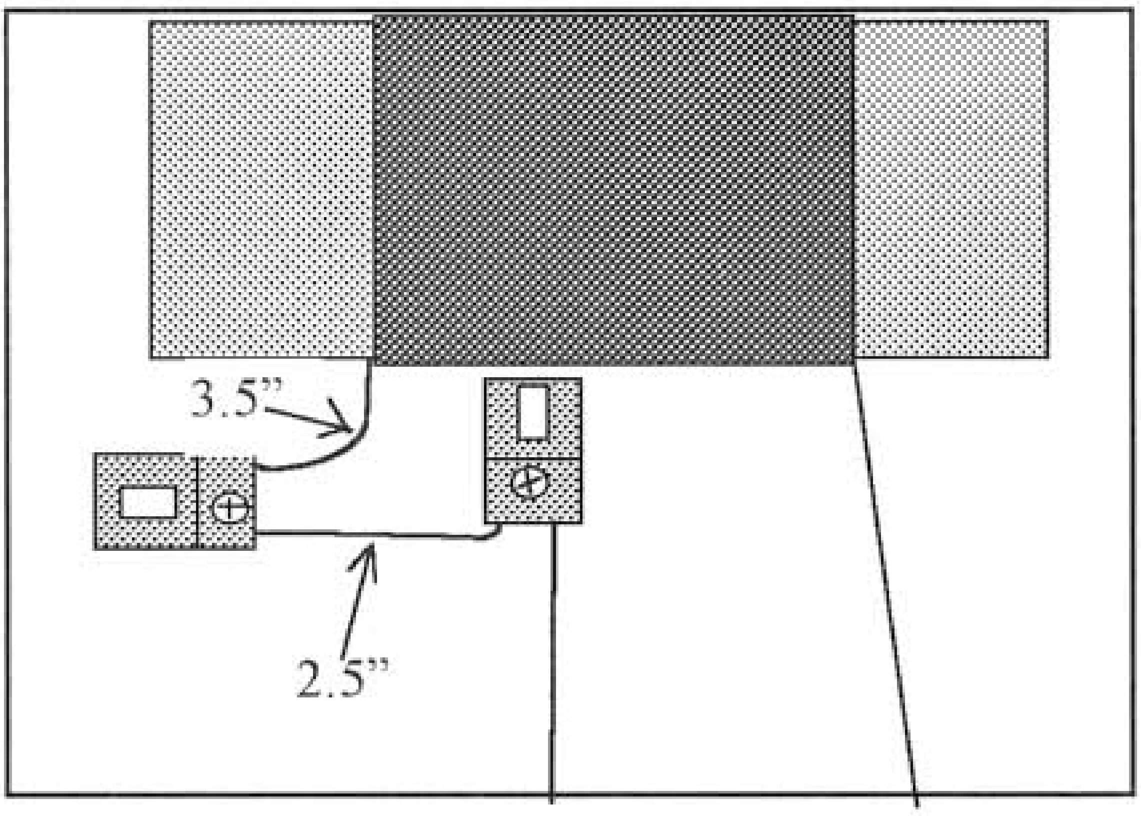


You have finished Phase 3 of your crystal set receiver project. In Phase 4, we'll be doing the wiring between the crystal set's components.

Phase 4: Wiring the crystal set

In phase 4, most of the wiring will involve using the two 16" coil wires. For clarity, we are only showing the components we are going to be working with.

You need to know where the wire leads need to be sanded to make connections. Route the coil wire, as shown in the following diagram, by loosening the Phillips screws mounting the two Fahnstock clips labeled ANT and DET1 (as shown):



☐ Measure and mark the coil wire lead at the left-hand side of the crystal set at 3.5 inches. The measurement is taken from the point where the wire exits the form.

☐ Remove about 1" of insulation at the 3.5" mark.

☐ Form the wire so the area stripped of insulation forms a *through connection*.

☐ Loosen the Phillips head screw for the *ANT* Fahnstock clip.

☐ Route the *through-connection* loop so it passes between the *ANT* Fahnstock clip and breadboard.

☐ Tighten the *ANT* clip mounting screw so it is snug.

☐ Measure and mark the wire lead emerging from the antenna clip at 2.5".

☐ At the 2.5" point, remove 1" of wire insulation, and form a second *through-connection* half loop.

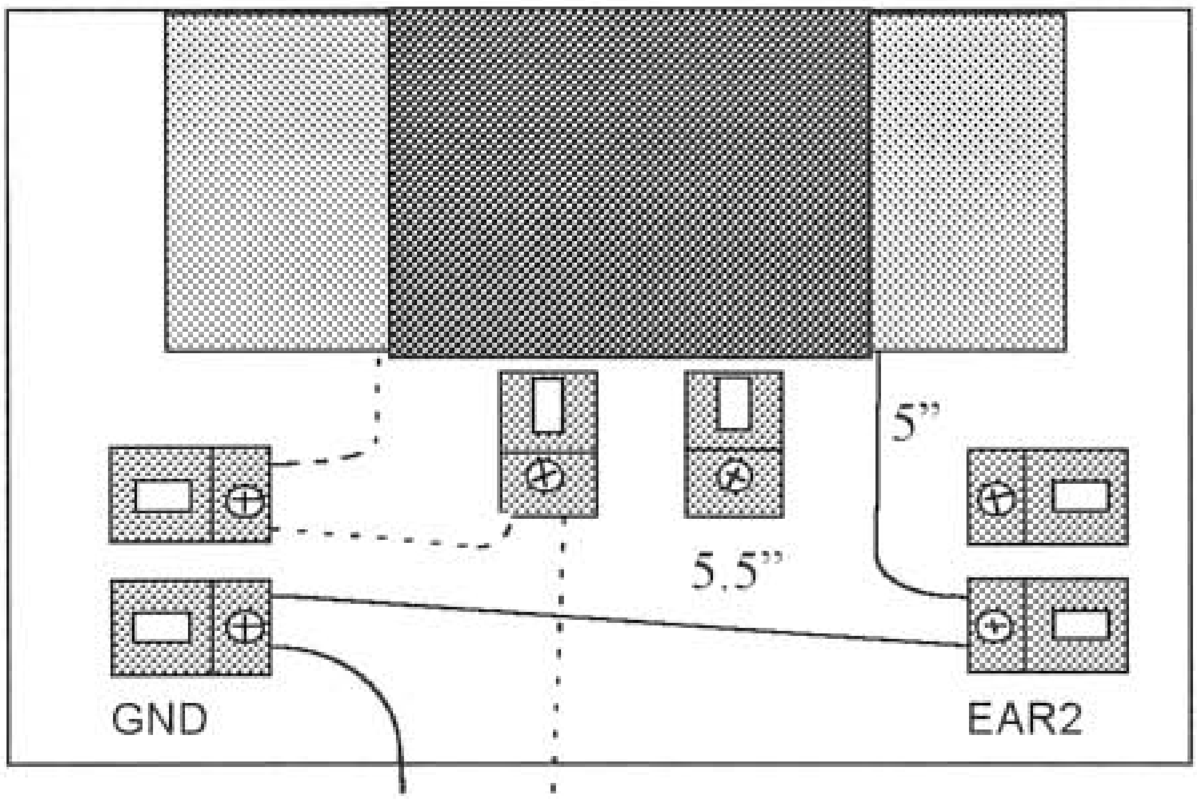
☐ Loosen the Phillips screw mounting the *DET1* Fahnstock clip.

☐ Route the second through connection so it passes under the *DET1* Fahnstock, loops around the screw shank, and exits as shown in the drawings.

☐ Tighten the Phillips screw for the *DET1* clip so it is snug.

☐ Several inches of wire should remain from the *DET1* clip connection, this will be used later. ***Do not cut the wire until told to do so!***

In the next few steps you will be working with the right-hand coil wire. Refer to the drawing below for the following steps:



Important Note: The "dotted" lines show wiring done in previous steps.

☐ Mark the left-hand coil wire at 5" from where it exits the coil.

☐ At the 5" point, remove 1" of insulation from the wire.

☐ Form the area stripped of insulation into a *through-connection* half loop.

☐ Loosen the Fahnstock clip mounting screw for the *EAR2* clip.

☐ Pass the *through-connection* between the *EAR2* clip and breadboard, with loop going around the Phillips screw shank, as shown above.

☐ Tighten the mounting screw for the *EAR2* clip until snug.

☐ Measure the wire exiting from the *EAR2* connection, and at the 5.5" point remove 1" of insulation from the wire.

☐ Form the area of wire stripped of insulation into a second *through-connection* half loop.

☐ Loosen the Phillips screw that mounts the Fahnstock clip used for the *GND* connection.

☐ Pass the *through-connection* between the *GND* clip and breadboard, with the loop going around the Phillips screw shank, as shown above.

☐ Tighten the GND Phillips mounting screw until snug.

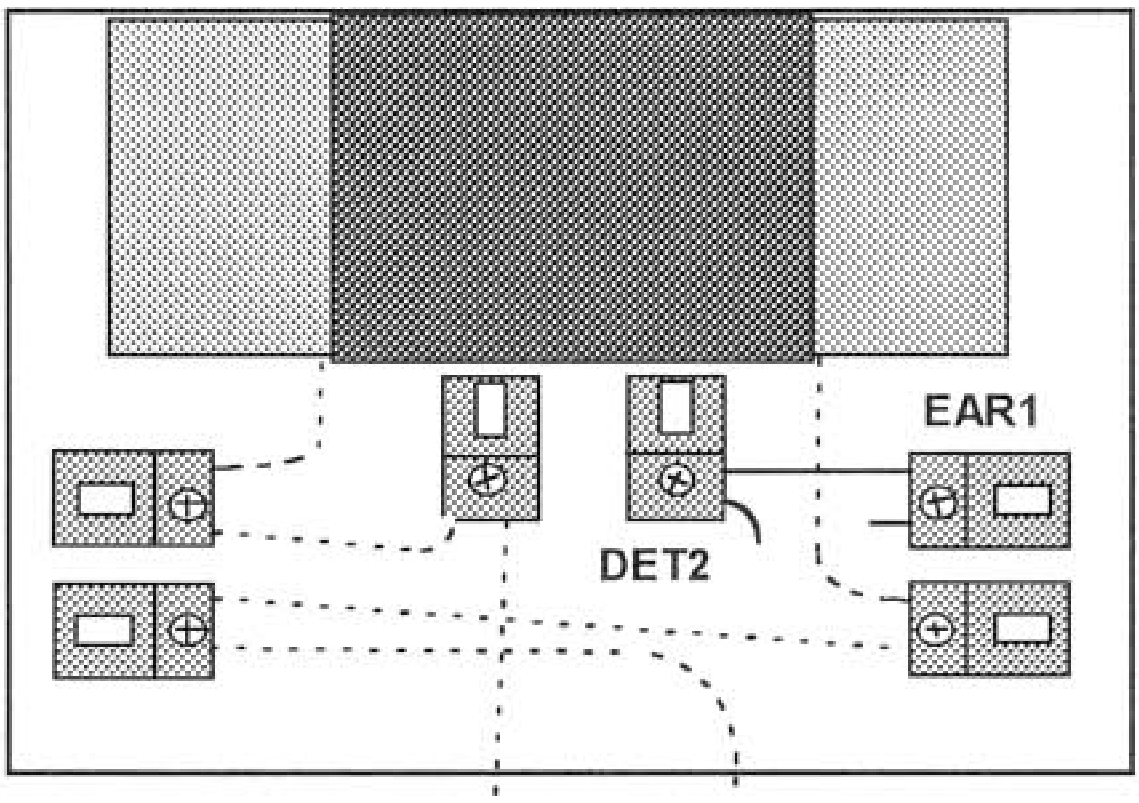
☐ Several inches of wire should remain from the *GND* connection. ***Do not cut this wire until instructed to do so!***

This completes Phase 4. You've come a long way since first opening the kit. Your little crystal receiving set is really starting to look like something.

Phase 5: Final wiring

Only a few more steps remain, and the set will be finished.

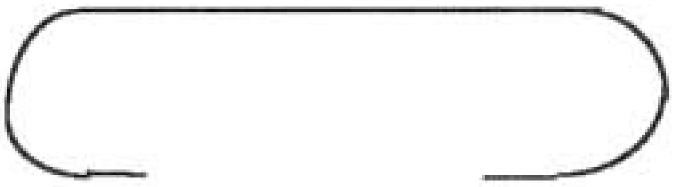
Refer to the drawing below for the last wiring steps.



☐ Cut a 4½" length of 18 AWG enamel wire from the wire spool in the kit.

☐ Remove 1" of insulation from each end.

☐ Form each end of the wire into an *end* connection.



☐ Loosen the screws mounting the Fahnstock clips *DET2* and *EAR1*.

☐ Take one of the wire *end* connections and place between the *DET2* clip and breadboard.

☐ Tighten the mounting screw for the *DET2* clip until snug.

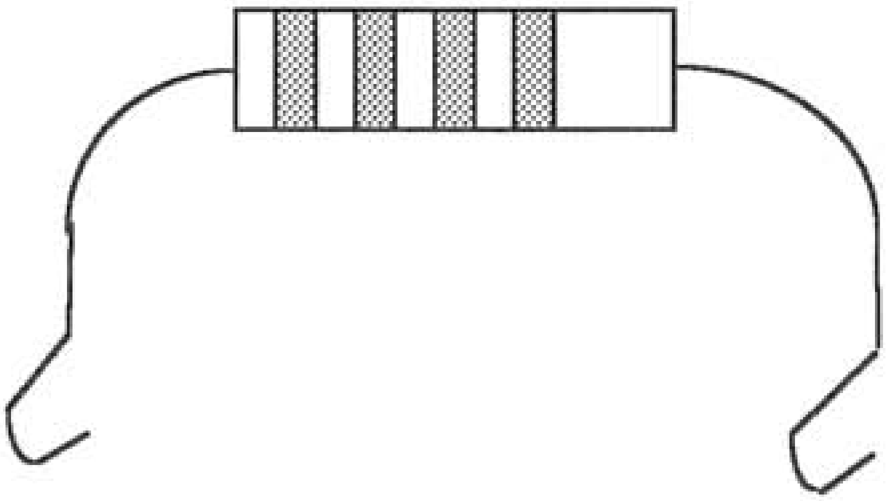
☐ The remaining *end* connection is placed between the *EAR1* clip and breadboard.

☐ Tighten the mounting screw for clip *EAR1* until snug.

☐ The wire should be routed so it crosses over the wire from the right end of the coil without the wires touching each other.

☐ Find the 27K ohm resistor (it has the Red-Violet-Orange-Gold colored bands) and form the leads as shown below:

Important Note: It makes no difference which lead is used for either connection.



☐ The ends of the resistor leads are formed into little half loop hooks.

☐ Loosen the two Phillips screws for *EAR1* and *EAR2* clips.

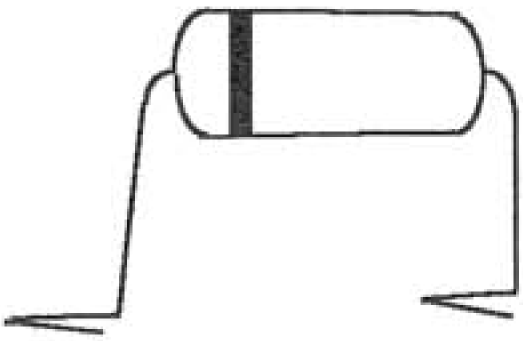
☐ Put one of the half loop connections between the *top* of the clip body, and the *bottom* of the screw head for the *EAR1* clip. Adjust the size of the loop so it fits snugly around the shank of the screw.

☐ Tighten the mounting screw for clip *EAR1* until snug. The resistor lead should remain firmly attached.

☐ Place the remaining loop between the screw head and body of the clip *EAR2*. Re-form the loop so it fits snugly around the screw body.

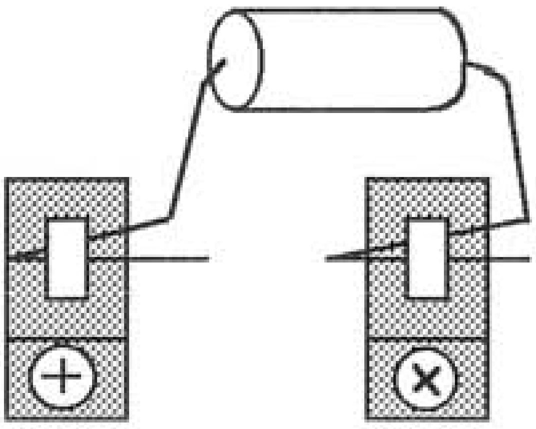
☐ Tighten the screw for clip *EAR2* until snug. The resistor lead should remain firmly attached.

☐ Find the germanium detector diode. Form the leads as shown below.

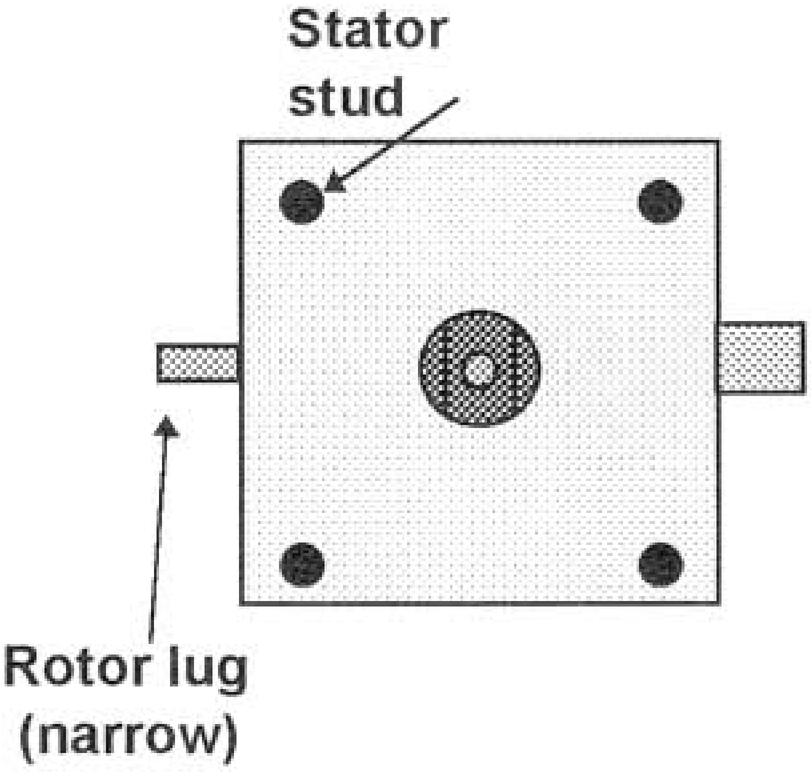


☐ A 3/8" length of each of the diode's lead ends is sharply folded back on itself. This is done because the diode will be mounted in the *DET1* and *DET2* Fahnstock clips. The diode lead wires are a very small diameter, and may not be held tightly enough by the clip unless the leads are made a bit thicker.

☐ Follow the diagram below, and clip the diode's anode lead into the *DET1* Fahnstock clip, and the cathode lead (the lead with the band close to it) into the *DET2* Fahnstock clip. Gently pressing down on the clip opens the jaw, permitting the wire lead to be inserted.



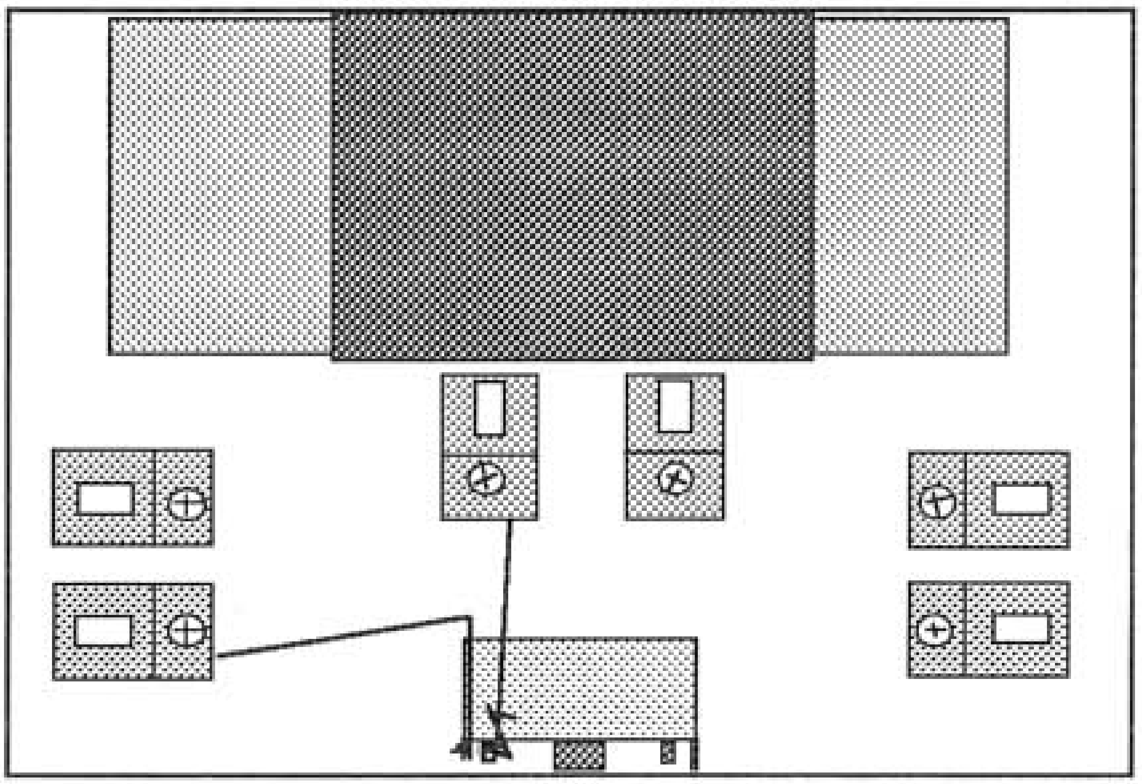
Find the tuning capacitor. Refer to the drawing below for the following steps.



This is the correct orientation for installing the capacitor. Note that the narrower rotor lug must be at the left hand side!

Variable capacitors have two sets of plates. One set of plates remain stationary, and are called the "*stator*" plates. The tuning shaft is attached to another set of plates that rotate as the shaft is turned. They are called the "*rotor*" plates. As the shaft is turned, the plates are either meshed or unmeshed, changing the capacitance value. This is how the tuning capacitor works.

The tuning capacitor will be mounted at the front center of the breadboard using the double-sided foam tape. The remaining enamel wire lead coming from the *GND* Fahnstock clip will be connected to the narrow *rotor lug* terminal on the tuning capacitor. The remaining enamel wire lead from the *DET1* Fahnstock clip will be connected to the round *stator stud* on the front of the capacitor.



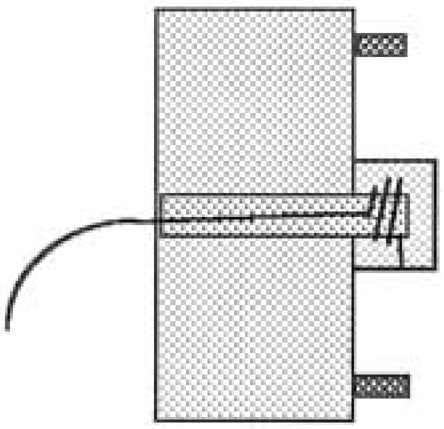
The above drawing shows how the wires will be routed to the tuning capacitor connections.

Connecting the stator lead

- ☐ Temporarily place the tuning capacitor as shown in the drawing. ***Be sure the narrowest stator lug is at the left hand side!***
- ☐ Cut the free enamel wire lead from the *GND* clip to a length of five inches.
- ☐ At the end of the wire, remove 2" of insulation.
- ☐ Route the enamel wire from the *GND* clip so it reaches to the capacitor body. At that point, the wire goes up to the middle of the capacitor, and then makes another sharp bend towards the front of the board.

Study how the capacitor is made. If you look into the capacitor through its clear plastic housing, you can see how the narrow rotor lug continues to the rear of the capacitor. At that point, there is a tiny opening in the plastic capacitor housing.

- ☐ Take the wire from the *GND* clip and insert it into this capacitor opening. Carefully feed the wire so it passes through the capacitor body (it will be between the plastic housing and narrow metal strap) and finally emerges at the front end of the capacitor.
- ☐ Continue feeding the wire until 1" of bare enamel wire clears the front opening in the capacitor.
- ☐ Using your long nose pliers, carefully wrap the enamel wire around the narrow rotor lug until two or three full turns are made. Trim off the excess wire.



- ☐ Gently, but firmly, squeeze the turns wrapped around the rotor lug, using the long nose pliers, until they are compressed tightly--making a good, tight electrical connection.

Important Note: If for some reason the narrow rotor lug is damaged while trying to attach the lead, use the wider rotor lug as an alternate connection point.

Making the stator connection

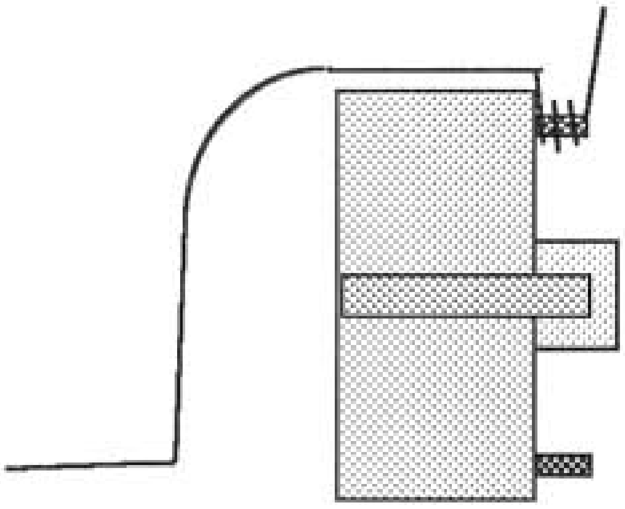
☐ Temporarily place the capacitor at its mounting location.

☐ Route the free enamel wire coming from the *DET1* Fahnstock clip so it follows the breadboard, and comes up and over the top of the capacitor until it reaches the stator stud. (Refer to the drawings to identify the proper stud.)

☐ Trim the wire coming from the DET1 clip to a length of 4½".

☐ Remove 1½" of insulation from the wire end.

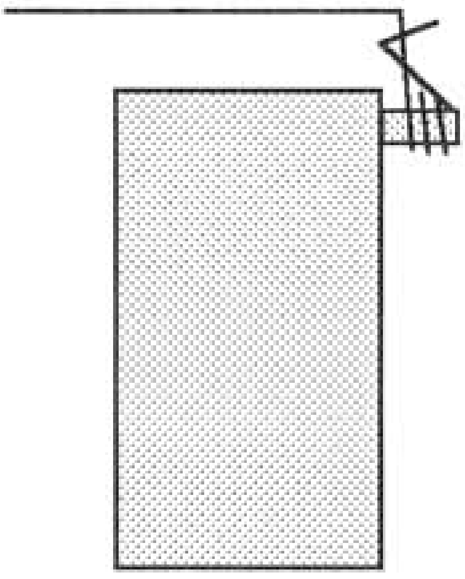
☐ Wind the wire over the stud to form three *tightly* wound turns. See the following drawing. Use enough wire so when finished you have a small ½" pigtail remaining.



☐ You need a good, tight electrical connection. Slide the turns off of the stud—note how they make a little coil. Gently tighten the coil by twisting the coil so it is smaller.

☐ The coil should slide back on with some difficulty—otherwise the turns are to loose.

☐ To make an even tighter connection, take the pigtail, and wrap it back over the wire in a half-loop.



☐ Using the long nose pliers, gently twist the half loop to take up wire slack and tighten the wire wraps made over the stud.

Important Note: If the stator stud is damaged beyond use, the stud located directly beneath it may be used as a backup. The two right hand studs may not be used.

☐ Place the capacitor at its mounting location at the center front of the board. The body of the capacitor should sit about 1/8" back from the board edge. Use a ruler to center the capacitor body at 3" from either outside board edge.

☐ Mark the capacitor body outline by tracing its outline onto the breadboard with a pencil.

☐ Find the double-sided foam tape.

☐ Remove one of the protective covers from one side of the tape. Place the sticky side over the capacitor outline on the breadboard. Firmly press the tape to set the adhesive.

☐ Remove the protective cover over the top of the tape.

☐ While being careful to keep the capacitor centered on the board, and parallel to the front edge of the board, press it to the foam tape. Apply gentle, but firm, pressure to set the adhesive.

☐ Find the ¼" diameter aluminum tuning shaft extension. Align the threaded screw end with the opening in the capacitor tuning shaft. Screw the extension into the tuning capacitor.

☐ Unscrew the tuning shaft about 1 or 2 turns, to open a gap between the two shafts.

☐ Using the dispenser, allow a small drop of contact adhesive to flow into the gap and onto the threaded portion of the extension. *Quickly* screw the extension back into the tuning capacitor to close the gap. If you are using model airplane cement, unscrew the shaft extension, and lightly smear a small amount of glue over the threads. Quickly screw the extension back into the capacitor shaft.

☐ Allow time for the glue to harden.

☐ Using a small screwdriver or hex tool, install the tuning knob on the shaft extension.

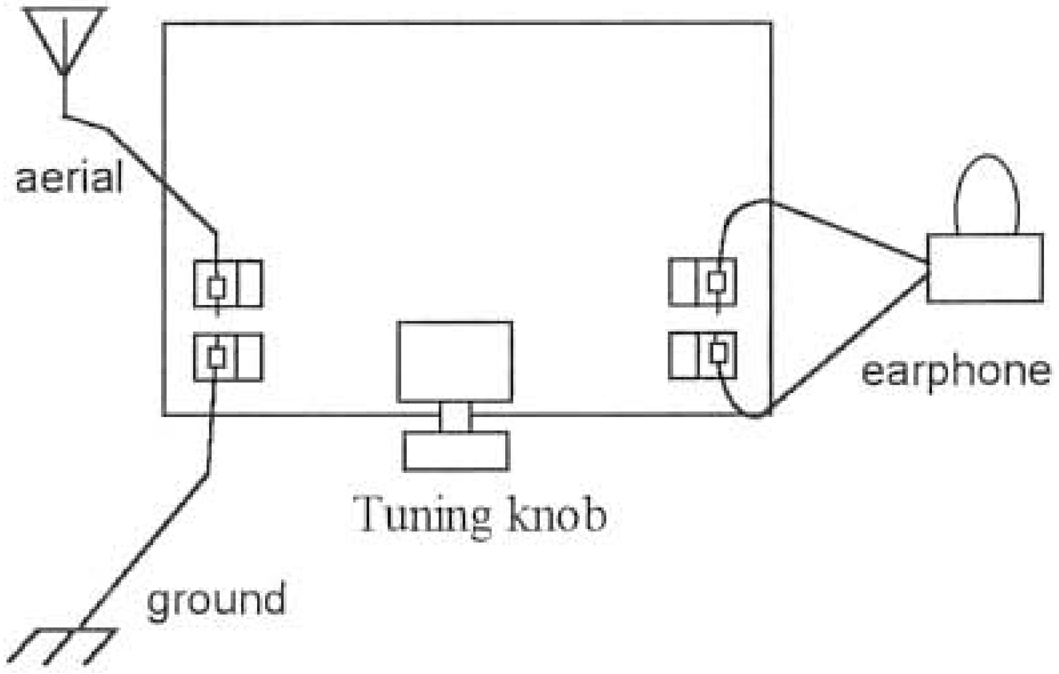
This completes the construction of the VEC-121K crystal set receiver.

TESTING AND ALIGNMENT

1. Turn the capacitor shaft in a counter clockwise direction until the stop is reached.
2. Loosen the tuning knob set screw, and align the tuning indicator on the knob so it corresponds to the 9 o'clock position.
3. Tighten the set screw.
4. Verify that the knob indicator properly corresponds to the capacitor stops at the 9 and 3 o'clock positions.

OPERATING INSTRUCTIONS

1. Use the hookup shown in the following diagram to make the antenna (aerial), ground, and earphone connections.



2. Connect the earphone wires to the Fahnstock clips at the right hand side of the radio.

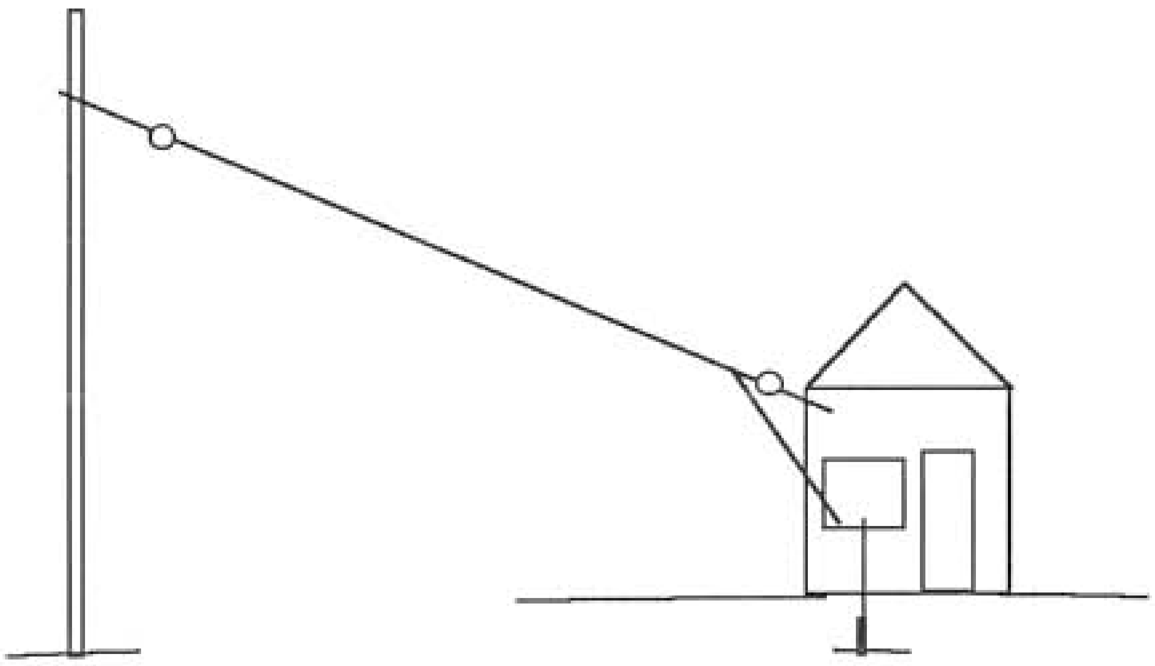
3. Connect a good ground connection to the crystal receiver. Use the 7 foot length of stranded hookup wire supplied with the kit to make the ground connection between a good earth ground and the Fahnstock clip on the receiver.
4. Connect a long wire antenna to the Fahnstock clip on the receiver.
5. Carefully tune the tuning knob while listening for signals in the earphone. You should be able to copy at least one, and maybe several, stations without difficulty.

What can I hear? You should be able to hear local stations without much difficulty. The crystal set tunes the entire broadcast band from 530 kHz to 1700 kHz. The antenna and ground system are the keys to success when using crystal sets. Where you live affects how well you receive signals. If you live in a salt marsh, or along the shore, you may experience exceptional reception. The fellow living in an arid area with poor soil moisture may have much poorer reception.

When to listen? You should hear local stations at any time of the day. At dusk, radio signals propagate over greater distances. Listening just before the sun goes down may yield some pleasant surprises! Also, as the seasons change, you may find you can hear different distant stations at sundown. Keep a simple log of new stations when you receive them. Note the time, call letters and frequency. It's always fun to add a "new one" to the list.

Erecting a good antenna

Your radio will work only as good as the antenna and ground it is connected to do. The best antenna for a crystal set is located outdoors, it is between 100 and 30 feet long, and is mounted high and in the clear. Your kit includes enough wire to make an outdoor 40 foot wire antenna and short lead-in wire to the crystal set receiver.



This diagram shows an aerial going between a pole (or tall tree trunk) and location where the receiver is located. A small length of lead-wire connects the antenna to the crystal set inside of the house. (Make sure the lead-in wire makes good electrical connection to the antenna wire!) Note the insulators between the antenna wire and the supporting structures. A good earth ground is provided by a short ground rod driven into the earth outside of the window where the crystal set is located. You may make your own insulators from scraps of 1" plastic pipe, or small sections of 1" by 6" Lexan™ or Plexiglas™ . Drill holes at the ends of the insulators for tie-points for the antenna wire and support rope. Clothesline is a good way to tie the insulator to the supporting structures.

The antenna wire should not be allowed to touch leaves or rub against branches. Doing so will affect your reception. Keep your antenna wire away from power lines.

Finding the elusive ground

Several feet of insulated stranded hookup wire is included in your kit. This is provided to connect a *ground* to the crystal set. But, what is a good *ground* and how can you make or find one?

Ground rods. Many times a crystal set will work quite well without a ground connection, especially if a very good antenna is being used. The most effective ground is a 10 foot ground rod driven into the earth. If you have a TV antenna on your home, it should be connected to a ground rod for lightning protection. If it is near your operating position, you may be able to tie a wire between your crystal set and the TV antenna ground rod. Even four or five feet length of old copper pipe driven into the earth will do in a pinch! But, be sure you use some sandpaper to remove any corrosion on the pipe that would prevent making a good electrical connection to your ground wire lead in.

Water pipe grounds. If you live in an older home that uses metal instead of plastic plumbing, you have a good ground point at the nearest water pipe or radiator. Connect a short wire between the crystal set ground and the water pipe. Remember that the pipe must be free of corrosion or paint to make a good electrical connection.

Counterpoise grounds. The reason the crystal set needs a ground is because a single wire antenna is really only one-half of a complete antenna! The ground makes up for the missing half of the antenna, and gives the wire antenna something to "work against". If you have 50 or 60 feet of scrap wire laying about, you can make what is called a "counterpoise" to serve as a ground for the crystal set. Simply run the wire out on the ground in a straight line. The wire needn't be buried, it will "couple" to the earth due to "stray capacitance".

Connect one end of the counterpoise wire to the ground Fahnstock on the crystal set, and you're in business!

IN CASE OF DIFFICULTY

This crystal set almost *has* to work, if it was built according to the directions. If you can not hear any stations at all, go back over the assembly instructions and try to find any errors that you might have made during construction. Perhaps you missed removing the insulation from the wire at a connection. Or, a wire is in the wrong place. Have a friend check your work. It's very easy to look over a mistake, and a fresh pair of eyes will often quickly find mistakes that elude your detection. Factory repair is available for assembled kits that do not work. Consult the warranty for information regarding factory service.

Here's a quick check list of common problems.

The set receives several signals at once. This is normal for crystal sets. They don't have the ability to separate signals that very are strong or close in frequency.

The tuning control has no effect. Check that the connections to the tuning capacitor are tight, and that the proper connection points to the tuning capacitor were used.

Signals are very weak, or I can only hear one station. Again, this may be normal, if there are no strong signals in your area. Check your ground and antenna connections. A longer antenna or better ground may improve things.

Set works intermittently. This sounds like a poor connection. Check that the Fahnstock clips are making good connections to the antenna, ground and earphone wires. If a clip won't grip the wire properly, remove the wire and bend the clip upwards slightly. This should restore the clasping action of the clip's jaw.

There is a local station at the high or low end of the dial that I can't hear. The VEC-121K is designed to tune the entire broadcast band. However, there will be certain antenna lengths that will behave in unexpected manners at certain frequencies. Also, because of the way the antenna and ground are coupled to the receiver tuned circuits, they will also have some effect on the tuning range limits.

THEORY OF OPERATION AND SPECIFICATIONS

The tuning capacitor and coil form a parallel resonant circuit that tunes from about 530-kHz to over 1.6 MHz. The antenna and ground are directly applied across the resonant circuit. Thus, the set is optimized for use with short, high-impedance antennas under 100' long. The parallel resonant circuit acts like a very low impedance path to signals off resonance. (Signals that are not tuned in see a "short circuit".) At resonance, the parallel circuit becomes a very high impedance (offers little resistance to a signal it is tuned too).

Signals that are "tuned in" are "rectified" by the germanium detector diode. The radio signal is simply a high-frequency AC voltage. During rectification, better called detection, the signal is broken down into two components: a DC voltage and a AC signal that corresponds to the information being carried by the Amplitude Modulated signal. The AC signal maybe voice, music, or whatever program material the radio station is broadcasting.

Because the audio recovered from the radio station AM carrier is a very, very, small voltage, the ear piece must be very sensitive. The high-impedance crystal earpiece supplied with the VEC-121K meets those requirements. Because the crystal earpiece has almost no resistance, a 27K ohm resistor is placed across the earphone clips to provide a path for the detector diode current.

Tuning Range	530-1700 KHz (typical)
Detector diode	Fixed germanium, 1N34A or equiv.
Headphone impedance	2000-ohms or higher
Mode	AM receiver

High-performance electronic kits . . . fun to build and use!

Kit building is a super fun way to spend a quiet evening or weekend. You'll find it extremely satisfying to build your own electronic equipment. You'll have a useful electronic gadget that you can show off once you're through. You'll cherish it for years because *you built it yourself.* From shortwave converters to aircraft receivers and ham radio kits to an old fashioned crystal radio kit, you'll find many fun items in the VECTRONICS kit line for you.

VECTRONICS kits work! They're created by engineers who are hobbyists-at-heart to give you what you want -- a professional product at a hobby price. Each kit features a professional quality epoxy glass PC board with solder mask and screen printed component legend, simple step-by-step instruction manual and the highest quality components. Kit assembly is easy, and they work the first time.

Don't forget about our custom cabinets -- they turn your kit into a fabulous show piece that your friends won't believe that *you* built.

With VECTRONICS kits you get satisfaction, relaxation, and a super-fun product you'll be proud to use . . . *because you built it yourself!*

VECTRONICS has a worldwide reputation of building the finest quality amateur radio products made. You can trust our 30 years of experience to deliver super quality, high-performance kits.

All VECTRONICS electronic hobby kits are designed and kitted in the USA . . . *and built by you!*

A LADYBIRD BOOK

making a Transistor Radio

A crystal set – the tuned circuit

A crystal set, the simplest form of radio receiver, is the first stage of our radio. It can operate entirely on its own as a radio receiver, even if no further stages are added.

As we have read on page 6, an aerial picks up all the radio signals (the radio frequency carrier waves) in its path. But we need only signals of a certain frequency—those sent out by a particular transmitter. We therefore need some sort of filter—to allow only one radio station to be received at once. A *tuned circuit* is this filter, because it can be tuned to any frequency we want, and can select one of the many radio frequency carrier waves reaching the aerial.

A tuned circuit consists of a *coil* of wire and a *tuning capacitor*. On the opposite page you can see a circuit diagram for a tuned circuit, and beneath are shown the actual components—a *coil* and *tuning capacitor*.

The particular radio frequency waves which a tuned circuit selects depends on the number of turns of wire on the coil and the 'value' of the capacitor. Since it is inconvenient to keep changing the number of turns of wire on the coil, the capacitor is made with movable plates so that the tuning can be varied and the signals we want selected.

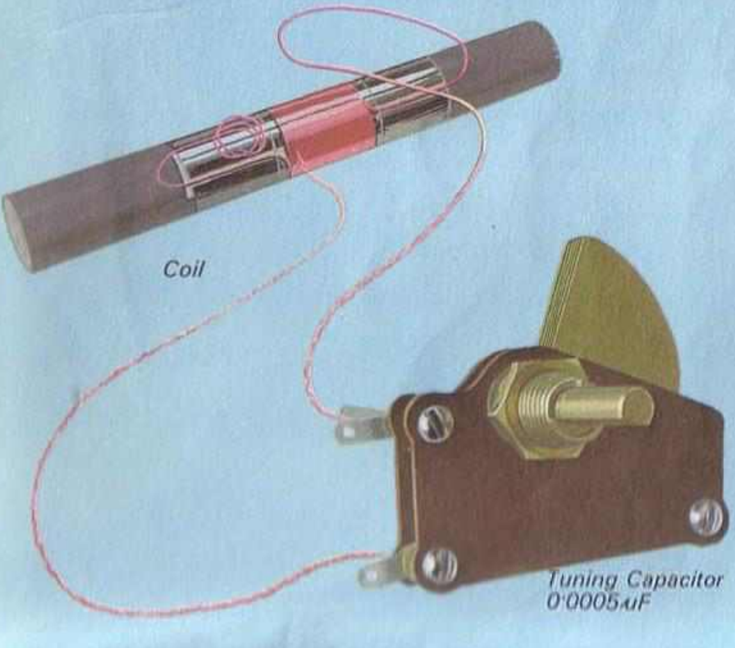
Tuning
Capacitor

A TUNED CIRCUIT



Coil
Tuning Capacitor
0·0005μF

A crystal set – the crystal diode

After the tuned circuit has selected the particular carrier wave frequency required, the audio frequency signal which it carries must be extracted from it. The *crystal* (sometimes referred to as a *diode*) is a simple device that does this by allowing current to pass only one way. It is used in the crystal set as a 'detector'. The action is a complex one, but we can simply say that it detects from the radio frequency carrier wave the *electrical* waves of the same frequency as sound (*audio*) waves and which a loudspeaker or headphone can convert into *sound*.

On the opposite page you will see a circuit diagram showing the tuned circuit mentioned on the previous page but with the symbols for the diode and the earpiece included. With the addition of the aerial and earth symbols, we now have a circuit diagram for a complete working radio set.

Also illustrated are a typical earpiece and a crystal diode.

Tools for radio construction

Simple radio construction, of the sort described in this book, requires few tools. Most of these can be found in a normal household toolbox or are inexpensive to buy.

During the building of the radio, wires have to be bent into place and sometimes cut to the correct length. Some components are joined by P.V.C. covered copper wire which has to be cut to size and its covering removed from the ends to make the connection. The most useful tool for this is a pair of pointed-nose pliers. These will also strip the plastic from the wire before the connections are made. A pair of wire cutters may also be used to cut and strip wire.

It is possible to buy an inexpensive little tool called a 'wire-cutter and stripper' to do both jobs. A pocket knife is useful for scraping the ends of the wire to clean them before the connections are made. Sandpaper or the rough edge of a matchbox can also be used to clean wires before they are connected. A medium-sized screwdriver will be needed for making the connections.

This radio is to be built on a wooden base, so a few simple woodworking tools—handsaw, gimlet, brace and bit—are also required.

CLEANING WIRES

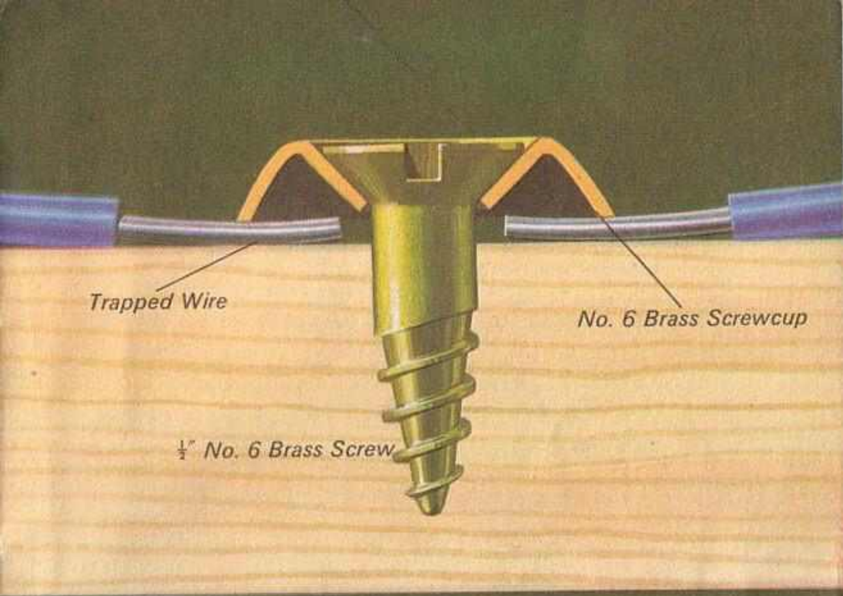
Fixing the components

In electronic construction it is usual to *solder* the components into their places in the circuit. This radio is designed for the beginner, so a non-soldering method of connection is used. For those who wish to solder the connections, the technique is explained on the inside back covers of this book.

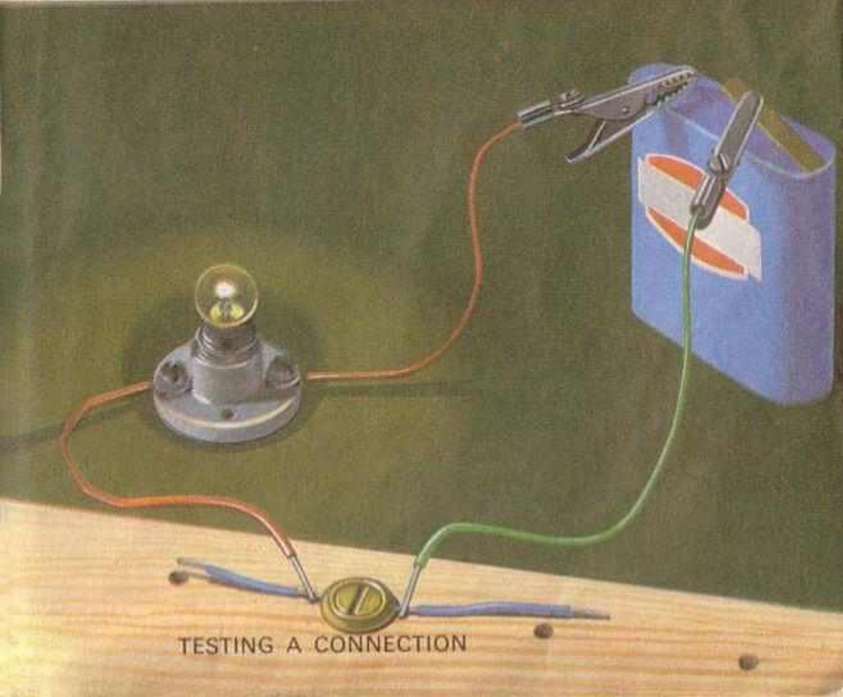
A simple method of connecting the components uses woodscrews and washers. The screws are No. 6 brass countersunk, half inch screws and the washers are No. 6 brass screwcups. Two dozen of each are required. All are obtainable from your local ironmonger.

The method is explained in the diagram opposite, but remember the following tips: (1) Make sure the wire to be connected is scraped clean until it shines. (2) Where several wires are trapped under one washer, do not finally tighten the screw until all the wires are in place.

It is possible to test a connection with the simple battery and bulb arrangement in the diagram. Touch the two leads onto some of the bare wire either side of the connection. If the connection is good, the bulb will light up.



Trapped Wire
No. 6 Brass Screwcup
½" No. 6 Brass Screw



TESTING A CONNECTION

Making the circuit board

In the early days of radio, receivers were made on a baseboard sometimes called a 'bread board'. We are using a form of bread board mounting.

Softwood is used for the base. Mount the screws and screwcups, used for connections, at one inch intervals in two rows of eight. The rows should be an inch-and-a-half apart. This is shown in the drawing facing this page. The two large holes are made with a brace and bit and are for mounting the control components.

The accuracy of the measurements is not vitally important, but it would be helpful to follow those given as closely as possible. Not all the screws are used in building the first part of the radio; the additional screws are needed later as the radio is completed. Although this board is very simple to make, it is important to try to get the screws in straight so that the screwcups press firmly onto the wires.

Winding the coil

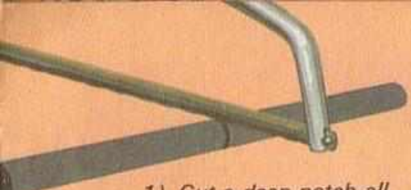
Before the crystal set can be built, we must wind a tuning coil for the tuned circuit. This is done on a piece of ⅜ inch diameter ferrite rod. Ferrite is iron dust stuck together. Usually ferrite rods are 6 inches long, so cut a notch all round the centre and smartly snap the rod in half (Figs. 1 and 2).

Wrap about 1½ inches of sticky tape around the centre of the rod on which to wind the coil (Fig. 3).

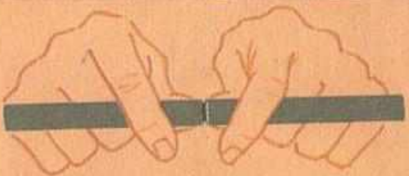
Obtain some 36 s.w.g. (standard wire gauge) enamelled copper wire from your radio or electrical dealer. Leaving about 3 inches of wire, secure one end of the wire with sticky tape (Fig. 4) and wind 5 turns, side by side, onto the rod (Fig. 5). Pull out a 3 inch loop and twist the wire until it is tight up to the rod (Fig. 6). Then wind a further 45 turns, side by side, securing the final end with tape. The whole coil can be covered with tape to keep the windings secure.

Remember to leave about 3 inches of spare wire at both ends and at the twisted wire (the 'tapping' point). Later the enamel must be scraped off so that connections can be made.

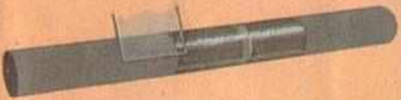
The illustrations opposite will guide you through each stage.



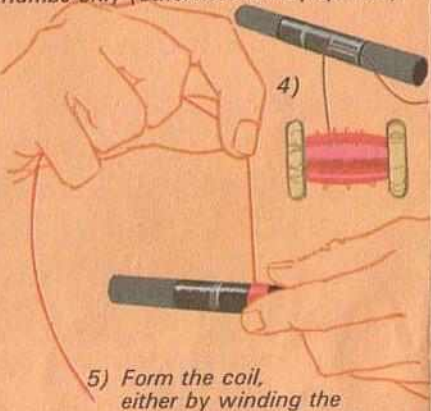
1) Cut a deep notch all the way around the rod



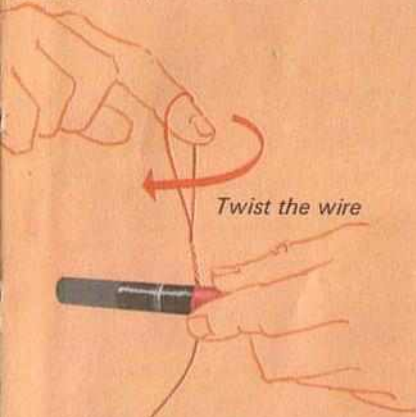
2) Snap the rod by holding close to the notch with forefingers and thumbs only (otherwise it may splinter)



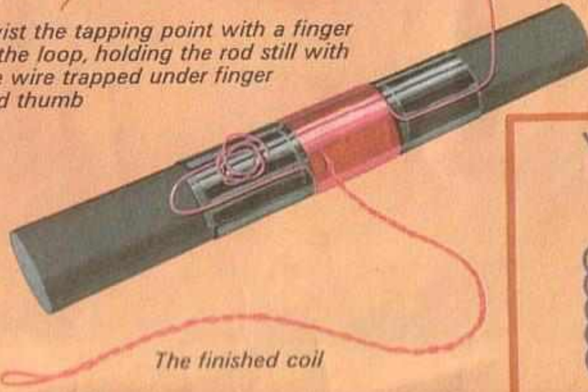
3) Wind the tape in separate parallel bands, slightly overlapping. (If spirally bound the tape will wrinkle)



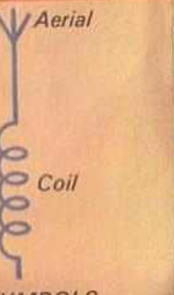
5) Form the coil, either by winding the wire or rotating the rod, whichever you find easier



6) Twist the tapping point with a finger in the loop, holding the rod still with the wire trapped under finger and thumb



The finished coil



SYMBOLS

Building the crystal set

Having made the coil, the ferrite rod can be mounted on the baseboard by twisting a loop of stiff wire around each end and screwing the wire under two screwcups, as shown opposite.

Next the tuned circuit can be completed by the addition of the tuning capacitor. You can buy one from your local radio dealer and you should ask for a 0·0005μF solid dielectric type. The illustration opposite shows how it is mounted on the baseboard, the capacitor spindle passing through the ⅜ inch hole. The wiring connections are made to the two terminal nuts on the back of the capacitor. The connecting wire used should be PVC covered copper wire, the ends being bared before they are trapped under the screwcups.

The illustration also shows how the diode is included in the circuit by means of the screwcups. The earpiece is also shown inserted. When purchasing this, you should ask for a crystal earpiece. A pair of high resistance headphones could be used in place of an earpiece, and may give even better results. *Resistance* is discussed on page 32, in the section headed 'Resistors'.

On the following two pages there is some useful information about the aerial and earth.

THE COMPLETED CRYSTAL SET

The crystal set – its aerial and earth

The aerial is the part of the receiver which 'picks up' the radio signals. Unlike our crystal set, many modern transistor radios are sufficiently sensitive to pick up enough signal from the ferrite core of the tuning coil. Although the final radio which we will make will not need an aerial and earth, the crystal set relies on the electrical current set up between a good aerial and earth to work well.

A suitable aerial can be made from inexpensive PVC covered copper wire. The idea is to suspend as much of this wire as possible, as high as possible. The far end can be attached to a tree, the top of a pole or even the eaves of a friendly neighbour's house, but this can be dangerous and is best done by an adult or under the supervision of an adult. The wire should be fastened onto a large screw eye or hook. The near end of the wire may be taken in the top of an upstairs window and connected to the aerial connection on our radio.

For the aerial to be effective, the other side of the tuned circuit has to be connected to earth. The simplest method is to attach the earth lead to the nearest household water pipe. These pipes lead to the ground. If your water pipes are plastic, make your own earth by driving about a yard of copper pipe into soft earth and connecting the earth wire to the top.

An experimental P.O.W. radio

During the last war, some prisoners in prison camps used home-made radios to keep in touch with events in their native lands. Often, all the components had to be made from items picked up within the camp. Diodes were almost impossible to obtain, so several ingenious home-made alternatives were tried.

The diagram shows one simple method of improvising a diode. Take a small piece of wood, about 1 inch thick, and a piece of washed coke about the size of a pea. Mount the coke on the wood as shown, using a screw and screwcup, and taking a lead from beneath the screwcup. Wind about a foot of steel wire—a length of piano or guitar wire is ideal—around a number 4 or 6 knitting needle, leaving about 1 inch on each end. The wire should now be slightly springy. Fasten one end to the board with a screw and screwcup, taking another lead from this screwcup. Stretch the wire until the free end lightly touches the coke.

Remove the diode from the crystal set and screw the wires in its place. It should be possible to hear some local stations by adjusting the tuning capacitor. If nothing is heard, keep moving the position of the wire on the coke until a signal is heard.

The transistor

To most people the word TRANSISTOR means a small radio set, but a transistor is really a single electronic component. The transistor is one of the most important inventions of the last 25 years. It has helped to make electronic equipment smaller and less dependent upon high voltages.

A transistor is like two diodes working together inside one case. Most transistors have three leads, emitter, collector and base. A transistor can be damaged unless the correct leads are used when connecting it into a circuit. The base lead is usually the middle wire and the collector lead is set slightly apart from the other two wires. The transistors we are to use also have a red spot painted on the casing to indicate the collector lead.

We shall be using transistors as amplifiers; that is, to make electrical signals stronger. Transistors are designed so that a small, changing current between the base and emitter produces a large current change between the collector and the emitter. So small signals applied to the base will appear amplified (or made bigger) at the collector. Our first transistor will be used to make louder the sound coming from the crystal set.

Adding a transistor

The circuit diagram shows how a simple transistor amplifier is inserted where previously we had the earpiece. Compare this diagram with the circuit diagram of the crystal set on page 23.

The transistor used is an OC71, and other extra components for this stage are a 2·7K resistor and a 9-volt battery. The battery is the small transistor radio type PP3, for which can be obtained an inexpensive snap connector. Resistors are discussed on the next page. This resistor forms an output 'load' for the collector, and the earpiece is connected across the resistor.

Take care to connect up the circuit as shown in the drawing. The connections of the transistor are important. Join the emitter to screw 5, the base to E and the collector to F. The earpiece is removed and reconnected to F and G. Connect the red battery connector lead to screw 5, and the black lead to screw G. The radio is switched on by pushing the connector into place on top of the battery.

This one transistor should make a big improvement to the crystal set; the same stations will be heard but they will be much louder.

Resistors

Resistors are very common components in electronic construction. Look at most pieces of equipment and you will see several small, wire-ended tubes with brightly coloured bands. These are called resistors because they 'resist' the flow of electrical current in the circuit. This is done to adjust the voltages and flow of current at various places in a circuit.

The little tubes are filled with a carbon composition, and the coloured bands give the *value* of the resistor. This value is called the *resistance* and is measured in *ohms*. When one knows the colour code opposite, it is easy to work out the resistance from the coloured bands. The tolerance of the resistor, that is, how close one can expect it to be to the value, is sometimes indicated with another coloured band. Our radio can use resistors of any tolerance, so this band may be ignored.

The symbol for resistance is the Greek letter omega Ω. Quite often, very high resistances are used—sometimes thousands or millions of ohms. To reduce the number of noughts, we call thousands K Ω (Kilo ohms) and millions M Ω (or Mega ohms). The ohm sign is usually omitted from circuit diagrams when the Kilo (K) and Mega (M) signs are used.

Biasing the transistor

The transistor amplifier we have built is the simplest arrangement possible. If a transistor is to be used efficiently, one has to supply the correct voltages to its various parts; this is called *biasing*. In our simple arrangement the signal from the diode provided a voltage to *bias* the base of the transistor. Resistors can be added to make the biasing correct.

The circuit shows how the transistor is biased with two resistors. (33K Ω—orange, orange, orange, and 150K Ω—brown, green, yellow.) They give the correct voltages between the collector, base and emitter. Take care to connect the resistors in the places shown or the effect will be ruined.

This addition to the radio will not increase the volume in any noticeable way, but the biasing is essential before the next stage is added.

The wire ends of resistors, like any other components, can become dirty and greasy, so scrape the wires clean before screwing them into place.

Adding a second transistor

Before we can add another transistor to our radio, two new components must be introduced—a *potentiometer* and a *capacitor*.

The potentiometer is a variable resistance. Look at the drawing on the opposite page and you will see that it has three contacts. The outer two are each end of a circular carbon track. The centre tag is joined to a movable contact which slides over the track when the shaft is rotated. By moving the shaft, which is usually fitted with a plastic knob, any part of the resistance can be used and tapped off through the centre tag. Potentiometers are often used, as in this case, as volume controls.

A *capacitor* is a component which allows the signal to pass but not the fixed voltages used to power a circuit. It consists of two plates which are separated by insulating material; the circuit symbol shows this. Electrolytic capacitors must be connected into a circuit the right way round. One end is marked either with a red band or a + sign, and this side goes to the positive side of the circuit. The negative (—) wire is connected to the metal can which forms the body of the capacitor, and which may be marked with a black band. Sometimes this is not obvious, but follow the circuit and layout diagrams with care to avoid mistakes. Other fixed capacitors can be connected either way round: we will meet these later. The value of capacity is written in microfarads, (μF or sometimes MFD). We require 10μF at a working voltage of 16-volts.

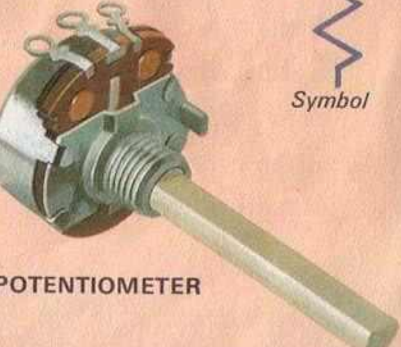
ELECTROLYTIC CAPACITOR



POTENTIOMETER

The second transistor stage

The circuit for the second stage is shown on the previous page. The signal is taken from the collector of our first transistor, through the capacitor to the sliding contact of the volume control potentiometer. The nearer the centre contact is adjusted to the base side of the control, the more signal is allowed to go to the base of the second transistor. The greater the signal reaching this transistor, the louder will be its output.

The potentiometer is mounted in the spare ⅜ inch hole. Its tags are too close together to use the large screwcups, so small screws are used. These are screwed down through the holes in the potentiometer tags, trapping the leads under the tags.

Remove the 2·7K resistor from F and G and connect in the new components carefully, following the layout diagram facing this page. As you work, compare the layout diagram, connection by connection, with the circuit diagram. This additional transistor will greatly increase the volume, enough to drive a loudspeaker, which is the next addition.

The world of radio

Today, radio is part of our everyday life, yet only at the beginning of this century it was a miracle. It is still something to marvel at—and a fascinating subject to study.

With this book you will learn, stage by stage, how to build more than one simple receiver. Everything you should know is explained simply and illustrated clearly, and you will have the pleasure of constructing something marvellous that really works.

All the components used are easily available, usually from your local radio dealer. Most large towns have shops specialising in stocking components, but it is also very easy to obtain any you need by post. All the popular electronic construction magazines contain advertisements for mail order supplies. Many of these suppliers provide catalogues which list all the components you will need.

0 7214 0324 7

Adding a loudspeaker

Using our radio with an earpiece means, of course, that only one person at a time can hear the programme. A loudspeaker changes electrical waves into sound waves in the same way that an earpiece does, but it has a large cardboard cone so that several people can hear the sound. Loudspeakers can have very large cones, but a smaller cone speaker with a diameter of 3 inches is ideal for our purpose.

Loudspeakers are made with inputs of varying resistances, and our radio requires a 3 or 5 Ω type. Unfortunately the loudspeaker cannot directly replace the earpiece because its resistance is much lower than that of the earpiece, so it has to be matched into the circuit with a *transformer*. A transformer can change a current of one voltage to a smaller current of a higher voltage or to a larger current of a smaller voltage. It consists of a 'primary' and 'secondary' winding of fine wire round a metal 'former'. The transformer we require is the Eagle LT700. This transformer has rather long leads, and these may be shortened by winding them tightly round a knitting needle. This makes spiral leads which can then be pulled out to reach the screws.

Screw the transformer onto the base, as shown; remove the 2·7K resistor across G and H and connect the correct leads (colour coded) to the screwcups. Two more screwcups are added at the end of the board to connect the output leads to the loudspeaker, using two small crocodile clips.

Regeneration

We shall now replace our simple crystal set stage with a transistor stage, using *regeneration*. Regeneration will enable our first transistor in the radio to be used three times.

The circuit shows the regeneration stage. The signal from the aerial is tuned by the coil and variable capacitor, the orange marked signal then passes through capacitor C1 to be amplified by the transistor and appear at a *radio frequency choke* (R.F.C.). Part of this signal, marked in blue, passes through C2 to a pair of diodes which change the radio signal into an audio signal, which is amplified again by the transistor. The signal, now marked red, passes through C3 back to the coil. The part of the coil tapped between the transistor collector (through C1) and earth, allows the signal to reach the collector again.

This means that some of the signal at R.F.C. has been amplified three times, so this is a very economical use of one transistor. Passing signals back again like this is called *feedback*. If the feedback is too great, the circuit will produce a howling sound, so C3 is an adjustable capacitor to control the amount of feedback. The final signal is taken from R.F.C. through capacitor C4.

HOW REGENERATION WORKS

In circuit diagrams, wires which cross one another, (but do NOT touch and are NOT connected), are sometimes shown like this + (as in the diagram) or like this —⌒—. Shown like this —●— always means they are connected.

Adding regeneration

The circuit shows the new stage with the components added. The adjustable capacitor is a 10 pF (picafarad) *trimmer*. This consists of two copper plates mounted on a pot base; the distance between the plates can be adjusted with the small screw.

Fixed capacitors may be flat or cylindrical with two leads; the type we require, *ceramic capacitors*, may look like a disc.

The *radio frequency choke* is really a coil with a lot of turns of wire on a small former. The choke acts like a resistance to radio-frequency waves.

Two diodes are needed to provide the feedback path from the 500pF capacitor. If the top diode were omitted, the signal would not be changed into audio frequencies before it reached the transistor base, and if the bottom diode were omitted, the signal would go straight to earth and be lost.

The 1K resistor lowers the battery voltage needed to power this stage. It is possible for some of the audio signal to feed back to this stage through this 1K resistor and distort the signal. This is prevented by the 100μF capacitor which takes any stray signals to earth without affecting the battery voltage.

Wiring the regeneration stage

The drawing shows how this stage is wired onto the board. Before wiring the stage, all the components from the crystal stage, up to screws E and 5, are removed except for the coil and tuning capacitor. The diode is removed to become one of the two diodes in the new stage. Follow the drawing carefully, adding one component at a time and checking its position on the circuit diagram. There are many bare wires which come close to each other, and great care must be taken to ensure they do not touch each other. The 1K resistor must not touch screws E and F.

The trimmer is trapped by its tags under screws A and B; if it is too long or too short, the screws may be moved. All three connections to the coil are now used, and if the wires are not placed in the correct positions, regeneration will not occur. The drawing shows how to place these three wires. The 10μF capacitor takes the signal from the new stage to the base of the next OC71 transistor. The advantage of this new stage is that our radio will have a greater output and no longer need a large aerial and an earth. Regeneration is tricky to get used to, but once mastered, the results are surprising.

Using the radio

Operating a regenerative radio requires care at first because the trimmer has to be adjusted to suit the strength of each signal. Begin by connecting about 3 yards of wire to the radio as an aerial; no earth is required. Set the tuning capacitor about midway and screw in the trimmer until the radio begins to howl. Unscrew the trimmer until the noise just stops, and try to tune in a station. The trimmer should then be adjusted until it is just short of the point when the radio howls. The general method for receiving any station is to tune it in with the tuning capacitor and to adjust the feedback trimmer until the howling just disappears.

The feedback not only makes the radio more sensitive but also the tuning becomes sharper, so the tuning knob must be rotated very slowly. This sensitivity makes the radio ideal for the medium wave band, which is rather overcrowded. The tuning should be sharp enough to tune in individual stations without the background sounds of other stations. In areas of good signal strength, it will be possible to use the radio without an aerial at all, merely relying upon the signal picked up by the ferrite rod coil.

The completed radio

Now that the radio is completed, you may wish to make the circuit board into a simple case. The circuit board is used as a front panel, and end and bottom panels are added.

These can be made from similar wood to the circuit board (4 inch by ½ inch planed softwood). The bottom panel is the same size as the circuit board and the measurements for the end panels are shown opposite. The end panel next to the output transformer may be used to hold the loudspeaker. A series of ⅜ inch holes are drilled with a brace and bit to allow the sound to leave the case, and the speaker is secured with screws and cups. The panels are joined with panel pins and glue.

The battery may be firmly mounted above screws D and E on the circuit board, using 2½ inches of ¼ inch elastic and two screws and cups. Two smart plastic pointer knobs and a tuning scale complete the front panel. The tuning scale is a paper gummed label which can be marked with the positions of the main stations.

If you have followed these pages carefully, you will now have a useful working radio. You will also have shared the thrill of thousands of other radio constructors, listening to sounds coming from a radio receiver which is your own work.

THE COMPLETED RADIO

Radio reception

Radio waves cannot be seen or heard. They are *electro-magnetic* waves, and they flow backwards and forwards (*oscillate*). Each backward and forward movement is known as a *cycle*. The rate of this backward and forward movement (*oscillation*) is known as the frequency of the wave.

A radio wave is also a *carrier* wave. It can 'carry' an electro-magnetic wave of a frequency exactly similar to the sound waves of the speech or music which is being transmitted. This frequency, which is imposed on the carrier wave, is known as an *audio* frequency. It is this electro-magnetic *audio frequency* that a radio receiver translates into sound via the loudspeaker. For a more detailed explanation of this, you might like to read pages 20-26 of the Ladybird book: 'How it Works—Television'.

When radio waves carrying an audio frequency arrive at a receiver, three things happen:

1. *TUNING*. The radio frequency carrier wave is picked up by the aerial. Along this same aerial pass the radio frequency carrier waves from many other transmitting stations, but the signal we want from a particular transmitter must be selected (tuned) from them.

2. *DETECTION*. The next stage is the detection stage, in which the electro-magnetic audio frequency wave is detected from the carrier wave.

3. *AMPLIFICATION*. The electro-magnetic audio signal wave is amplified, or made bigger, and translated from an electrical signal into SOUND by the loud-speaker, from which we hear a reproduction of the transmitted sound.

Reading circuit diagrams

Before building a piece of electronic equipment, a constructor needs to know how to wire up the various components. This can be done with the help of a diagram showing how the components are joined. Electronic engineers have developed a 'shorthand' method of showing the various components and their joining wires. This is the *circuit diagram*.

A circuit diagram is like a map. All the electronic components have symbols, and the connecting wires are shown as straight lines. The positions of the components on the circuit diagram do not normally correspond to their *actual* positions in the completed equipment. Sometimes a *layout diagram* is also used to show where to position the components on a base board.

Many symbols are used in circuit diagrams and we will learn them as we meet them in the course of our construction. To make construction easier we will use both circuit and layout diagrams.

TOOL YOU MAY NEED

- Long-nose pliers
- Wire,cutters
- Ph llipslype screwdrlver
- Pencil or ballpoint pen

INTRODUCTION

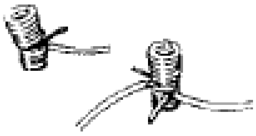
With your "Crystal" Fadio Kit you can tune in AfV radro stattons without using batteries or AC powerl This device works on the same principle as the early crystal rad¡o, but the crysta has been replaced with a more reliable modern device called a d¡ode. Your C'ysta, Bad o Kit 'coü.es ro p.evious experience with electronics. You can build and operate it by fo lowing the simple instructions in this manual.

ASSEMBLING YOUR CRYSTAL RADIO

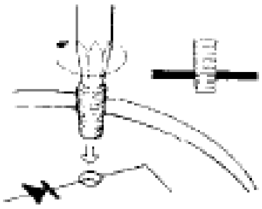
Follow the instructions in the order given, beginning wlth Step 1 .

Notes:

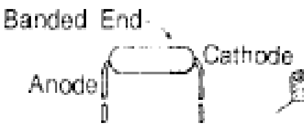
Don't rush. Take your time and enjoy bu¡ld ng your KIl,
You can check off each step as you finish it to besure yo{r don't forget an},thing.a
Allthrough these instructions you're asked to make various conr'reclrons. Secure electrical connections are very mponant In eiectronic devices. One poor connect,on can keep your crystal set from
Be sure all your connections are good ones
To con¡ect a wjre 10 the sprjng terminals:
A - Bend ihe spring to one side with your f nger.
B - Insert the end of the wire into one of the gaps i n : t r e spring.
C - Re ease the sp|ng. I t wi i hold the wire tirrn ly.

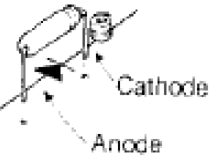


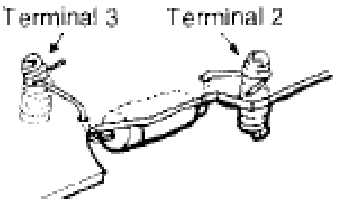
Be sure you connect clean. bare wire to each terminal. Some of the wires have insulation that has been stripped of the ends. Other wires have been "t¡nned" (coated with solder) at the ends so that they can make a good connection.
Nake sure lhat you insert the bare end of the wire into the spring terminal Be careful to keep the nsu,ated part out of the spring.
If a w¡re has a shiny t¡nned part at the end, Insert the shiny part into the spring.
Step - 1 Using your pencrl or pen, punch out the nine larger holes and the tour srnaller holes in the panel.
Step - 2 Copy the term¡nal numbers lrom the frontof the panel to the corresponding positions on the back side
Step - 3 Install the spring terminals :
A - Press the smaller end of each sprlng terminal into one of the punched holes.



B - Use the pointed end of a pencil to tw¡st each term nal firmly into place.
Step - 4 Mount lhe diode as follows:
A - Use your long-nose pliers to bend each of the diode's tvr'o wires as shown.
B - Inserthe wire from the diode's stnped (cathode)end thro!gh lhe hole nearest Terminal 3.
C - Insert tnc ,/rire lrom lhe diode's other (anode) end through the small hole nearesl Terminal 2.
D - Attach the wlre from the diode's strlped end to Terminal 3
E - Attach the wire from the d¡ode's other end to Terminal 2.



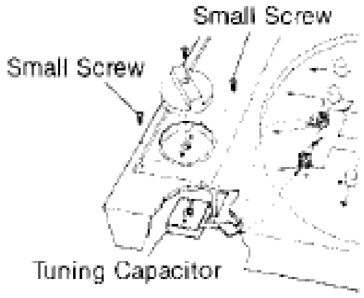




Note: A diode allows currento pass through it in only one direciron, from anode to cathode. fhis ability to block alternating current and pass direct current makes it useful rn many types of electron¡c c¡rcu¡ts.

Slep – 5 Mount th tuning capacrlor :

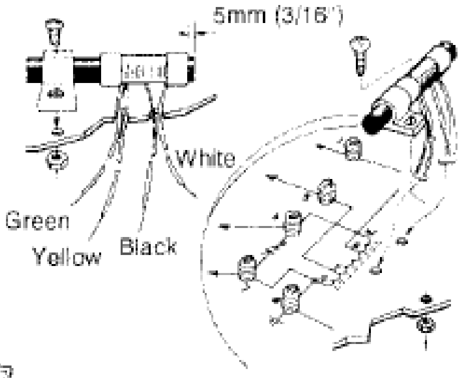
A - Position the capacrtor beneath the panel opening that is just above the word TUNING.
B - The metal shaft ol the capacitor should extend through the openrng.
C - Faslen the capacitor to the panel using the two srna screws.



Step - 6 Install the luning capacitor's knob :
A - Turn the tuning capacitor's shaft all the way to the left.
B - Piace the tunjng knob on the upper end of the shaft
C - Llne up the dot on the knob wlth the 0 on lhe paner.
D - Faster :he knob in place using the reinaining smalll screw.

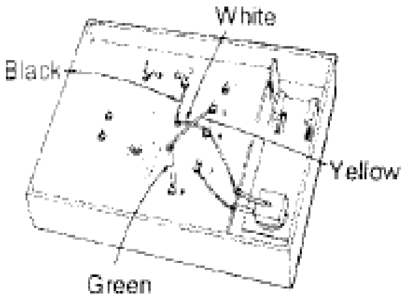
Step - 7 Connect the tuning capacitor's wires:
A - Connect the wire from the tuning capacitor's langet silver strip to Terminal 6.
B - Connect the wire from the tuning capacltor's sho,lcr silver strip to Termina 7.

Slep - 8 Install the antenna coil :
A - Position the antenna coil on the panel near the three rernaining small punched holes.
B - lnsert the antenna coil's green and yellow wires through the hole nearest the Y on the diagram.
C - insen the black and white wires through the hole nearest the W on the diagram.
D - Fasten the antenna coil in place wiih lhe nylon clip, medium screw, and nut, using the last of the small punched holes.



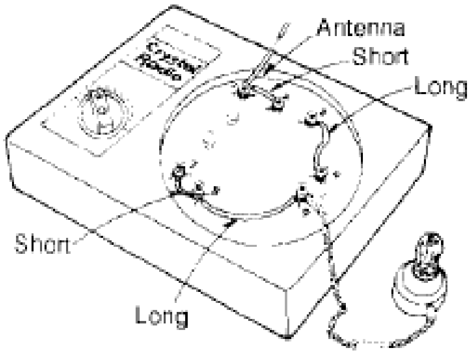
Step -9 Connect the antenna coil wires:

A - Connecr the black wire to Terminal 2.
B - Connect the yel¡ow wjre to Terminal 5
C - Connect the while wire to Terminal 6.
D - Connect the green wire to Terminal 8.



Step - 10 Instafl the blue and white connecting wires:

These connecting wrres can be instailed either on the front or the back of the panel. We suggest that you pul thern on the front, so that you can see how the wiring relates to the diagram on the panel.
A - Connect a short wire between Termrnals I and 2
B - Connect a lo¡g wlre between Terminals 3 and 4.
C - Connect a short wire belween Terminals 7 and 8 .



Step - 11 Use your wire cutters to neatly trim the ends of all the w¡res.
Step - 12 Connect the earphone wires to Termrnals 4andL

Step - 13 Install your ground wire:
The ground wire is an lmportant part ot your crystal radjo. Conneci it as caretully as you have connected ail the other parts.
A - From the co¡l of green wire, cut off about 5 feet (150crn)
B - Remove about 6 inches (15cm) of insuiation from one end of the wrre.
C – Find a metal cold water pipe
D - Scrape any paint or d¡rt from the pipe untll you see bright metal al the way around the pipe.
E - Wrap the bare end of the wire several ttmes around the Scraped part of the pipe and twrst the w¡re tightly.
F - Remove % Inch (7mm) of insulatron irom the other end of the ground wire
G -Connect this end of the ground wire to Terminal B of your radio.

Step - 14 Install your antenna:
Your antenna ¡s a very impoftant part of your crystal radio. Connect it as carefully as you have connected all the other parts.

A - Flemove % inch (7mm) of Insulation lrom one end of the remaining length of green wire.
B - Connect this end to Terminal 1 oi your radio.
C - Extend the anlenna w re horizontaily to its full length.

You have oow completed the building of your crystal Iadio. If yoLr have followed the instructions carefully, you should be able to tune n one or more AM,4 radio statrons right away.

USING THE CRYSTAL RADIO

A – Place the earphone in your ear.
B - Adjust the tuning capacitor's knob for the Clearest reception of a local Station.
C - Remember that your crystal radio has no amplifier, so the stations you receive might not be as loudi as if you were listening to a modern radio.

Notes:
- If you ive rn a city, you might be able to receive several stat¡ons.
- Il you do not live near a radlo station, you might need an outside antenna (not supplied), 35 io 85 feet (101o 25m) long, connected to Terminal 5.

lf your radio does not receive stations well, try connecting the antenna w¡re to term nal 6 instead of terrninal 1 or 5. If reception is still poor, change the antenna coil connection as follows :

White wire from terminal 6 to terminal 2
Black wire frorn terminal 2 to terminal 6

HOW YOUR CRYSTAL RADIO WORKS

All radio broadcast stations do basically the same thing. Thcy combine sound, or audio waves with a radio carries wave. The carrier wave travels great distances. and carries with its information about the strength and pitch of the sound waves

One method of combining the radio carrier wave and the audio wave is called Amplitude Nodulation (AM)

Your AM radio antenna prcks up tne carner wave seni by the radio statlon.

Your crystal radio then does three inlportant thlgs (with sorne help from you) to allow you to hear the radio program. These are:
- Tuning
- Detect¡on
- Changing of an electrical current to sound waves

TUNING

When you turn the tuning capacitor's knob, you are adjusting a circuit formed by the tuning capacitor and the antenna coil. This circult allows only one radio station's carrier wave at a time to enter your radio.
By tuning this circuit, you se{ect the carr er wave lo the station you want to hear'

DETECTION

The d¡ode gets rid oi the carrier wave by sendlng it to the ground through your cold water pipe At the same time. it allows a tiny electric current that represents the sound (audio) inlormation to go to the earphone.

CHANGING ELECTRICITY INTO SOUND

When the electric current reaches the earphone, It causes a small piece of ceramic material to vibrate. The movement of this ceramic to vibrates the crating the sound waves that you hear.

Your crystal radio works very much the sarme way as the early ones. Of course, the “old-time” crystal sets didn't have diodes. They used a piece of galena crystal (lead ore) held in contact with a fine wire called a “cat's whisker.”

This earlier type of radio, like yours, had no amplification. Then as now, more complicated radios amplified the audio waves to vibrate a loudspeaker and produce ouder sound.

All radios slill use the basjc combination of (1) a tuned circuit that selects the carrier wave sent by tne radio station, (2) a detector that separates the sound inforrnatror from the carrier wave and (3) an earphone or loudspea ker yo let you to hear the sound

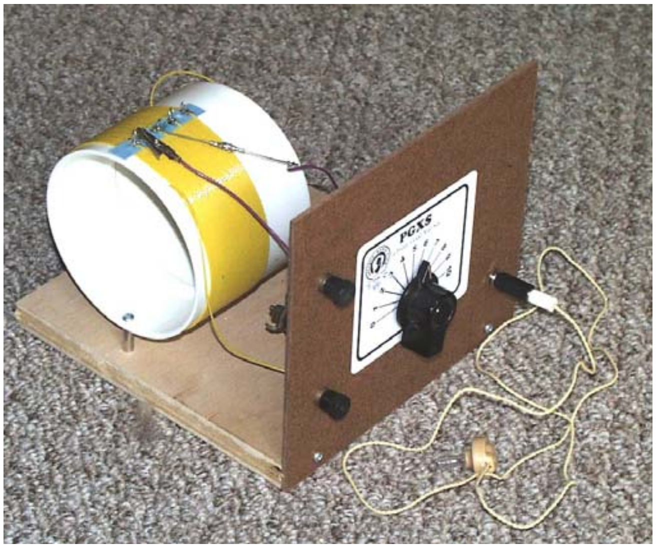
KIT RECOMMENDED FOR CHILDREN From 8 YEARS OLD, ACCOMPANIED BY ADULTS

A Pretty Good Crystal Set – Mark II

By Al Klase, N3FRQ, http://www.skywaves.ar88.net/

This is a revised version of the original New Jersey Antique Radio Club PGXS with minor changes to improve performance with short antennas in strong-signal areas. This radio will give a good account of itself on the AM broadcast band.

OK! It's time to build a crystal set. This time it's going to be a good one.



Countless millions of crystal radios have been built over the last 100 years, but the performance of most of these leaves a lot to be desired. The design of this radio goes back to about 1990 when I was a den leader for my son's Cub-Scout pack. I wanted the guys to have the experience of listening to a radio they had built with their own hands. However, we were in the deep suburbs of Philadelphia (actually half way to Reading). There were no strong local stations, so an average crystal set combined with the sort of makeshift antenna most families would erect, wasn't going to get the job done. The result was the Den Two Crystal Radio. (See "Crystal Set Projects," The Xtal Set Society, 1997.) This radio was based on a spider-web coil that 10-year-old hands could wind with a little supervision. It was sensitive enough to hear distant sky-wave stations at night, and selective enough that you could usually listen to just one station. Seven were constructed and at least six of those went into service at home. Everyone was duly impressed. We even had reports of hearing Radio Japan! (That was from Ontario, however.) We'll use the same circuit with a better solenoid-style coil.

Selecting Components

First, let's deal with the headset. Look around for a traditional pair of 2000-ohm 'phones. That's the DC resistance, they'll have an AC impedance of about 10,000 ohms. Test the 'phones by putting them on your head, holding on to one of the tips and touching the other to an electrical ground such as a water pipe or the screw on an outlet plate. You should hear a click or maybe a hum. If not, they probably won't be sensitive enough for our purposes. Check the DC resistance with an ohm meter, it should be in the range of 1-5 K-ohms. Sometimes the cords are open.

An acceptable alternative to a vintage headset is one of the crystal (ceramic) ear plugs available from Mouser.com for about two bucks. It's best to install a 50-100K resistor in parallel with these capacitive devices to provide a DC load for the detector to eliminate audio distortion.

Modern low-impedance headsets with a matching transformer might work if you have a lot of signal strength, but most are designed to sacrifice sensitivity for flat frequency response.

Next comes the detector. Stick to a germanium diode or the base-emitter junction of a germanium transistor for openers. A digital voltmeter in the diode position will indicate the forward voltage drop. Germanium devices will show 0.2-0.3 while silicon will indicate 0.5-0.7 volts. You can use a modern silicon device, but you'll be giving up a lot of sensitivity. The basic germanium diode is the 1N34A, but the part number doesn't mean much. They vary widely. Dump out the junk box, try them in a radio, and pick the best one. You can move on to mineral detectors and cat's whiskers for a little nostalgia after you have a working radio.

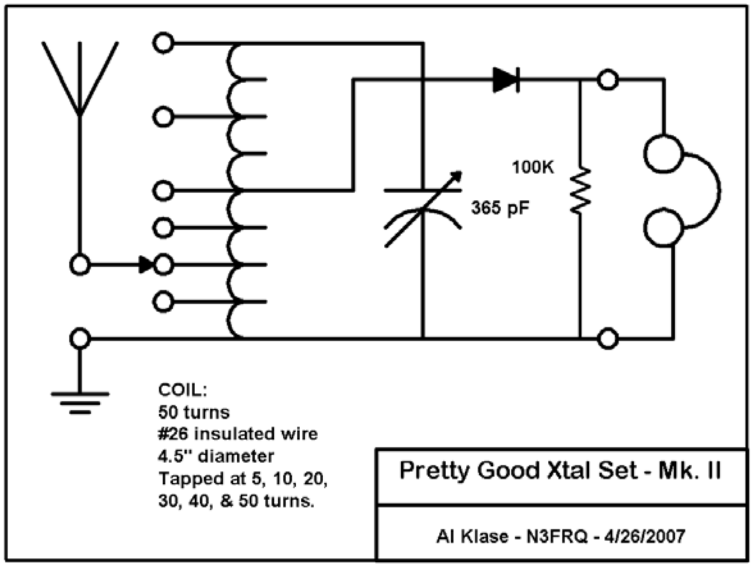
Now you'll need an antenna, the higher, longer, and more in the open the better. Sixty feet long and forty feet high would be excellent, but wire in the attic will probably suffice, especially if you're a "city mouse." A wire to a hose clamp around a water pipe or a connection to the screw on an outlet plate (AC safety ground) will complete the antenna-ground system.

Start Simply

Now it's time to build the simplest possible radio: Clip-lead the diode across the headset and then connect one side to the antenna and the other side to ground. You should hear something, quite possibly three stations at once. This will verify that you have a usable headset and detector, and that you have enough antenna for the available signals.

Construction of the PGXS

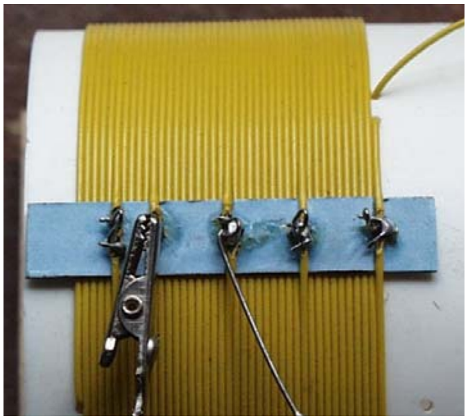
To make this kludge into a serviceable radio we'll add a resonant "tank" circuit consisting of a coil and a variable capacitor to allow us to select the station we want to hear. The coil has multiple taps so it can serve as an autotransformer to achieve a good impedance match, allowing optimal energy transfer, between the antenna-ground system and the tank circuit as well as between the tank and the detector and it's load, the headset.



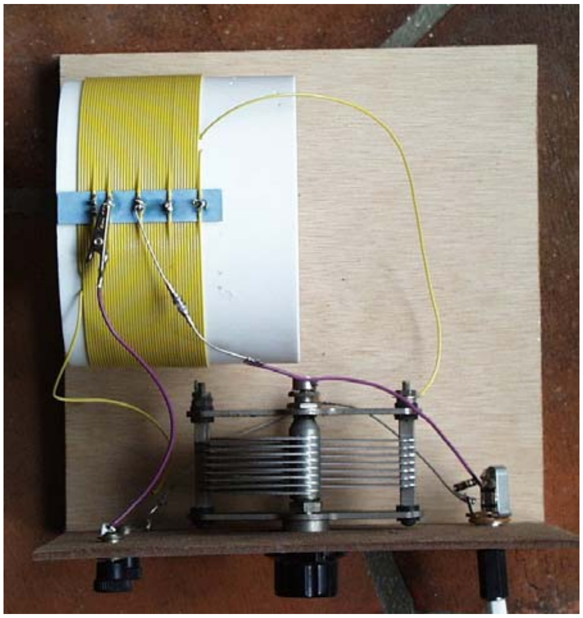
The target value for the cap is 365 pico-farads (mmF or pF), but a 500 pF unit as found in some of the old battery sets will work nearly as well. You could also use the large half of the two-gang cap from a junked all-American-five radio, etc.

The coil is wound on a 4-inch ABS pipe coupling from the “home center.” Wire is generally expensive and hard to buy retail. You can use #20 insulated bell wire, also from the “home center” because it is easily available. The down side is that it’s twisted pair that needs to be untwisted, and they make you buy 500 feet, for about 30 bucks, when you only need 85 feet for the project. Any plastic insulated wire between #26 and #20 will do, but you may need to adjust the total number of turns after you get the radio working to cover both ends of the broadcast band. The best option, for maximum performance, is silver-plated Teflon-insulated hook-up wire if you have any in the junk box, but even common vinyl-insulated tinned stranded wire will work just fine. Close-wound enameled magnet wire is a bad bet, as eddy currents in the closely spaced turns cause considerable loss.

Winding the coil: Tie one end of an 85-foot length of wire to a solid support. Drill two small holes about 3/8 of an inch from the end of the coil form. Keep the drill handy. Put your wire cutter and a strip of thin cardboard about 3/8 inch wide and 3 inches long in your shirt pocket. Lace the end of the wire into one hole and out the other, leaving about a foot protruding from the form. Grasp the coil form firmly and pull the wire taught against the tied off end. Wind 5 turns on the coil keeping the wire close-wound and tight. Place the end of the cardboard strip under the 5th turn. Wind four more turns, sneaking them under the strip. Wind the 10th turn over the strip. Continue winding placing the 20th, 30th, 40th, and 50th turns on top of the cardboard. Holding the wire firmly in place with your left thumb, clip the wire leaving about a foot to terminate the coil. Drill two more holes in the form just beyond where the 50th turn crosses the cardboard, and lace the end of the wire through them.



Use a utility knife to whittle away the insulation where the turns cross the cardboard. Wrap and solder a piece of bare wire at each of these sites to form the coil taps.



"Beadboard" the radio with clipleads or tack-solder joints to make sure everything works before committing to a physical design.

The radio in the picture is built on an 8-inch square piece of ¾" plywood with an 8 x 6-inch front panel of tempered hardboard. An alligator clip is used to connect the selected coil tap to the antenna terminal. The 100K-ohm diode load resistor is installed on the ¼-inch phone jack. An adaptor is used to plug in the ceramic earpiece. Print out and paste the dial scale to the front panel. A large knob with a pointer is the way to go. You can install a rotary switch for the coil taps if you want to get fancy. Layout is not critical, but keep the coil in the approximate orientation shown so it can be coupled to the antenna tuner to be described in "Phase II."

Operation

Connect the antenna, ground, and headset. Put the alligator clip on the middle tap where the diode connects. Tune in a station. Move to another tap, and retune looking for the best performance. The optimum coil tap will be dependent on the frequency your tuning.

In strong signal areas, you can just connect your ground wire to the top (right most) tap. The headphone cord and your body will serve as the antenna.

A reasonably high 50-75- foot outdoor antenna should allow you to hear night-time stations hundreds of miles away.

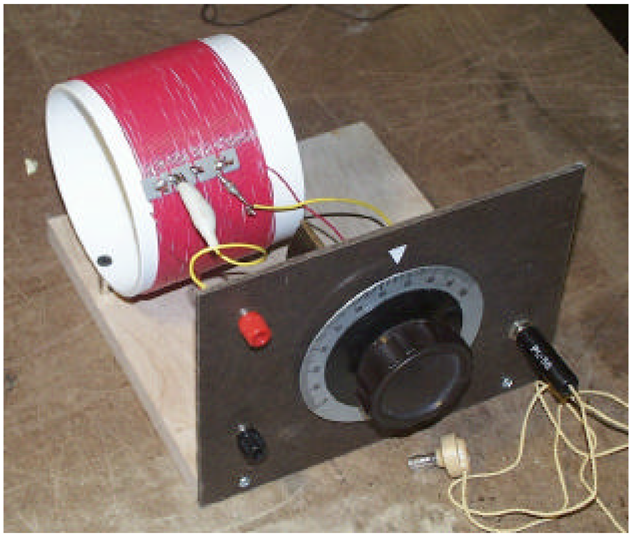
A Pretty Good Crystal Set

By Al Klase, N3FRQ, http://www.skywaves.ar88.net/

OK! It's time to build a crystal set. This time it's going to be a good one.



Countless millions of crystal radios have been built over the last 100 years, but the performance of most of these leaves a lot to be desired. The design of this radio goes back to about 1990 when I was a den leader for my son's Cub-Scout pack. I wanted the guys to have the experience of listening to a radio they had built with their own hands. However, we were in the deep suburbs of Philadelphia (actually half way to Reading). There were no strong local stations, so an average crystal set combined with the sort of makeshift antenna most families would erect, wasn't going to get the job done. The result was the Den Two Crystal Radio. (See "Crystal Set Projects," The Xtal Set Society, 1997.) This radio was based on a spider-web coil that 10-year-old hands could wind with a little supervision. It was sensitive enough to hear distant sky-wave stations at night, and selective enough that you could usually listen to just one station. Seven were constructed and at least six of those went into service at home. Everyone was duly impressed. We even had reports of hearing Radio Japan! (That was from Ontario, however.) We'll use the same circuit with a better solenoid-style coil.

First, lets deal with the headset. Look around for a traditional pair of 2000-ohm 'phones. That's the DC resistance, they'll have an AC impedance of about 10,000 ohms. Test the 'phones by putting them on your head, holding on to one of the tips and touching the other to an electrical ground such as a water pipe or the screw on an outlet plate. You should hear a click or maybe a hum. If not, they probably won't be sensitive enough for our purposes. Check the DC resistance with an ohm meter, it should be in the range of 1-5 K-ohms. Sometimes the cords are open.

An acceptable alternative to a vintage headset is one of the crystal (ceramic) ear plugs available from Mouser.com for about two bucks. It's best to install a 50-100K resistor in parallel with these 'phones to provide a DC load for the detector to eliminate audio distortion.

Modern low-impedance headsets with a matching transformer might work if you have a lot of signal strength, but most are designed to sacrifice sensitivity for flat frequency response.

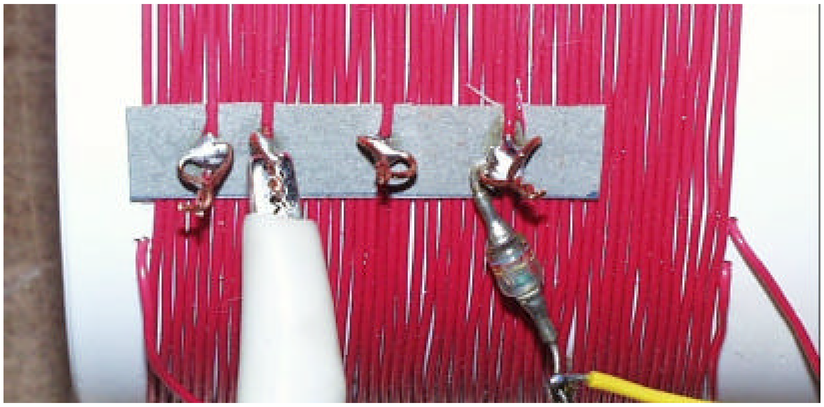
Next, comes the detector. Stick to a germanium diode or the base-emitter junction of a germanium transistor for openers. A digital voltmeter in the diode position will indicate the forward voltage drop. Germanium devices will show 0.2-0.3 while silicon will indicate 0.5-0.7 volts. You can use a modern silicon device, but you'll be giving up a lot of sensitivity. The basic germanium diode is the 1N34A, but the part number doesn't mean much. They vary widely. Dump out the junk box, try them in a radio, and pick the best one. You can move on to mineral detectors and cat's whiskers after you have a working radio.

Now you'll need an antenna, the higher, longer, and more in the open the better. Sixty feet long and forty feet high would be excellent, but wire in the attic will probably suffice, especially if you're a "city mouse." A wire to a hose clamp around a water pipe or a connection to the screw on an outlet plate (AC safety ground) will complete the antenna-ground system.

Now it's time to build the simplest possible radio: Clip-lead the diode across the headset and then connect one side to the antenna and the other side to ground. You should hear something, quite possibly three stations at once.

To make this kludge into a serviceable radio we'll add a tuned "tank" circuit consisting of a coil and a variable capacitor. The target value for the cap is 365 pico-farads (mmF or pF), but a 500 pF unit as found in some of the old battery sets will work nearly as well. You could also use the large half of the two-gang cap from a junked all-American five radio, etc.

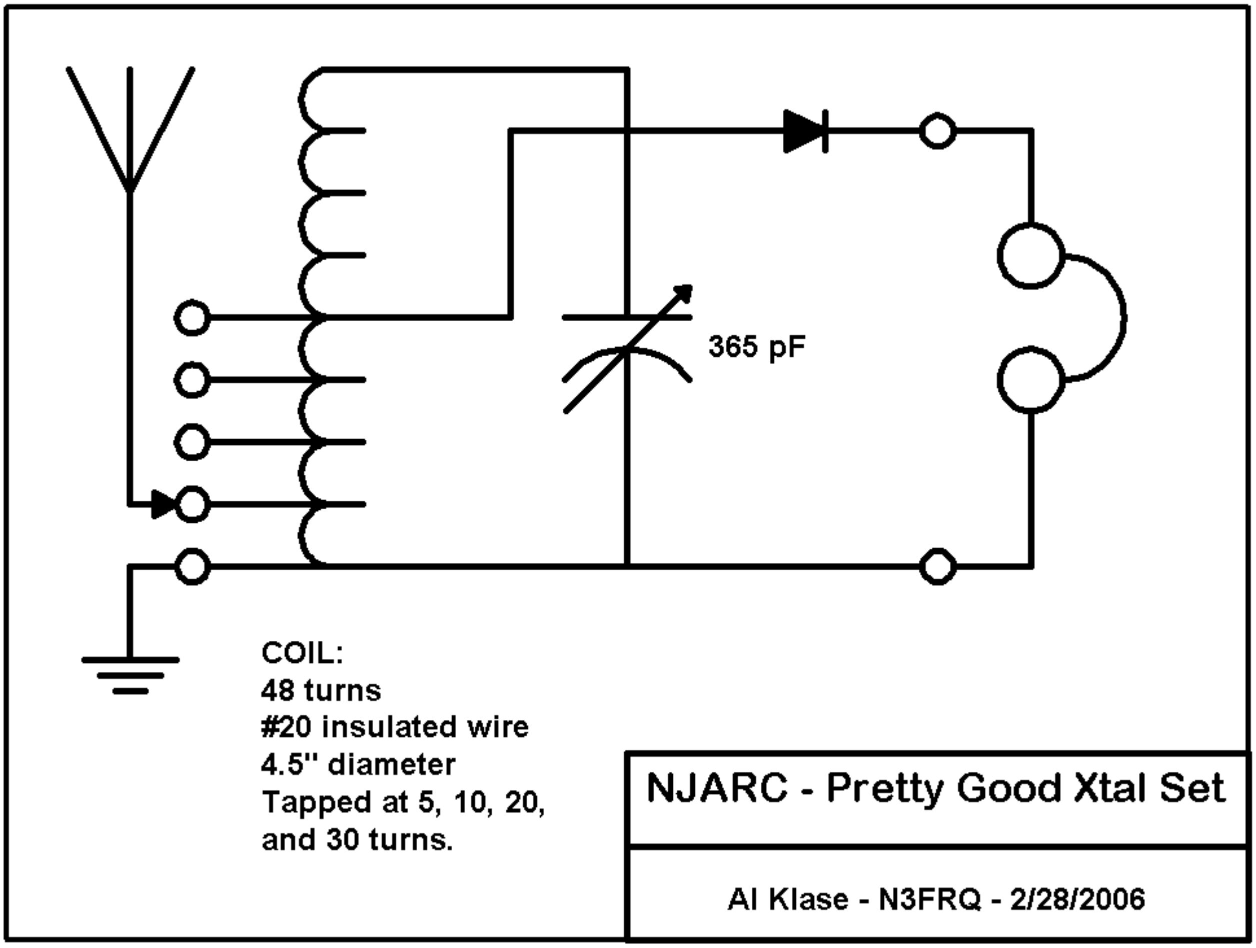
The coil is wound on a 4-inch styrene pipe coupling from the "home center." Wire is generally expensive and hard to buy retail. I've specified #20 insulated bell wire, also from the "home center" because it is easily available. The down side is that it's twisted pair that needs to be unwound, and they make you buy 500 feet, for about 30 bucks, when you only need 85 feet for the project. Any plastic insulated wire between #26 and #20 will do, but you'll probably need to adjust the total number of turns after you get the radio going to cover both ends of the broadcast band. The best option, for maximum performance, is silver-plated Teflon-insulated hook-up wire if you have any in the junk box, but even common vinyl-insulated tinned stranded wire will work all right. Close-wound magnet wire is a bad bet, as eddy currents in the adjacent turns cause considerable loss.



Winding the coil: Tie one end of an 85-foot length of wire to a solid support. Drill two small holes 3/8 of an inch from the end of the coil form. Keep the drill and wire cutters handy. Put a strip of thin cardboard about 3/8 inch wide and 3 inches long in your shirt pocket. Lace the end of the wire into one hole and out the other, leaving about a foot protruding from the form. Grasp the coil form firmly and pull the wire taught against the tied off end. Wind 5 turns on the coil keeping the wrie close-wound and tight. Place the end of the cardboard strip under the 5th turn. Wind four more turns, sneaking them under the strip. Wind the 10th turn over the strip. Continue winding placing the 20th and 30th turns on top of the cardboard. Wind 18 more turns for a total of 48. Clip the wire leaving about a foot to terminate the coil., drill two more holes in the form, and lace the end of the wire through them.

Use a utility knife to whittle away the insulation where the 5th, 10th, 20th, and 30th turns cross the cardboard. Wrap and solder a piece of bare wire at each of these sites to form the coil taps.

“Beadboard” the radio with clipleads or tack-solder joints to make sure everything works before committing to a physical design. The radio in the picture is built on an 8-inch square piece of ¾” plywood with an 8 x 6-inch front panel of tempered hardboard. Layout is not critical, but keep the coil in the approximate orientation shown so it can be coupled to the antenna tuner to be described in “PGXS – Phase II.”



365 pF
COIL:
48 turns
#20 insulated wire
4.5" diameter
Tapped at 5, 10, 20,
and 30 turns.

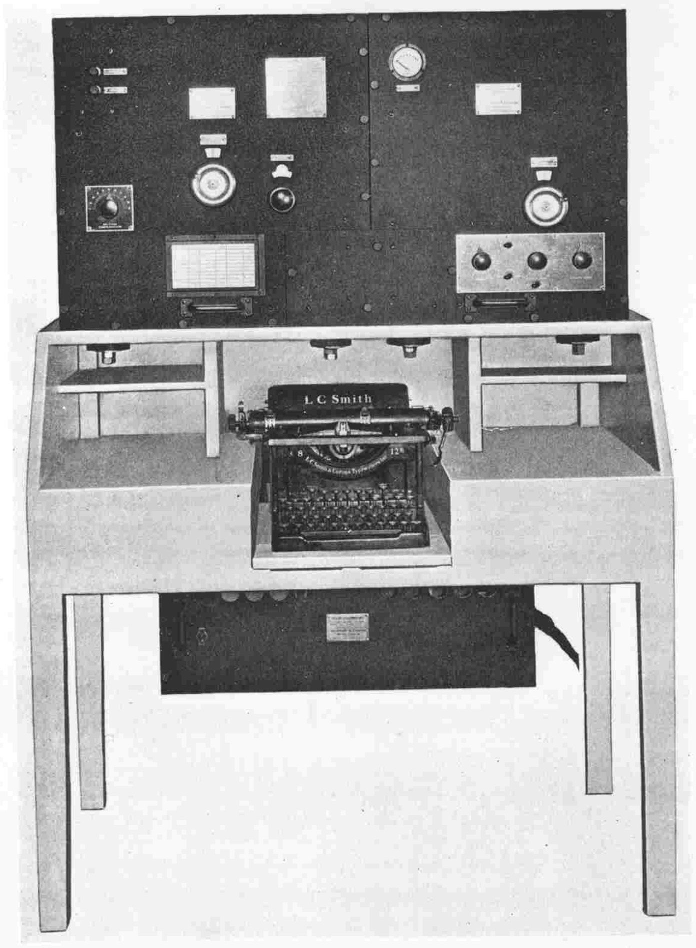
RCA RAB Receiver

An Exercise in No-Holds-Barred Receiver Design Ca. 1931

This is an ongoing investigation. Any information on the history of this radio would be greatly appreciated. This information is from the instruction manual dated 30 June 1931.

The United States Navy became one of the early adopters of long-range short-wave communications as a result of positive results obtained during fleet maneuvers in 1925. Early receiving sets were TRF-autodynes, but by the early 1930's the state of the art had progressed far enough to allow the design of a truly effective super-heterodyne for the HF range. The RAB was probably the first mass-produced short-wave superhet, and had a number of advanced features that would not appear in commercial sets for years.



Frontispiece—Typical Installation Model RAB Equipment

Model RAB Radio Receiving Equipment

- Range 1,000 - 30,000 KC in eight band-switched ranges
- 2 Tuned RF stages for effective image rejection
- 2 IF stages with 8 tuned circuits for a modicum of selectivity.
- IF frequencies: 600, 1450, 3250, 7200 KC The higher IF's ease the image problem at higher frequencies, and widen the bandwidth to compensate for transmitter instability.
- IF frequency depends on band in use
- Remote-cutoff tubes in RF and IF for excellent manual gain control
- Regulated PS for LO and BFO
- Audio filtering for AM and CW
- Audio limiter (AVC)
- Weight: 455 lb (plus table and typewriter)

RF Tuner CRV-4552
(rear view)

RF and oscillator coils are mounted on the top and bottom of the main chassis.

Band selection is accomplished by a sliding assembly containing the five-gang tuning capacitor and tubes. This carriage is moved by a lead screw actuated by the milling-machine-like knob on the front panel.

BENJAMIN AND DAVID GOLDENBERG 'S VERY-FINE

OLD-TIME CRYSTAL RADIO

Parts List:

Item	Qty.
PVC pipe, 1" outside diameter (3/4” size) x 4" long	1
Aluminum or steel sheet metal, 0.5” wide x 5” long	1
Coil wire (#24 magnet wire)	36 ft
Hook-up wire (#22)	25 ft
Crystal earphone (GC electronics, cat. no. 30-5302)	1
Jack for the earphone plug	1
Crystal diode (1N34A)	1
Capacitor, 470 picofarad	1
#8 sheet metal screws	8
8-32 machine screw, 1" long	1
8-32 nuts	2
flat washers	6
Ring terminal	1
Board, 3/4" thick, approximately 7" x 9"	1

What else you need:

Vise-Grip pliers
Wire cutters
Soldering iron and solder
Drill, with 1/8", 3/16” and 3/8” bits
File or motorized grinder (e.g. Moto-Tool)
Screwdriver
Scotch tape

Instructions

I. CONSTRUCTION OF SPECIAL PARTS.

The following steps involve making a few special parts for the radio. Some of these steps are most easily performed using power tools and some involve soldering. This work should be done by someone old enough and knowledgeable enough to handle these tools safely. Once these parts are made, however, the rest of the project requires only hand tools and can be completed by nearly anyone.

1. Coil Form

The coil form is a piece of PVC pipe, 1” in diameter (outside) and 4” long. (For reasons fully understood only by plumbers, pipe of this diameter is referred to as 3/4”.)

To facilitate mounting the coil to the board, drill two sets of holes, on opposite sides of the form. On one side of the form, drill two holes, 3/16” in diameter and 3/8” from the ends. Directly opposite from these holes, drill two more holes 3/8” in diameter. Screws will be placed through the smaller holes, while the larger ones make it easy to reach the screws with a screwdriver.

2. Slider

Drill two 3/16” holes in the piece of sheet metal, each 1/4” from an end. After the holes are drilled, place a bend in the metal 3/4” from each end, as shown in the figure on page 3. Use a vise or pliers to bend the metal. Use a file to smooth all of the edges and corners of the metal.

CAUTION: Drilling sheet metal can be very dangerous! If the bit catches on the metal, you can have a very sharp edge flying through your hands. Hold the metal firmly with a pair of pliers (preferably Vice-Grip type), not with your hands! Also, place a piece of wood under the metal as you drill. This will help keep the metal from tearing and grabbing the bit as the passes through.

3. Pointed screw for slider

Using either a file or a grinder, grind a point on the 8-32 machine screw. The point doesn’t need to be very sharp; about like the tip of a medium ball-point pen is ideal.

4. Earphone jack with wires.

Cut two pieces of hook-up wire 2” long. Remove 1/4” of insulation form one end of each wire and solder the wires to the terminals of the earphone jack. Remove 1/2” of insulation from the other ends of the wires.

Note: Headphone jacks often have more than two terminals. Make sure that the terminals you solder to are the ones that will be connected to the tip and side of the plug when it is inserted.

5. Ring terminal with two wires.

Cut two pieces of hook-up wire, one 7” long and the other 2”. Remove 1/4” of insulation from one end of each wire. Solder the two wires to the ring terminal. Remove 1/2” of insulation from the other ends of the wires.

6. Board

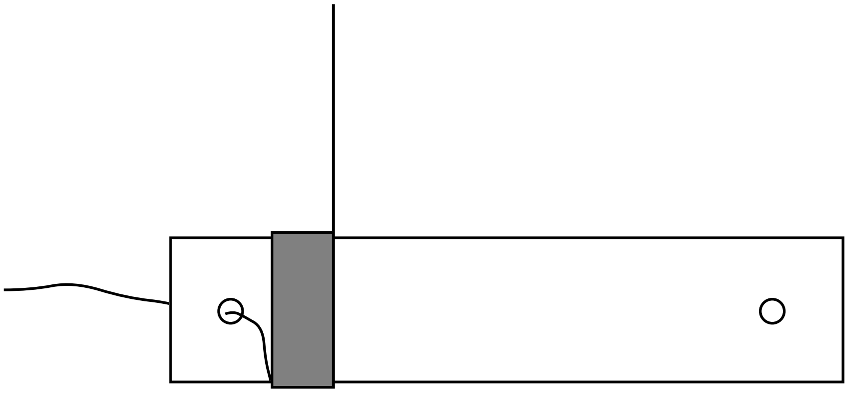
Tape the layout template (the last page of this document) to a board, approximately 7” x 9”, and drill a 1/8" hole at each position marked with a cross.

II. ASSEMBLY

1. Wind the coil.

The coil is made by wrapping the #24 magnet wire onto the coil form, which is made from a piece of PVC pipe. The magnet wire is the wire that looks like it has no plastic insulation on it. But, it is actually coated with a thin layer of enamel. This coating must be removed from the ends of the wire before making any connections.

The best way to wind the coil is with two people, one to hold the wire taught (the holder) and the other to wind it onto the coil form (the wrapper). First, thread the end of the coil wire from the outside of the form through one of the large holes and out the end of the form. Leave about 4" of wire going out the end. Hold onto the other end of the wire and begin wrapping it around the form, starting right next to the hole. After you have wound a few turns on, push the wire together so it is nice and neat and put a piece of Scotch tape over it. The coil should look like this:



Now, the "holder" should hold the spool of wire loosely while the "wrapper" walks across the room unwinding the wire. Then, the holder should hold the spool very tightly so that the wrapper can wind the wire onto the pipe evenly. Each turn should be wrapped on right next to the previous turn, but shouldn't overlap. As the wire is wrapped on, the wrapper slowly walks across the room keeping the wire tight. When the wrapper reaches the holder, hold the wire that has been wrapped onto the form tightly, while the holder lets the wire on the spool unwrap. The wrapper then walks back across the room unwinding the wire from the spool, and the same procedure is repeated.

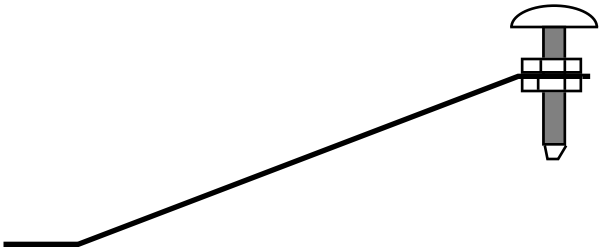
When the coil is within about 1/8" of the holes at the other end of the coil, stop winding. Put a piece of Scotch tape on the end of the wrapping, and cut the wire a few inches from the end of the coil. Thread the end of the wire through the large hole in the form.

2. Attach the coil to the board.

Use two of the #8 sheet metal screws to attach the coil to the board, using holes B and C that you drilled. Place the screws through the small holes in the coil form from the inside. You can then use the large holes on the other side of the form to reach the screws with a screwdriver. Make sure the coil is attached snugly to the board.

3. Assemble the slider.

Find the slider, the 8-32 screw and the two 8-32 nuts. Thread one of the nuts onto the screw until it is about 3/8" from the head of the screw. Put the screw through one of the holes in the slider and thread the other nut on, so that the slider looks like this from the side:



Tighten the second nut against the slider and the first nut with a wrench.

4. Attach the slider to the board.

Find a sheet metal screw, a washer and the ring terminal with two wires attached to it. Put the screw through the ring terminal, the washer and finally the open hole in the slider assembly (from the top of the slider as shown above). Attach the entire assembly to the board with the screw at hole E. Tighten the screw so that it is snug but still allows the slider to move back and forth. The pointed end of the machine screw at the other end of the slider should press firmly against the wire on the coil. If necessary bend the slider so that it makes firm contact with the coil but can still move.

Move the slider back and forth on the coil to scrape the enamel insulation from the coil wire where the pointed end of the machine screw touches it. The screw should be able to make an electrical contact with the coil wire at any position along the length of the coil.

5. Put the remaining screws in the board.

Screw the remaining sheet metal screws into holes A, D, F, G and H, with a washer on each screw. Do not tighten the screws yet.

6. Wire the components of the radio together.

Use the circuit drawing as a guide. For each connection, make sure that the insulation is removed from the end of the wire. Wrap the bare ends of the wires around the screw between the screw head and the washer underneath.

a. Wrap the two wires from the earphone jack around screws F and H. Do not tighten these screws yet.

b. Take the short wire from the slider and wrap the bare end around screw F (which should already be attached to one of the earphone jack wires). Do not tighten the screw yet.

c. Take the long wire from the slider and wrap the bare end around screw A. Do not tighten this screw yet.

d. Find the crystal diode, the small cylinder with two bare wires attached to it. Wrap one of the wires around screw H (attached to the other earphone jack wire), and tighten the screw.

e. Take the other wire from the diode and wrap it around screw G. Do not tighten this screw yet.

f. Find the capacitor, the small disc with two bare wires attached to it. Wrap one of the wires around screw F and tighten the screw.

g. Wrap the other wire from the capacitor around screw G, but do not tighten this screw yet.

h. Cut a piece of hook up wire about 6" long and remove about 1/2" of insulation from each end. Wrap one end around screw G and tighten the screw. Wrap the other end of the wire around screw D, but do not tighten this screw yet.

i. Take the wire from the right hand end of the coil and remove the insulation from about 1/2" from the end of the wire. To remove the insulation, either lightly scrape the wire with a knife or use a small piece of sandpaper. Wrap the bare end of the wire around screw D, but do not tighten the screw yet.

7. Connect the radio to ground.

In order to work, the crystal radio must be wired to a good ground connection. Often, the easiest way to make a ground connection is to use the grounding circuit for the house's electrical system. Cut a piece of hook-up wire long enough to reach from the radio to a nearby electrical outlet. Remove 1/2" of insulation from each end of the wire. Wrap one end around screw A of the radio and tighten the screw. On the electrical outlet, loosen the screw that holds the plate on the box. Wrap the other end of the wire around this screw and tighten it.

CAUTION: Be sure not to let the wire or anything else touch the 120 V socket!

Alternatively, you can use a cold water pipe to connect the radio to ground. Remove a few inches of insulation from the wire from screw A of the radio and wrap the bare end around a cold water pipe.

8. Connect an antenna to the radio.

Use the rest of the hook-up wire to make an antenna. Remove 1/2" of insulation from one end of the wire and wrap it around screw D. Tighten the screw. Unwind the wire from the spool and try to place it as high as possible in the room.

In areas with many powerful radio stations nearby, an inside antenna should be adequate to receive a few stations. If you have trouble hearing anything, it may help to set up a long outside antenna. Radio Shack sells a kit with the necessary wire and other parts (cat. no. 278-758).

9. Try the radio!

Plug the earphone into the jack. Listen to the earphone and slowly move the slider across the coil. Try to find the position where a station is loudest. You should be able to hear a few different stations with the slider at different positions.

10. If the radio doesn't work, check the following:

a. Make sure all of the connections are correct and that the insulation has been removed from the wires where they are wrapped around screws. Also check that there aren't any short circuits between the screws or bare wires.

b. Make sure that you scraped the insulation from the coil wire with the slider so that the slider can make good contact with the coil.

c. Make sure that you have a good ground connection. Try a different electrical outlet or a cold water pipe.

d. Place the antenna higher up or try a longer wire.

piedini 4 e 5 per 12V

Ricevitore FM in super reazione con ECC81-12AT7

Building a receiver like this nowadays may seem like suicide.

Why embark on a critical realization and doubtful functioning from the point of view of quality, when it would be enough to buy one of the many monolithic chips all do in which virtually attack the antenna, headphones and battery, and you have better results than this.

Yeah, why ?!

Do you want me to list them point by point or do you imagine them?
I know, I know the answers you would give me, colorful, funny, offensive and elusive, accusatory and vaunting.
The truth is that I needed to get involved.

Everyone talked, talked, talked about the social crisis in which we find ourselves, everyone pretended nothing, everyone put the ham on the eyes and the prepaid TV in the ears so that via cell phone we were more stoned than what in the end not we would always be lost in futile artfully created problems to mislead us from the real terror we are slipping into.
With only one salary and a wonderful family, I did what the state does not pass in the mind to do, cut the unnecessary expenses and, among these, the first to be eliminated, were the outlays for the purchase of radio, books and magazines.
At the beginning it was particularly frustrating, I do not deny it, I felt like a failure, but then I made myself a reason and I realized that, in the bad, I had found a lifeline to cling to.
I rediscovered the radios and books that surrounded me, I realized that I no longer considered them, occupied as

I was to accumulate as much as possible, to fill the void that left you the fact of not feeling part of a community indeed, a group of people who now thought only of their business.
So I went to the basement to dust the dust cover but, above all, to open all the shoe boxes full of disassembled components over the years and start their cataloging in order to build, build anything, equipment, joke, havoc, provided I felt alive again by putting myself to the test.

In all this psychological, psychiatric, sociological chaos, my friend Stefano Leopardi arrived and offered me an advanced radio editing course at his school, for the afternoon activities chosen by the boys. Advanced course because the base we had already done :-)
The project was ambitious, to build to the boys, after the galena in OM amplified with two transistors, a valve receiver but with the reception in MF.
After considering the few circuits that are on the net and on the books, the choice fell on the famous receiver of prof. Pegna and that you can find **here** . The first step was to find the material and to test the circuit, eliminating immediately the uninsulated power supply from the network and using a New Electronics kit for the supply of valve devices. The second step was the appointment at school, on the 29th of December 2012, during which we handled the welder and prepared the first prototype, working immediately even if with some difficulty.

I admit, a bit 'skeptical I was, not convinced of the potential of the circuit, not convinced of using high voltage to boys and, above all, not convinced that it worked just so much so that, three consecutive times, we misfired for assembly errors.
But then, after listening to the first notes and voices, and having found that, after all, the project was not so utopian, I went on to build my own version, to make possible problems that could have occurred to the boys, and that's where the vicissitudes started.

Do not expect me a mathematical treatment of superreaction, they practically do not exist (at least in the books and magazines in my possession). The only deals in Italian on the web, which have some validity, **here** and **here** . The disquisition is interesting and detailed, in an attempt to extrapolate the functioning of the FM superreaction, but does not draw a spider from the hole, in the sense that there are no certainties about the real mode of detection of frequency modulation.

Another help could come in an empirical form, using a whole radio frequency instrumentation, in order to have the possibility of achieving maximum performance using the equipment and the empirical replacement of the components, logically knowing why and what to replace. In one way or another, I wandered into the limbo of the evolved kit builder, that is, that freak being that is neither a designer, nor a graduate, nor a rich one who can afford the purchase of what you want , that is of that Sunday animal that has survived since the radio-electronic culture has had light.

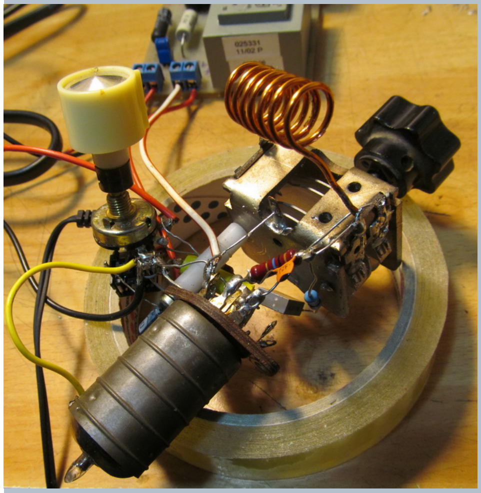
The devices in super-action are suitable for the reception of very high frequency signals and with excellent sensitivity, despite requiring a small number of components and allowing the detection of signals both amplitude modulated and frequency modulated.
They are easy to build and are very simple, but require a set-up that is often laborious and that makes mass production virtually impossible, as each receiver is a world apart.
They usually consist of a detector valve followed by one or two audio amplifying valves (the same is true for transistor circuitry).
The sensitivity of the detector valve in reaction is extremely high but it is for a very short time since immediately after the valve starts to oscillate making us hear the typical whistle in the speaker and starting to transmit disturbing the equipment of neighbors.
It has therefore been thought to prevent the valve from entering oscillation, by making its operation intermittent around the point of maximum sensitivity of the valve, that is to keep the operation of the valve suspended between the moment of triggering of the oscillations and the moment immediately before, turning off the oscillations every time they exceed a certain threshold.
If the intermittences were 100 per second, reception would be impossible because the resulting signal would be a dark buzz; as the intermittences increase, the buzzing gives way to a sharp whistle and then to a rustle, so it is from there that we try to create intermittences that are outside the upper hearing threshold of the human ear.
This intermittence, is called the *extinction frequency,* and in general, to obtain the above result, a frequency of 100Khz is applied to the detector, so that each positive half-cycle corresponds to the valve operation and to each negative half-cycle it corresponds to the valve locking same.
The drawback of this type of reception consists in the fact that at each operating interval many cycles of the incoming signal must correspond. If the shutdown frequency is 100KHz it will be impossible to receive long waves

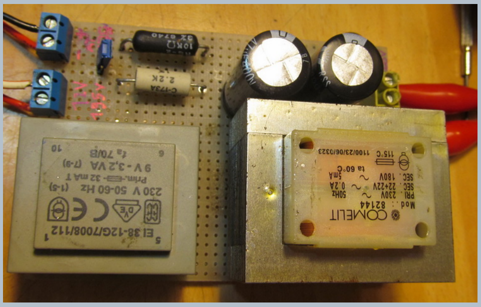
or medium waves, and if you want to receive ultra-short waves, receiving 100MHz signals would have 1000 cycles of incoming signal for each cycle.

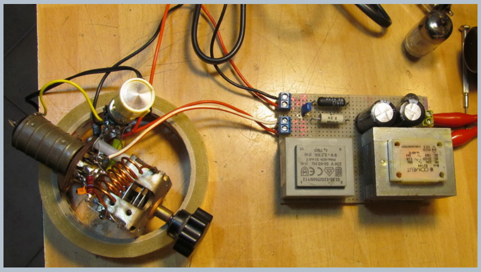
Our circuit is of the self-oscillating type, the left triode in the electric scheme acts as a grid triode detector and oscillating triode. The antenna group, in addition to performing the usual functions of tunable range, constitutes a Colpitts oscillator. The JAF1-C3-C4 group constitutes the cell that together with the triode generates the extinction frequency; the two resulting signals will subsequently be revealed in grid flaws.
The potentiometer R4, by varying the anodic voltage of the triode, varies its operation (switch off and oscillation). The left-hand triode is a simple low-frequency amplifier triode once the signal has been detected, in which the R5-R6-C5 components constitute the components that correctly polarize the trip. Capacitor C6 filters the spurious signals into radiofrequency to ground.

THE CONSTRUCTION AND THE LIST OF THE SAINTS

What you see is the first version of the receiver we have talked about so far.
It is built in an absolutely Spartan way, taking into account only the length of the wires and the terminals of the components. The power supply is essential but also spartan, without frills, even the filament is powered by the 9V transformer instead of the necessary 12V, as, under load, the transformer pulls out 12V instead of 9V mah, the mysteries of the copper electron !







In the first tests done with Stefano, they powered the radio at 150V of anodic, the power supply used in my case has two voltages, 170V and 200V, does not change practically anything to the ear deafly humanoid like mine, if I had the instrumentation, maybe some more info I gave it to you .... The only noteworthy difference is the displacement of the point where the reaction intervenes. You can even go down on 130V, but the more you go down, the more the reception, the reaction capacity and the output level decrease.
Turned on the circuit, I bowed to His Lordship Superreaction: although I found a house point (the usual closet) stingy with radio waves, I could easily receive many commercial stations with a good volume on the headphones, holding the command of the reaction just the typical rustling started, from nothingness to chaos in a light touch. Compared to the original scheme, the value of the double variable capacitor and the number of turns of the chord and oscillation coil had changed. In this situation there was a lot of buzzing in the background, a remnant of the alternate, although tolerable and there was an accentuated hand effect. There was no antenna and no loose coupling, just as the welder had created. Computer speakers, even if powered continuously by batteries, at maximum volume,
In all this beehive nest, antithesis of the measurement laboratory, listen to the number of stations that you receive and, in general, the quality of the stations received in function of the simplicity of the assembled circuit. In the evening, with the headphones, as the external noise and interference diminished, the audio quality increased.

After these comforting results and after verifying the problems that the boys might have encountered, I decided that I would have prepared a small wooden frame at least to give some solidity to the structure and a better arrangement of the components. Actually I just picked up the receiver and screwed it to the wooden front panel, putting the power supply on the insulating surface, always made of wood, so as not to risk unnecessary short circuits.
The result?
Disappointing.
The reception was no longer the same, the signal seemed to have given way to the noise, although the test locations were always the same, the reception seemed silenced, even changing the valve with other functions, the result did not change. Then I started to change the assembly plan, changing the arrangement of the components, moving away, approaching the distanced and approachable, but the only result I got was the displacement of the receivable band (I have also come to change the speakers. ...).
You can listen to the result of the second experiment and watch it in this video.

Disappointed and disheartened, I went to Stefano's house one Saturday to help me untangle the skein and learn something and instead, after a good coffee, my receiver started playing almost like a commercial superheterodyne: clear and strong sound, even with the addition of an external antenna, which considerably increased the audio output (which I had not been able to do at home because it was replaced by a strong buzz that obscured any transmission). In addition we had connected the valve amplifier that was the other part of the school project and the sound was powerful and full-bodied.
Perhaps the receiver had had a mystical transmutation in road transport or had been blessed by an intergalactic

wave coming from the XTY56 sector of the Bravosian galaxy or, simply, it was the usual c ... of the Sunday arrangist that in the presence of the supreme master bowed to the knowledge ....

I can not explain it, coming home from Stefano I felt relieved, all the hours lost to make changes and attempts, had led to the creation of a spectacular receiver, the results far above my expectations and the very good sound quality.

I returned home and, after falling asleep, I put on the headphones and I tried again the reception and .... I took the calendar and I enumerated in alphabetical order the sanctified progeny of past centuries. Joke, some dirty word I pulled it down, but nothing striking because if I had really named all those saints, you know the money I would have to pay in copyright ......

Nothing had changed, everything as before, but at least I had the certainty and awareness of what the good Ravalico and good Brazioli had been preaching for years now: every receiver in superreaction is a world in itself, both on the constructive side and in the context in which it is used.

The test was exhaustive, at Stefano's house it was received that it was a marvel, in my house a crap.

Since I had nothing to do, I changed the circuit again, which by now was taking on the definitive aspect and I started the tests again. The following is the result.

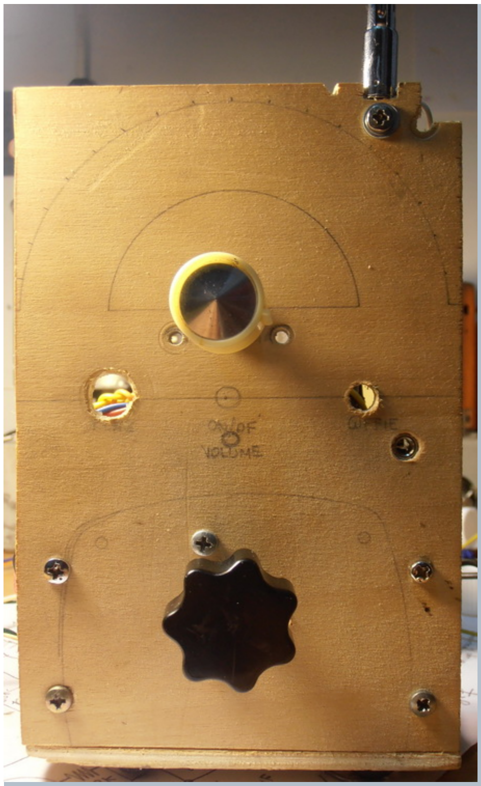
During the tests I notice a strange behavior: just before the sudden reaction comes into operation, there is a zone of rotation of the potentiometer in which there seems to be a clean radio reception from the noise. Since the grid voltage oscillated around 27V, I decided to extend this range of variability by replacing the 100Kohm potentiometer with a 47Koohm resistor series and a 22Kohm linear variation potentiometer. In this way, that point of radio grace was perfectly manageable and easily adjustable.

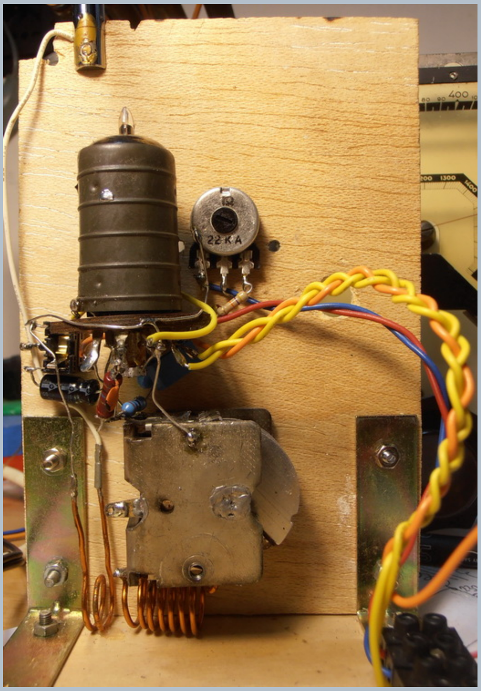
The receiver began to have its own soul and life.

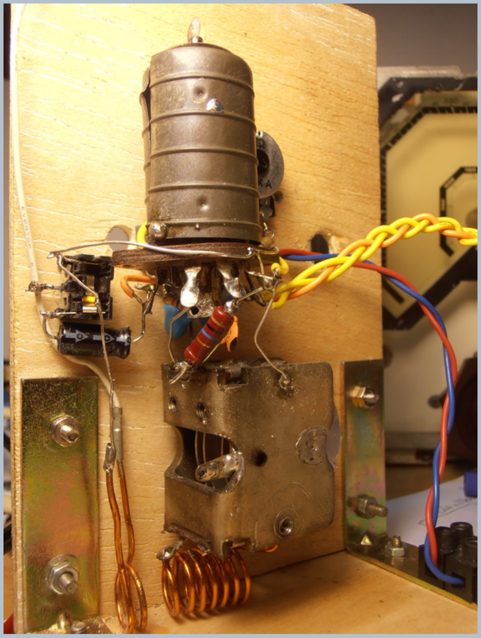
I get inspired by optimism and I also try to insert the antenna winding. Now the generation of the buzz is not as unmanageable as before, I make a thousand attempts between number of turns and positioning of the loop and arrival at the optimum, using two coils of the same diameter of the antenna coil with one end to ground and the other connected to a stylus antenna. Now the signal is strong enough and the sound is clean enough. I block the antenna coil with the cyano-acrylic glue and I relax by scrolling through the frequency modulation range, enjoying the long-awaited success and letting myself be lulled by the silence that only night can give you.

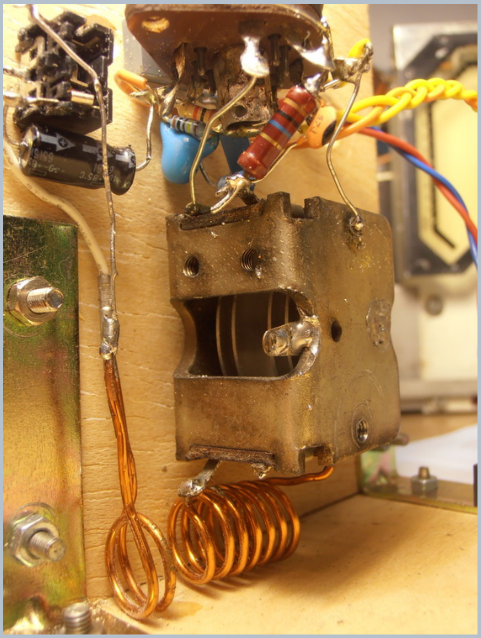
This is the final result, divided into two videos due to Crozza's intervention in Sanremo.

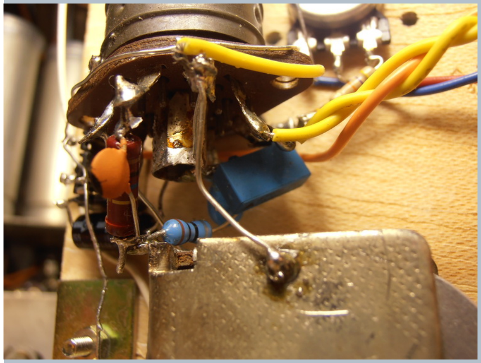
This time I let the video talk rather than the images, I inserted the photos of the initial realization and I finish by inserting the photos of the final version.
As usual, I did not pay attention to the aesthetics, but rather to the final result I had proposed. I am certain, because experienced, that the receiver built in this way will give its best under all circumstances, as improved in the worst reception conditions, those of my house.
I do not want to, an excellent project is the combination of all the aspects that compose it, I always defect in the aesthetic one but I will improve, one day.
The complete project involves the construction of the power supply and the low-frequency power stage, but these topics will see the light editor later. **BUILDING TIPS, WORKING EXPERIENCES AND FINAL IMPRESSIONS** Where do we start? I do not know, I go in random order, just like memories come back to me. **Defects and advice.** The circuit has its own heart and, therefore, its own independent life. Mine will be different from yours and the constructive or implemented strategies that you will adopt will be similar, but it is said that they reach the same result.

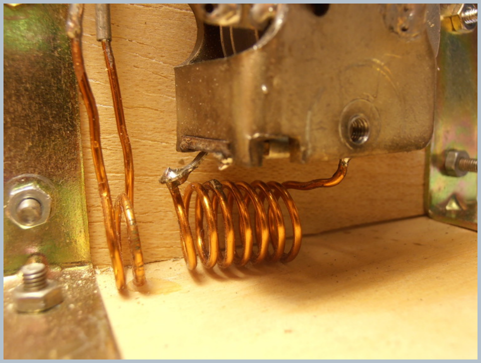












Do not use long, parallel or 90 ° links as well as hieroglyphs: high frequency editing has few basic rules and these are some of those. If you can, use rigid wire not interwoven as those normally used in electronics, for example the resistance terminals are excellent, use links like those, sell them already made but you can also find them in vintage wires peeling. You can use the copper wire of the transformers that you will have scrapped, but you will

have the hassle of the peeling and the subsequent welding before putting them in place.
As usual, it is a must to use what you have at home, especially in this period of crisis (and then become an anti-consumerism philosophy).

The circuit is not very selective, not because of me, but because of how it was conceived.
Trying to get a high sensitivity has had to give way to selectivity. In OM and OC low there is the problem that between one channel and the other there are 9-10Khz with a signal of amplitude however very strong of the order of mV. However, having to do with the high frequencies, the view is reversed, we must go to look for very weak signals, from 5uV up but with bandwidths of separation between one channel and another of about 200KHz. So when you have two stations nearby, or you hear them together, or the most powerful will overwhelm the weaker. You can maneuver the variable capacitor to try to get the best reception, perhaps using a manopolone or reducing the rotation (in this case it would go against the cheapness of the realization if you buy a knob specially gutted, try to invent a tuning system with lanyard or use a large knob, maybe the cap of one liter bottles of fruit juice, in short, the choice that is most congenial to you).

You'll probably need a valve shield. It is a choice that you will have to face straight away, otherwise you will have to lose the track again. The screen isolates the valve from the hand effect and the residual humming but becomes part of the tuning and reaction circuit. It is one of the faults of the circuit: the construction, the components, the connections, everything becomes part of the reception and the reaction, first you understand this and first you will be able to understand the behavior of the receiver, without the need for mathematical formulas and instruments scientific.

The capacitor used in this receiver, is a double variable in air 8-19pF then, thinking about the small capacities involved,

In the absence of a tuned signal, a loud background noise is heard, which disappears almost completely when a sufficiently strong station is tuned in, noise that still annoys, especially in prolonged listening or in headphones.

The receiver, as a reaction, is an excellent transmitter on the tuned frequency: you must then duly measure the reaction in order to avoid that the roommates of the building, aware of your passion, waiting for you outside the door and beat you to the sound of music.

It is possible that the hand effect is present, an effect that leads your hand to be part of the tuning circuit and that leads to the variation of the tuned frequency according to the distance of your hand from the variable. You can avoid this problem by using the aluminum front panel, to the ugly use aluminum to cook in film, try what happens if you put it to ground or not. In the final configuration the hand effect was not there while it was present in the initial one.

Give the valve a few minutes to warm up and arrive at an equilibrium temperature with the environment in which it is located; this will lead to no frequency shift during listening.

For all the observations reported so far, we understand how the use of these receivers is limited to amateur receivers or particular applications, but despite everything is a configuration that gives enormous satisfaction to those who venture into the world of VHF with the superreation for the first time: it is a great bench on which to experience and learn new concepts.

Highs

After having exposed all the problems that may arise, I guess I'll find mica so many advantages ....

The receiver is built with very few components, without coils with strange initials, with pieces that you can easily find in your drawer or at fairs (I'm talking about the condenser and the valve). The receiver is cheap, the valve, fortunately, is not widely used by audiophiles, so its price does not suffer the mood of the market. The variable condenser Stefano paid him at the fair € 2.50 ....

The receiver, once you have worked on it, it works really well.

You can use the headphones that you use for media players, so you can purchase them at little cost, or you can connect external speakers for computers, even if the sound output will not be particularly powerful. When you go to the usual Chinese store, check the specifications that the headphones are from 32ohm impedance, otherwise a low and distorted sound output.

The receiver allows you to experience in high frequency and allow you to learn new things, which is not a little. It is possible to receive a wide range of frequencies, modulated both in amplitude and in frequency, giving you the possibility to discover amateur ranges otherwise out of reach.

The power supply can be obtained using two transformers sold in Chinese shops, those with primary to 220V and multiple secondary, from 1.5V to 12V. I bought two for other purposes, from 1A and I paid € 4.5 each, if you take those from 500mA cost you € 1 less. If you use the 6V or 12V outputs you can also feed the filament in series or in parallel. The anodica requires at most 5mA (remember primary-secondary-secondary-primary).

In short, I do not have other things to say only that, as you have heard, the receiver works really well (and unfortunate not to have registered at Stefano's house ...).

Last-minute tips

I recommend using the earphones: the closer they approach the 64ohm required impedance, the greater the volume in headphones and the better the sound quality. I have tried 7 of earphones and only two have given the desired results, even if no one takes me out of my head that at most are 32ohm headphones. As mentioned previously, an incorrect and low output impedance leads to increased distortion and headphone output volume.

The impedance L1 regulates the tuned band and the type of oscillations. With the double variable capacitor in my possession that does not exceed 20 + 20pF and the copper wire of that diameter, 7 turns were needed to have the whole FM band receivable with only a few degrees of rotation of the lost capacitor. Depending on the capacitor in your possession you have to jig on the turns and their distance to have the whole band and avoid the overlap between the stations and the same applies to the diameter of the wire you have, must still be close to that indicated in the original scheme. If the thread was unglazed but silvered, things should be better.

The coil L2 you have to try with the assembly that you will have: you will have to test the distance from the L1 for which you have greater coupling and therefore output signal strength and minimum residual hum. Test.

As for the JAF1, try all the reels you have, as long as the value is between 5 and 10 micro Henry. The higher the value, the less stations you receive, the more difficult it will be to react. At the moment there is a commercial 10uH reel mounted, I had mounted one when I went to the house of Stefano that his digital inductance measured 7uH, commercials less than 10uH I had to try.

I tried to mount an ECC83 but the result was not exciting. He behaved well, some stations felt limpid, but the management of the reaction became impossible and the point of work of grace that I had found was no longer found. You probably have to rebuild the circuit on that valve, you can try if you do not already have it in the drawer and you do not want to spend the money.

Depending on whether you use the headphones or the external speakers of the computer, you will have to manage the socket for female audio jack: if you use the computer speakers, the head that goes to ground connect it with the control unit of the female jack.

Depending on whether you use the headphones or the external speakers of the computer, you will have to manage the socket for female audio jack: if you use the computer speakers, the head that goes to ground connect it with the control unit of the female jack, the output will be monophonic but the output power and quality will increase significantly.

Remember to connect the screen to ground and place the wire so as to have as little buzz as possible.

In the receiver mounted by me, three operating modes can be identified.

Before arriving at the threshold where the reaction is abruptly inserted, there is a state of grace that allows you to listen to the stations without the shadow of rustle, as you can hear from the last video. In this state the outgoing sound volume, although still manageable through the potentiometer, does not have a particularly high level.

When it comes to the actual reaction, noise and volume increase significantly. Once the station is centered, the noise will disappear almost completely but it will still be present. The higher the level of the signal that we will receive in the antenna, the less will be the noise in the headphones.

There is the third and last state, in which, continuing to increase the reaction, it will be possible to tune a station as if it were at the center of the minus flex of a sine wave. By turning the potentiometer slightly to the right and slightly to the left, you will hear a whistle soaked in rustle; in the background to the centered station you will always find the usual rustle. Generally, this behavior occurs when a very weak station is received.

List of components

V1 = valve ECC81 or 12AT7
R1 = 10Mohm
R2 = 100Kohm
R3 = 47Khohm
R4 = potentiometer 22Kohm linear
R5 = 1Mohm
R6 = 1Kohm
C1 = variable capacitor in air 20 + 20pF
C2 = ceramic 47pF
C3 = 10nF minimum 100V
C4 = 2.2nF
C5 = 25uF 16V electrolytic
C6 = 10nF 250V or more
L1 = 7 spiers spaced 1.5mm, diameter 1.4mm thread on 1cm support
L2 = 2 spaced spaced 1.5mm, diameter 1.4mm thread on 1cm support
JAF1 = 5-10uH Noval
valve plinth with screen support or take the screen separately.
Stereo jack to be connected with the two earphones in series (do not connect the central mass terminal).
2 knobs for tuning and reaction.
mammoths for connections.
Directional stylus antenna.
For resistances to the maximum use from half a watt but also 1 / 4W should not give problems.

It is time to conclude.
I set up the article as if it were a conversation between friends. I hope that the time taken to read the article and watch the videos was pleasant and relaxing.
See you next time.
Carlo.

PS I remembered, when I inserted the biography, that the third electronic kit that I bought in the distant youth, was just LX441 present in the number of Nuova Elettronica 74. I remember that I was very bad at the end of the editing because I only heard rustle and I could not to capture no station, even in FM. If only someone had taught me how superreaction was managed and how was it to be received, I would probably be another man today, better? worst? boh !!!! I tried to find it in the cellar, but I could not find it, who knows what happened to it, I would have liked to lose my hands today ......

WHAT ARE THE BASICS OF CRYSTAL RADIO RECEIVERS?

Here is the schematic diagram for a very basic crystal radio set without any particular embellishments. This basic old time radio uses no power other than that provided by the transmitting antenna from the radio station. Free power from the sky eh!. It truly is a marvel!.

As a matter of interest, some amateurs and experimenters living in the vicinity of high powered AM Radio transmitters have literally used crystal radio sets to trickle charge their batteries. Now THAT is real COOL! If the demand exists we will do it too!.

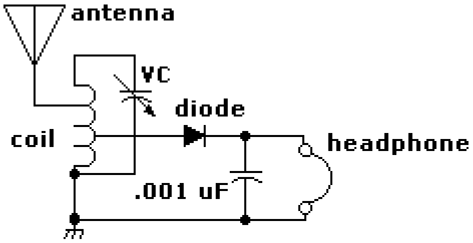

Figure 1 - schematic of a basic crystal radio set

NOTE: For people unfamiliar with metric measurements used here 25.4 mm equals 1"

This circuit consists of an **inductor** (also called a coil), a **variable capacitor** (used to be called a variable condenser), a germanium **diode** (formerly called a crystal), a filtering capacitor and finally very high impedance headphones.

The inductor has taps on it:

(a) one to connect the antenna to.
(b) one lower down to connect the detector diode to.

These taps are often best determined by experimentation

The variable capacitor is usually connected across the whole of the inductor to form a **tuned circuit** for our crystal radio set.

Note: the bottom junction of the inductor and variable capacitor is connected to ground / earth - **literally**.

Earth connection for crystal radio set

For the crystal radio set circuit to perform at all well you will need a very good earth connection. A length of old steel water pipe driven **deep** into damp earth is ideal. The electrical earth or water service at home is **NOT** a good or safe earth for this project, in fact it is **VERY DANGEROUS**. - see **earth dangers**.

The funny looking symbol connected to the top of the inductor or coil and variable capacitor denotes an antenna. The higher and longer (50' or 17 metres) this antenna is, the better the likely reception. Reality says of course you can erect an antenna in the space available with the material available. Consider running the antenna around the top of your fence line if is not metallic.

Safety comes first with our crystal radio set

KEEP WELL AWAY FROM POWER LINES AND POWER SOURCES - **REPEAT AFTER ME** - I PROMISE TO KEEP WELL AWAY FROM POWER LINES AND POWER SOURCES.

Always remember the motto "safety first in everything". At this site here I stress that all the time - "safety first" and I can never stress it enough. See my important page about **earth dangers**

Antenna for crystal radio set

Remember we're using the antenna (aerial) to get free power here and we want to capture as much as possible from the sky for our crystal radio set.

Perhaps you might like to review some **antenna basics** before proceeding.

Technical Note: Radio signals (waves) such as we encounter in the am radio band have two halves. One half travels across the surface of the earth at the speed of light through people, buildings and other objects. The other half, a mirror image, travels beneath the surface of the earth. This radio wave has a definite length. Its length is the speed of light divided by the frequency. For frequencies in the megahertz region this approximates to 300 divided by the frequency in megahertz. These radio waves we want to detect with our crystal radio set

An example which we use later is the **am radio band** of 530 Khz to 1650 Khz. These frequencies when converted to .53 Mhz and 1.65 Mhz respectively give wavelengths of 566 metres and 182 metres.

Now some critical aspects:

Variable Capacitor: Here you should try and salvage one from an old time radio. Just make sure the radio is not in the "vintage" class and now worth hundreds of dollars. The ideal ones are nearly impossible to buy now. Unless you have access to measuring equipment you will have to guess the capacitance. A lot of old time radios had capacitors which tuned about 15 pF to 365 pF.

Inductor or Coil: Here we are normally dealing with an air cored inductor wound on some suitable **non metallic** form. Some examples are - cardboard toilet roll former, a short length of PVC tubing 40 mm, 50 mm, 90 mm or 100 mm diameter.

Diode: In lieu of the old crystal detector we use a germaniumdiode of the 1N34 or OA90 type. Do NOT use a 1N914 type.

Fixed Capacitor: This is for filtering and may be .001 uF, 1 NF or 1000 pF type (all those values are the same - just expressed in different units). Something near in the same values is quite O.K.

Headphones: This is by far the hardest part to obtain. The type used for hi-fi **WILL NOT** work here. Ideally you need high impedance 2,000 ohm types but these are nearly impossible to find. You can sometimes buy 1,000 ohm crystal earpieces (no **not** the usual transistor radio type). The headphone is a high impedance load for the crystal set and as we are working on free power from the air we can't load it down. If you used the 8 ohm hi-fi type it would be like trying to run your electric toaster off a very small battery. The power is not available. Remember we're using free power from the sky.

Further reading on **Headsets for Crystal Radios** by Alan R. Klase.

Frequency range: The frequency range of a set like this is mainly determined by the square root of the *ratio of Maximum Capacitance to Minimum Capacitance of the variable capacitor.* In the example above this would be the square root of 365 divided by 15 or about 4.9:1. In the real world there are other capacitance's in the circuit that you can't see (called "strays") and they affect the minimum value. In practice I would expect a real range of about 3:1

A.M. Radio band: Depending upon your country this would cover about 530 Khz to about 1650 Khz. This is slightly more than a 3:1 ratio.

Let us assume for discussion our capacitor was as described above. And for convenience we have strays of about 25 pF (typical). If we add this to both the Max and Min capacitance we get 390 pF Max and 40 pF Min - a ratio of 9.75 the square root of which is 3.122. Happily this also happens to be nearly the ratio of Freq $_{max}$ divided by Freq $_{min}$ or 1650 Khz / 530 Khz. How about that?

Of course these variable capacitors were deliberately manufactured that way for that very reason!

Well now we have to resonate our capacitor with the inductor. What inductance do we need?. The easiest formula is this - take the frequency in Megahertz (i.e. freq in Khz divided by 1000) and square it. Using our two frequencies 530 Khz and 1650 Khz we would have to square both .530 Mhz and 1.65 Mhz which of course become 0.2809 and 2.7225

And you thought maths at school was/is a waste of time!.

These two figures are divided into the standard figure of 25330.3 respectively. The 530 Khz one (0.2809) would give us LC 90175 and the 1650 Khz one (2.7225) will give us LC 9304. Now when tuning a crystal set the more capacitance you use (plates meshed further in) the lower the frequency you receive. In our case we are using a max of 365 pF + 25 pF strays or 390 pF total. At our lowest freq of 530 Khz the LC (L means inductance and C means capacitance) is 90175 and when divided by our C of 390 pF we get a needed inductance of 231.2 uH (uH means micro henry, a unit of inductance).

Similarly if we go to the highest frequency of 1650 Khz our required LC is 9304 and when divided by our minimum capacitance's (reduce the capacitance by withdrawing plates from one another and go higher in frequency) of 15 pF + 25 pF strays or 40 pF we get a required inductance of _______ uH?. Go on work it out. And remember we are only interested in whole numbers because we have made a number of approximations here.

Now how do we get a needed inductance of about **230 uH?**.

Gee whizz not more maths headed our way!

The formula for inductance - using toilet rolls, PVC pipe etc. can be well approximated by:

$$\text{Inductance L} = \frac{0.394 * r^{2} * N^{2}}{(9 * r) + (10 * \text{Len})}$$

Here:

r = radius of the coil i.e. form diameter (in cm.) divided by 2
Len = length of the coil - again in cm.
L = inductance in uH.
* = multiply by

Now assume we have used a piece of PVC pipe of about 104 mm (10.4 cm) diameter. This has a radius of 5.2 cm. Let us wind a coil consisting of 57 turns (with taps at about every 5 turns) over a length of 104 mm or 10.4 cm. For the Mum's and Dad's who work in old measurements that's 4". This is a piece of standard 4" PVC sewer tube.

Politely ask any plumber on any building site for a scrap off-cut about 150 mm (6") long. In another life I'm also a plumber and we like to help polite people.

Let's put those numbers into the our formula above and do some sums:

0.394 * 5.2 * 5.2 * 57 * 57 = 34614

AND (9 * 5.2) + (10 * 10.4) = 46.8 + 104 = 150.8

AND 34614 divided by 150.8 = about 230 uH

Boy am I a clever kid or what. Did you work through that on paper all by yourself? I do hope so.

Why and how taps every 5 turns?. The why first - in the beginning I said connections from the antenna (aerial for old timers) and diode would need to be experimented with. With taps you can select different spots along the inductor.

How?. Easy! Wind your inductor as follows:

You will need a length of enamelled copper winding wire (about 24 gauge or 0.5 mm dia) about 20 metres long - yes you will need just about all of it. You will also need some matches (used are O.K.). Assuming you have a 150 mm piece of sewer tube or similar, drill a small hole approx 25 mm (1") from one end. Drill a similar hole 104 mm further away toward the opposite end (or even 20 mm in from the opposite end). Basically the idea is for the holes to be nearly 10.4 cm apart. or *the length of the coil you are winding*.

Push through about 15 cm (150 mm) of wire and wind the short end through a couple of times to form an anchor (knot) at that point. Then holding the wire tightly wind 5 complete turns spaced about three wire diameters apart from each other (you really need a helper here). Under the 5th turn slip a very short length of match, continue winding very tightly placing a match piece under every 5th turn until you have wound 57 complete turns. Tie a knot similar to the other end and again leave about 150 mm left over. **CAREFULLY** with a sharp knife scrape the enamel insulation away on all 5th turns as well as about 5 mm from the end of the two end pieces.

Presto! there you have a 57 turn inductor of about 230 uH with accessible taps at about every 5th turn.

How it works: (simple version)

Well we have the antenna. This picks up the radio signals from the sky and with our real good earth we hopefully get lots and lots of signals.

The inductor combined with different settings of the variable capacitor selects the frequency you want to listen to and discards all others.

This selected signal goes through the germanium diode and is rectified. This means we are left with the audio frequencies a human being can hear (music - words). This audio has been stripped off the radio signal by the diode. The small .001 uF capacitor gets rid of any of the radio signal left. We can then listen to these very tiny audio signals through our headphones or crystal earpiece.

How it works: (complicated version)

Your long wire antenna and earth wire will pick up thousands and thousands of radio signals from the air. The exact setting of your variable capacitor will determine a set amount of capacitance and this in conjunction with the fixed inductance of your coil we have a **resonant circuit**.

As an example, in my locality we have a very strong AM station at 630 Khz. Using the formula above for **resonant frequency** we find the LC combination (inductance times capacitance) required to receive this signal is:

$25330.3 / (0.63)^2 = 63820$

Therefore if we had a fixed inductance of 230 uH then our variable capacitor (including strays) would need to be set at the point where it exhibits 63820 / 230 **OR** 277 pF. In other words a capacitance of 277 pF in conjunction with an inductance of 230 uH resonates at 630 Khz. We can rather generalise here and say, although not strictly accurate, that this coil / capacitor combination will **ACCEPT** only signals at 630 Khz and **REJECT** all others. This is the way we select our particular frequency from among the thousands and thousands of other signals on our antenna.

Our signal at 630 Khz has been "modulated" at the radio station with audio frequencies (speech and music). Because it is **A**mplitude **M**odulated it is called **A.M.**

This means the original 630 Khz signal strength (amplitude) at the transmitter is expanded and contracted by the audio frequencies.

After being selected by our coil / capacitor combination the 630 Khz signal is passed to the germanium diode. As the signal passes through the diode only one half of the signal is used and the fixed .001 uF capacitor dumps the 630 Khz signal to ground leaving a very tiny audio frequency which is an exact replica of the audio frequencies (speech and music) as they originated in the radio station's studio.

This very tiny audio signal then drives our crystal earpiece or high impedance headphone so we can hear the words and music. If it were amplified many, many times over it would then have the power to drive a loudspeaker. The speaker cone goes in and out at the same audio rate as the original 630 Khz signal is modulated. The moving loudspeaker cone creates a tiny sound pressure level in the room to which your ear is able to respond.

Radio Kits for Beginners and Youngsters of ALL Ages!

My special amateur radio friend Bruce Kizerian, KK7ZZ who has worked tirelessly for years helping the young and not so young get effortlessly into radio now has a site devoted to "Radio Kits for Beginners and Youngsters of ALL Ages!".

There has been a crying need for these kits and Bruce now fills that need.

Check out Bruce's **"Radio Kits for Beginners and Youngsters of ALL Ages!"**

NEW! - "High Sensitivity Crystal Set"

Build a “crystal radio ” by using a new zero-voltage-threshold MOSFET. By Bob Culter, N7FKI as printed in QST [Amateur Radio Magazine] January 2007

Check out the PDF file of the whole article - **"http://www.arrl.org/files/file/Technology/tis/info/pdf/culter.pdf"** 467 kB. **PS:** The article can be more than somewhat highly technical for newcomers though.

NEXT:

Put it all together and reload this page by typing in the URL - www.electronics-tutorials.com/receivers/crystal-radio-set.htm and **tell me how your crystal set works** for you.

If you are real keen you can also check out the **crystal set society's** home page.

Another excellent article (in pdf format) is from the ARRL. From QST December, 1997 **The Crystal Radio**

Fox Hole Radio

Another VERY interesting project is the **Fox Hole Radio**. Building a foxhole radio is rewarding and the basic setup is very simple. It is, however, difficult to adjust, and it may take several

attempts to find a proper razor blade for the detector. This is a project that requires patience and much trial and error, but it will pay off once it begins to work. It will help to be versed in the construction and operation of crystal sets before building one. These sets are extremely simple in construction, but tuning and modification require some basic understanding of theory, as well as practice. All sets presented here are based on old articles, notes, and people's recollections. There are fairly major variations in design and materials among these plans. It must be remembered that these were improvised under often adverse conditions; there was no "standard" design. With this in mind, take this entire article as a whole, and use it a bit here, a bit there, to build towards a Fox Hole Radio design that works best using modern materials.

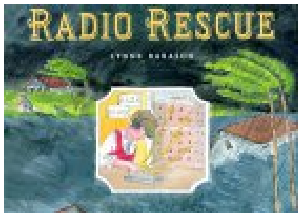
A Candle powered Radio

Yep a World Book Science Project from a looooonnnng time ago.
See: **Candle powered Radio**

A BOOK I THOROUGHLY RECOMMEND FOR YOUNG PEOPLE

Radio Rescue
by Lynne Barasch



From Booklist
Gr. 2-5. In 1923, a 10-year-old New Yorker became the youngest licensed amateur wireless radio operator. In a clear, first-person voice, the boy describes what Morse code is, how operators used wireless radios to send and receive signals, and his experiences setting up an in-house transmitting station. The boy finds fame when he picks up a signal from Florida hurricane victims and radios for help, and the story concludes with a reproduced newspaper photograph and the full Morse code alphabet. An introductory note reveals that the story is based on the author's father and gives readers background information on the era's telephones and the alternative that the wireless offered, including examples of how Morse code has been used throughout its history. In a well-designed mix of insets, brief sketches, and full-page drawings, the author's uncluttered color cartoons do an excellent job of illustrating the technology and the code, at the same time creating likable, expressive characters. Tehnology-minded children may see parallels between the freedom and excitement of the wireless and the Internet in this engaging read. *Gillian Engberg Copyright © American Library Association. WHAT ARE THE BASICS OF CRYSTAL RADIO RECEIVERS?

Here is the schematic diagram for a very basic crystal radio set without any particular embellishments. This basic old time radio uses no power other than that provided by the transmitting antenna from the radio station. Free power from the sky eh!. It truly is a marvel!.

As a matter of interest, some amateurs and experimenters living in the vicinity of high powered AM Radio transmitters have literally used crystal radio sets to trickle charge their batteries. Now THAT is real COOL! If the demand exists we will do it too!.

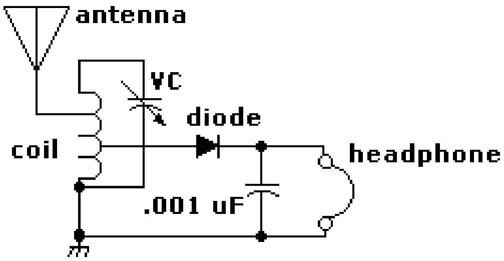

Figure 1 - schematic of a basic crystal radio set

NOTE: For people unfamiliar with metric measurements used here 25.4 mm equals 1"

This circuit consists of an **inductor** (also called a coil), a **variable capacitor** (used to be called a variable condenser), a germanium **diode** (formerly called a crystal), a filtering capacitor and finally very high impedance headphones.

The inductor has taps on it:

(a) one to connect the antenna to.
(b) one lower down to connect the detector diode to.

These taps are often best determined by experimentation

The variable capacitor is usually connected across the whole of the inductor to form a **tuned circuit** for our crystal radio set.

Note: the bottom junction of the inductor and variable capacitor is connected to ground / earth - **literally**.

Earth connection for crystal radio set

For the crystal radio set circuit to perform at all well you will need a very good earth connection. A length of old steel water pipe driven **deep** into damp earth is ideal. The electrical earth or water service at home is **NOT** a good or safe earth for this project, in fact it is **VERY DANGEROUS**. - see **earth dangers**.

The funny looking symbol connected to the top of the inductor or coil and variable capacitor denotes an antenna. The higher and longer (50' or 17 metres) this antenna is, the better the likely reception. Reality says of course you can erect an antenna in the space available with the material available. Consider running the antenna around the top of your fence line if is not metallic.

Safety comes first with our crystal radio set

KEEP WELL AWAY FROM POWER LINES AND POWER SOURCES - **REPEAT AFTER ME** - I PROMISE TO KEEP WELL AWAY FROM POWER LINES AND POWER SOURCES.

Always remember the motto "safety first in everything". At this site here I stress that all the time - "safety first" and I can never stress it enough. See my important page about **earth dangers**

Antenna for crystal radio set

Remember we're using the antenna (aerial) to get free power here and we want to capture as much as possible from the sky for our crystal radio set.

Perhaps you might like to review some **antenna basics** before proceeding.

Technical Note: Radio signals (waves) such as we encounter in the am radio band have two halves. One half travels across the surface of the earth at the speed of light through people, buildings and other objects. The other half, a mirror image, travels beneath the surface of the earth. This radio wave has a definite length. Its length is the speed of light divided by the frequency. For frequencies in the megahertz region this approximates to 300 divided by the frequency in megahertz. These radio waves we want to detect with our crystal radio set

An example which we use later is the **am radio band** of 530 Khz to 1650 Khz. These frequencies when converted to .53 Mhz and 1.65 Mhz respectively give wavelengths of 566 metres and 182 metres.

Now some critical aspects:

Variable Capacitor: Here you should try and salvage one from an old time radio. Just make sure the radio is not in the "vintage" class and now worth hundreds of dollars. The ideal ones are nearly impossible to buy now. Unless you have access to measuring equipment you will have to guess the capacitance. A lot of old time radios had capacitors which tuned about 15 pF to 365 pF.

Inductor or Coil: Here we are normally dealing with an air cored inductor wound on some suitable **non metallic** form. Some examples are - cardboard toilet roll former, a short length of PVC tubing 40 mm, 50 mm, 90 mm or 100 mm diameter.

Diode: In lieu of the old crystal detector we use a germaniumdiode of the 1N34 or OA90 type. Do NOT use a 1N914 type.

Fixed Capacitor: This is for filtering and may be .001 uF, 1 NF or 1000 pF type (all those values are the same - just expressed in different units). Something near in the same values is quite O.K.

Headphones: This is by far the hardest part to obtain. The type used for hi-fi **WILL NOT** work here. Ideally you need high impedance 2,000 ohm types but these are nearly impossible to find. You can sometimes buy 1,000 ohm crystal earpieces (no **not** the usual transistor radio type). The headphone is a high impedance load for the crystal set and as we are working on free power from the air we can't load it down. If you used the 8 ohm hi-fi type it would be like trying to run your electric toaster off a very small battery. The power is not available. Remember we're using free power from the sky.

Further reading on **Headsets for Crystal Radios** by Alan R. Klase.

Frequency range: The frequency range of a set like this is mainly determined by the square root of the *ratio of Maximum Capacitance to Minimum Capacitance of the variable capacitor.* In the example above this would be the square root of 365 divided by 15 or about 4.9:1. In the real world there are other capacitance's in the circuit that you can't see (called "strays") and they affect the minimum value. In practice I would expect a real range of about 3:1

A.M. Radio band: Depending upon your country this would cover about 530 Khz to about 1650 Khz. This is slightly more than a 3:1 ratio.

Let us assume for discussion our capacitor was as described above. And for convenience we have strays of about 25 pF (typical). If we add this to both the Max and Min capacitance we get 390 pF Max and 40 pF Min - a ratio of 9.75 the square root of which is 3.122. Happily this also happens to be nearly the ratio of Freq $_{max}$ divided by Freq $_{min}$ or 1650 Khz / 530 Khz. How about that?

Of course these variable capacitors were deliberately manufactured that way for that very reason!

Well now we have to resonate our capacitor with the inductor. What inductance do we need?. The easiest formula is this - take the frequency in Megahertz (i.e. freq in Khz divided by 1000) and square it. Using our two frequencies 530 Khz and 1650 Khz we would have to square both .530 Mhz and 1.65 Mhz which of course become 0.2809 and 2.7225

And you thought maths at school was/is a waste of time!.

These two figures are divided into the standard figure of 25330.3 respectively. The 530 Khz one (0.2809) would give us LC 90175 and the 1650 Khz one (2.7225) will give us LC 9304. Now when tuning a crystal set the more capacitance you use (plates meshed further in) the lower the frequency you receive. In our case we are using a max of 365 pF + 25 pF strays or 390 pF total. At our lowest freq of 530 Khz the LC (L means inductance and C means capacitance) is 90175 and when divided by our C of 390 pF we get a needed inductance of 231.2 uH (uH means micro henry, a unit of inductance).

Similarly if we go to the highest frequency of 1650 Khz our required LC is 9304 and when divided by our minimum capacitance's (reduce the capacitance by withdrawing plates from one another and go higher in frequency) of 15 pF + 25 pF strays or 40 pF we get a required inductance of _______ uH?. Go on work it out. And remember we are only interested in whole numbers because we have made a number of approximations here.

Now how do we get a needed inductance of about **230 uH?**.

Gee whizz not more maths headed our way!

The formula for inductance - using toilet rolls, PVC pipe etc. can be well approximated by:

$$\text{Inductance } L = \frac{0.394 * r^2 * N^2}{(9 * r) + (10 * Len)}$$

Here:

r = radius of the coil i.e. form diameter (in cm.) divided by 2
Len = length of the coil - again in cm.
L = inductance in uH.
* = multiply by

Now assume we have used a piece of PVC pipe of about 104 mm (10.4 cm) diameter. This has a radius of 5.2 cm. Let us wind a coil consisting of 57 turns (with taps at about every 5 turns) over a length of 104 mm or 10.4 cm. For the Mum's and Dad's who work in old measurements that's 4". This is a piece of standard 4" PVC sewer tube.

Politely ask any plumber on any building site for a scrap off-cut about 150 mm (6") long. In another life I'm also a plumber and we like to help polite people.

Let's put those numbers into the our formula above and do some sums:

0.394 * 5.2 * 5.2 * 57 * 57 = 34614

AND (9 * 5.2) + (10 * 10.4) = 46.8 + 104 = 150.8

AND 34614 divided by 150.8 = about 230 uH

Boy am I a clever kid or what. Did you work through that on paper all by yourself? I do hope so.

Why and how taps every 5 turns?. The why first - in the beginning I said connections from the antenna (aerial for old timers) and diode would need to be experimented with. With taps you can select different spots along the inductor.

How?. Easy! Wind your inductor as follows:

You will need a length of enamelled copper winding wire (about 24 gauge or 0.5 mm dia) about 20 metres long - yes you will need just about all of it. You will also need some matches (used are O.K.). Assuming you have a 150 mm piece of sewer tube or similar, drill a small hole approx 25 mm (1") from one end. Drill a similar hole 104 mm further away toward the opposite end (or even 20 mm in from the opposite end). Basically the idea is for the holes to be nearly 10.4 cm apart. or *the length of the coil you are winding*.

Push through about 15 cm (150 mm) of wire and wind the short end through a couple of times to form an anchor (knot) at that point. Then holding the wire tightly wind 5 complete turns spaced about three wire diameters apart from each other (you really need a helper here). Under the 5th turn slip a very short length of match, continue winding very tightly placing a match piece under every 5th turn until you have wound 57 complete turns. Tie a knot similar to the other end and again leave about 150 mm left over. **CAREFULLY** with a sharp knife scrape the enamel insulation away on all 5th turns as well as about 5 mm from the end of the two end pieces.

Presto! there you have a 57 turn inductor of about 230 uH with accessible taps at about every 5th turn.

How it works: (simple version)

Well we have the antenna. This picks up the radio signals from the sky and with our real good earth we hopefully get lots and lots of signals.

The inductor combined with different settings of the variable capacitor selects the frequency you want to listen to and discards all others.

This selected signal goes through the germanium diode and is rectified. This means we are left with the audio frequencies a human being can hear (music - words). This audio has been stripped off the radio signal by the diode. The small .001 uF capacitor gets rid of any of the radio signal left. We can then listen to these very tiny audio signals through our headphones or crystal earpiece.

How it works: (complicated version)

Your long wire antenna and earth wire will pick up thousands and thousands of radio signals from the air. The exact setting of your variable capacitor will determine a set amount of capacitance and this in conjunction with the fixed inductance of your coil we have a **resonant circuit**.

As an example, in my locality we have a very strong AM station at 630 Khz. Using the formula above for **resonant frequency** we find the LC combination (inductance times capacitance) required to receive this signal is:

$25330.3 / (0.63)^{2} = 63820$

Therefore if we had a fixed inductance of 230 uH then our variable capacitor (including strays) would need to be set at the point where it exhibits 63820 / 230 **OR** 277 pF. In other words a capacitance of 277 pF in conjunction with an inductance of 230 uH resonates at 630 Khz. We can rather generalise here and say, although not strictly accurate, that this coil / capacitor combination will **ACCEPT** only signals at 630 Khz and **REJECT** all others. This is the way we select our particular frequency from among the thousands and thousands of other signals on our antenna.

Our signal at 630 Khz has been "modulated" at the radio station with audio frequencies (speech and music). Because it is **A**mplitude **M**odulated it is called **A.M.**

This means the original 630 Khz signal strength (amplitude) at the transmitter is expanded and contracted by the audio frequencies.

After being selected by our coil / capacitor combination the 630 Khz signal is passed to the germanium diode. As the signal passes through the diode only one half of the signal is used and the fixed .001 uF capacitor dumps the 630 Khz signal to ground leaving a very tiny audio frequency which is an exact replica of the audio frequencies (speech and music) as they originated in the radio station's studio.

This very tiny audio signal then drives our crystal earpiece or high impedance headphone so we can hear the words and music. If it were amplified many, many times over it would then have the power to drive a loudspeaker. The speaker cone goes in and out at the same audio rate as the original 630 Khz signal is modulated. The moving loudspeaker cone creates a tiny sound pressure level in the room to which your ear is able to respond.

Radio Kits for Beginners and Youngsters of ALL Ages!

My special amateur radio friend Bruce Kizerian, KK7ZZ who has worked tirelessly for years helping the young and not so young get effortlessly into radio now has a site devoted to "Radio Kits for Beginners and Youngsters of ALL Ages!".

There has been a crying need for these kits and Bruce now fills that need.

Check out Bruce's **"Radio Kits for Beginners and Youngsters of ALL Ages!"**

NEW! - "High Sensitivity Crystal Set"

Build a “crystal radio ” by using a new zero-voltage-threshold MOSFET. By Bob Culter, N7FKI as printed in QST [Amateur Radio Magazine] January 2007

Check out the PDF file of the whole article - **"http://www.arrl.org/files/file/Technology/tis/info/pdf/culter.pdf"** 467 kB. **PS:** The article can be more than somewhat highly technical for newcomers though.

NEXT:

Put it all together and reload this page by typing in the URL - www.electronics-tutorials.com/receivers/crystal-radio-set.htm and **tell me how your crystal set works** for you.

If you are real keen you can also check out the **crystal set society's** home page.

Another excellent article (in pdf format) is from the ARRL. From QST December, 1997 **The Crystal Radio**

Fox Hole Radio

Another VERY interesting project is the **Fox Hole Radio**. Building a foxhole radio is rewarding and the basic setup is very simple. It is, however, difficult to adjust, and it may take several attempts to find a proper razor blade for the detector. This is a project that requires patience and much trial and error, but it will pay off once it begins to work. It will help to be versed in the construction and operation of crystal sets before building one. These sets are extremely simple in construction, but tuning and modification require some basic understanding of theory, as well as practice. All sets presented here are based on old articles, notes, and people's recollections. There are fairly major variations in design and materials among these plans. It must be remembered that these were improvised under often adverse conditions; there was no "standard" design. With this in mind, take this entire article as a whole, and use it a bit here, a bit there, to build towards a Fox Hole Radio design that works best using modern materials.

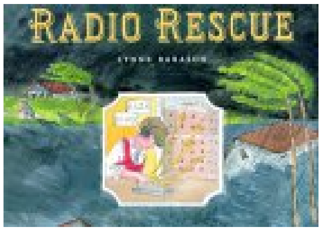
A BOOK I THOROUGHLY RECOMMEND FOR YOUNG PEOPLE

Radio Rescue
by Lynne Barasch

From Booklist
Gr. 2-5. In 1923, a 10-year-old New Yorker became the youngest licensed amateur wireless radio operator. In a clear, first-person voice, the boy describes what Morse code is, how operators used wireless radios to send and receive signals, and his experiences setting up an in-house transmitting station. The boy finds fame when he picks up a signal from Florida hurricane victims and radios for help, and the story concludes with a reproduced newspaper photograph and the full Morse code alphabet. An introductory note



reveals that the story is based on the author's father and gives readers background information on the era's telephones and the alternative that the wireless offered, including examples of how Morse code has been used throughout its history. In a well-designed mix of insets, brief sketches, and full-page drawings, the author's uncluttered color cartoons do an excellent job of illustrating the technology and the code, at the same time creating likable, expressive characters. Tehnology-minded children may see parallels between the freedom and excitement of the wireless and the Internet in this engaging read. *Gillian Engberg Copyright © American Library Association. Fun with Radio and Electronics!

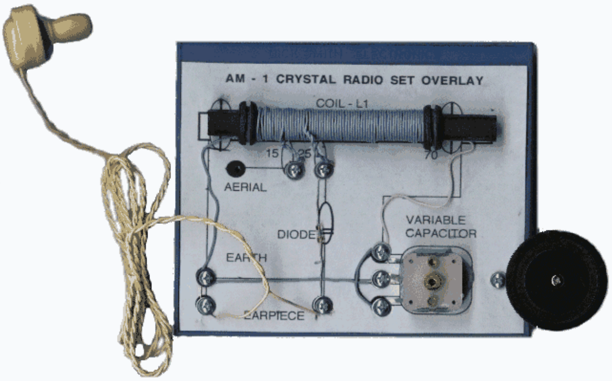
Print out this page and have a go at building a crystal radio set yourself!*

INTRODUCTION



If you're stuck inside on a Saturday afternoon with a junk box full of electronic parts and nothing much to do, you can spend an hour or so and build this very simple but effective Crystal Radio receiver. Often, the satisfaction of building these simple radios is lost amidst the latest computer program or the latest digital marvel chip!

THEORY

Briefly, a Crystal Radio receiver derives it energy from. the radiated power from the AM radio stations in your area, This energy travels in waves, and is induced into your Aerial/Earth wire system (more about safe Aerial and Earth wires later on) and then fed into the coil/capacitor circuit. This coil/capacitor combination is known as a "tank" circuit, because it. stores radiated energy. The coil stores this energy in a pulsating electro-magnetic field, while the. variable capacitor stores energy in 'an electro-static field between its fixed and moving sets of plates.

The Ferrite Rod acts as a bar magnet for radio waves. concentrating them inside the turns of the coil. When.you turn the knob of the variable capacitor you change the value of thisdevice. Changing the value of the capacitor will vary the frequency at which"the Crystal Radio receives. When you tune into a local AM radio station, the tank circuit experiences what is called "resonance". This is like a musician using a tuning fork to tune up the strings of his instrument. Each string will 'resonate' with the chosen tuning fork when they are both pitched at the same frequency.

!n the same way, when a radio station and the Crystal Radio are tuned into the same frequency, resonancetakes place. This state of resonance allows for maximum signal transfer between transmitter and receiver. The selected frequency is then fed into the Germanium Diode detector. This corn portent separates (rectifies) the radio station's "carrier wave" from the program signal (voice and music). The rectified signal is thenfed in the Crystal Earpiece where it is converted into sound waves that we can hear.

OVERLAY FOR CRYSTAL SET

(Refer to printable document for accuracy)

Parts List Dick Smith Electronics	
Ferrite Rod	R5107
Diode OA91	Z3040
VC1 220pf	R2970
Earpiece	C2765
Coil wire (3m)	W2123
Aeria/Earth wire	W2260
8 x screws	H1634
8 x washer	H1488
1 x b'board	H4050

CONSTRUCTION

Our radio set can be made up on a square of wood or plastic around 10cm by 12cm by 1cm. If you or a parent can solder, then feel free to drive nickel plated nails into the wooden baseboard. Then you can "tin" these with a bit of solder and use each nail head as a tie point to interconnect the component leads. **BE VERY CAREFUL** with soldering tools - wear eye safety glasses at all times. Alternatively, you can use a screw/washer combination with the DSE plastic baseboard. These should be the #4x9mm screws and the washers around 5mm in diameter (see parts list). If you decide to solder, take special care with soldering the Diode and the solder tags from the Variable Capacitor. The Diode should only be soldered by using a heat sink (a simple device that will draw any excess heat away from the Diode itself) and this can be a crocodile clip attached to either end of the Diode's leadouts (close to the glass bulb) during soldering. The caseing of the Variable Capacitor is made of plastic, and any excessive heat applied during soldering may well melt a part of this fragile case.

You can use other coils in this simple Crystal Radio design. You can either wind an air-cored coil (if you can't get hold of a Ferrite Rod easily) as shown below (comprised of the same number of turns -70) wound on a paper roll tube complete with taps (at 15 turns and 25 turns) or you can retrieve a factory made coil from an old, disused transistor radio. This coil actually has two windings, and you can tune the Crystal Radio by wiring a 120pF capacitor (instead of the variable capacitor) across the main winding (usually 'white and black wires) and sliding the square Ferrite Rod up and down inside the coil former to tune in local stations (see diagram below).

AERIALS AND EARTHS

The best Aerial is one that is at least two metres high off the ground (higher if possible) and at least ten metres long. You MUST stay well clear of overhead power and telephone cables for safety's sake. The safest Earth wire is one that's connected to a cold water pipe that is embedded in moist soil. A garden tap fitting just outside a window is ideal. Do NOT use the earth pin of a 240 volt power outlet, nor a hot water pipe, nor a gas pipe, as **these are all unsafe** to use as Earth connections, and may well result in electrical shocks or explosions occuring.

DO NOT operate this Crystal Radio receiver during an electrical thunderstorm.

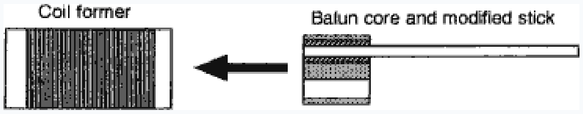
The Nic Nac Crystal Radio

Copyright © **Austin Hellier** 12/02/2001



How It Works

Radio signals are travelling through the atmosphere all the time. This simple radio receiver has been designed to capture them, and turn them into sound waves, so that you can hear what's going on. The Aerial and Earth wires form a return signal path from the AM transmitter, for these signals, and they are then fed into the coil and capacitor. This arrangement is known as a 'tank' circuit, because it stores radio energy, much in the same way your family car's tank stores petrol. The combination of a certain sized capacitor (68pF) and the amount of turns on the coil (around 120 turns) determines the frequency you will receive at. The Diode changes the signal from a radio one, to an audio one, and the Crystal Earphone changes the audio signal into sound waves that you can hear. the resistor adds stability by helping to prevent the Earphone from occasional 'dropout'.

Building The Radio

You'll need all the components listed below and a Tic Tac lolly box. Start by mounting the earphone jack into the lid of the box and then solder up each of the components into a tidy version of the 'rat's nest' construction method. Make sure you use a crocodile clip as a heat sink for the diode when soldering - they're pretty sensitive devices to heat. Then take the coil and remove the ferrite rod from inside it. Take the ferrite balun core and place one end of the plastic stick (obtained by cutting off both ends of a cotton bud) and glue it inside the hole, with its end level with the end of the balun core.

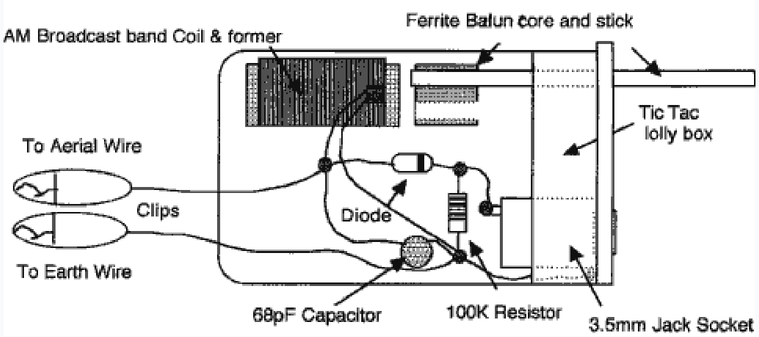


Diagram 2. Place balun inside coil former and use the stick to slide it up and down inside the coil to tune the Nic Nac Radio.

Experimenting With The Radio

You can perform a number of experiments with your new radio receiver, so try the following experiments and have lots of fun while you do:

1. Try hooking up your Aerial wire first, without the Earth wire, to see if you're close enough to a radio station, not to need the Earth wire.

2. Try using different things for an Aerial, instead of the long wire - e.g.: a wire clothes line, a Hills Hoist clothes line, a metal window frame, a metal security door, a cyclone fence, bedsprings etc.

3. If you live really close to a radio transmitter, try rotating the Crystal Radio without an Aerial or Earth wire, to see if you can pick up these local stations.

I hope that you have as much fun making the **Nic Nac Radio**, as I did in designing it.

Building The Radio

You'll need all the components listed below and a Tic Tac lolly box. Start by mounting the earphone jack into the lid of the box and then solder up each of the components into a tidy version of the 'rat's nest' construction method. Make sure you use a crocodile clip as a heat sink for the diode when soldering - they're pretty sensitive devices to heat. Then take the coil and remove the ferrite rod from inside it. Take the ferrite balun core and place one end of the plastic stick (obtained by cutting off both ends of a cotton bud) and glue it inside the hole, with its end level with the end of the balun core.

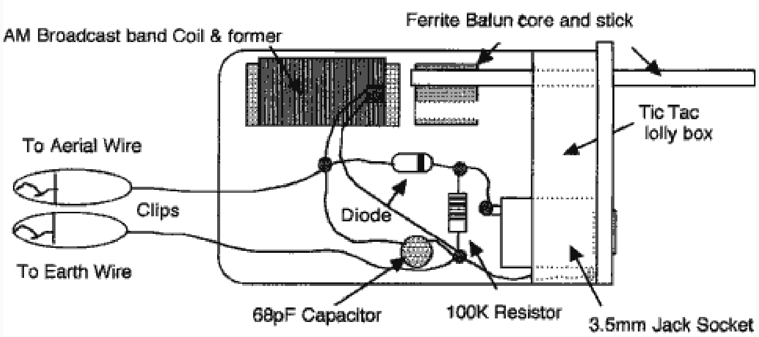

Diagram 2. Place balun inside coil former and use the stick to slide it up and down inside the coil to tune the Nic Nac Radio.

Experimenting With The Radio

You can perform a number of experiments with your new radio receiver, so try the following experiments and have lots of fun while you do:

1. Try hooking up your Aerial wire first, without the Earth wire, to see if you're close enough to a radio station, not to need the Earth wire.

2. Try using different things for an Aerial, instead of the long wire - e.g.: a wire clothes line, a Hills Hoist clothes line, a metal window frame, a metal security door, a cyclone fence, bedsprings etc.

3. If you live really close to a radio transmitter, try rotating the Crystal Radio without an Aerial or Earth wire, to see if you can pick up these local stations.

I hope that you have as much fun making the **Nic Nac Radio**, as I did in designing it.

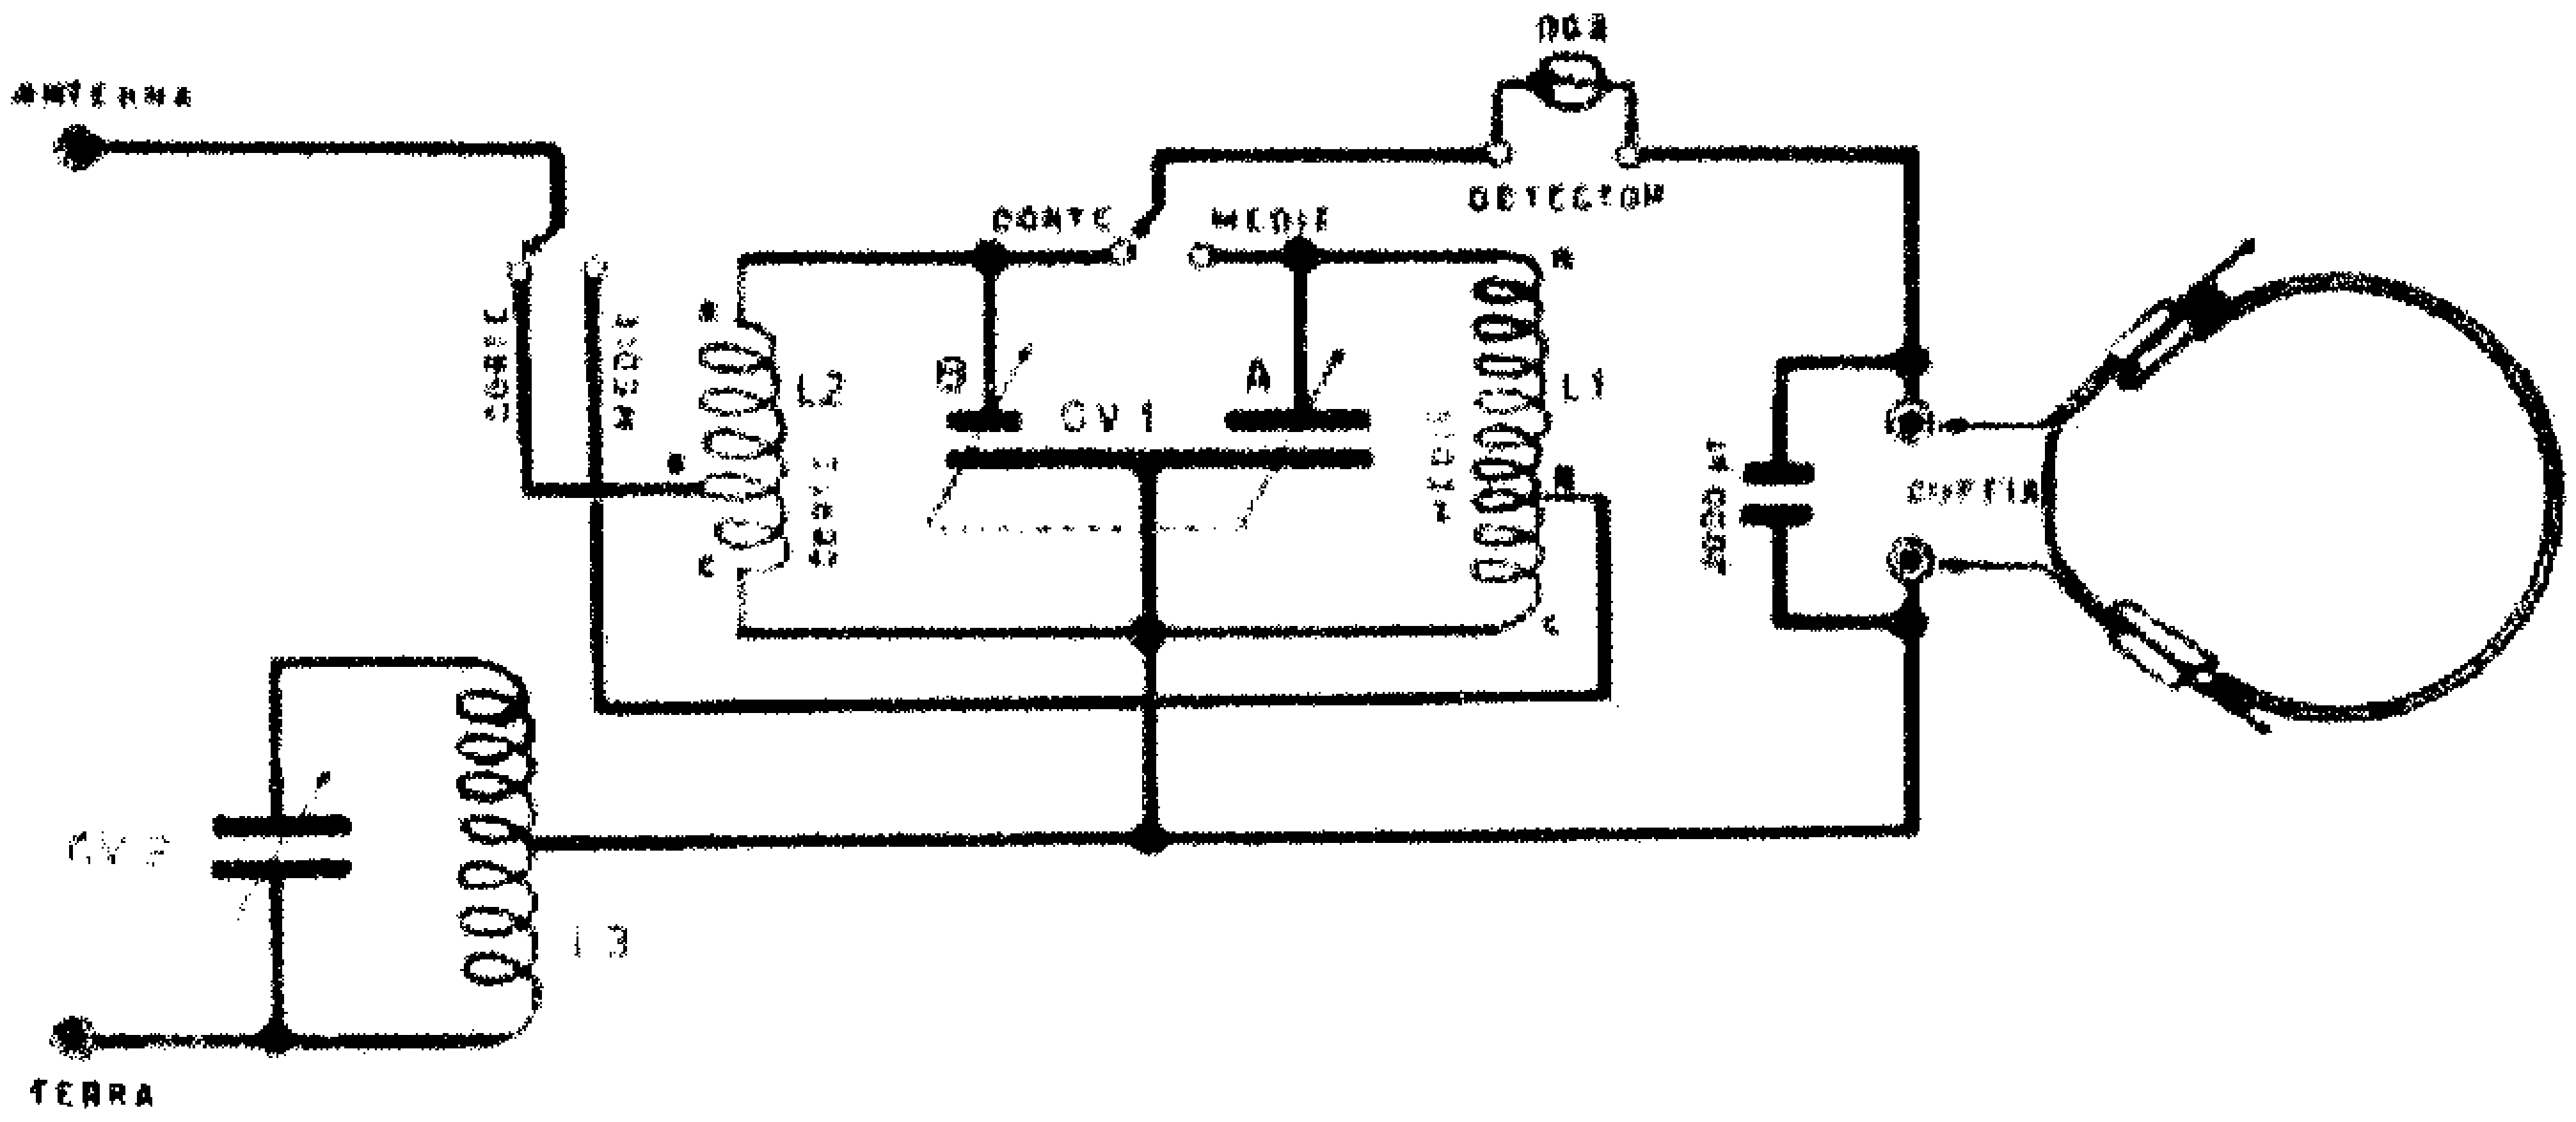
IL FIDO

Un eccellente ricevitore a galena

Forse parte dei nostri lettori sorrideranno a leggere questo titolo pensando che la galena è un apparecchio ormai passato di moda, e che ad altro non serva che a figurare in un museo o in una esposizione retrospettiva di radio. Questa è una supposizione sbagliata, infatti la prima cosa che fanno coloro che desiderano entrare nel campo radio, è quella di affrontare la costruzione di un ricevitore a galena, poi quella di un ricevitore ad una valvola e li vediamo poi in un anno o due, diventare perfetti radiotecnici. Non solo, ma tutti coloro che desiderano avere il loro piccolo ricevitore da usare magari a letto, cosa costruiscono? un apparecchio a galena.



Vi è poi chi deve dimorare per vario tempo in un ospedale, chi non può disporre di una qualsiasi sorgente di alimentazione per far funzionare un ricevitore a valvola, ed infine tutti coloro che non possono, causa il prezzo elevato, costruire o acquistare un apparecchio normale, trovano nel ricevitore a galena il loro unico mezzo per godere di una bella trasmissione. Possiamo quindi affermare che il ricevitore a galena, non è abbandonato, ed anzi ora che i diodi di germanio semplificano ancora di più il circuito, e la loro sensibilità è maggiore, accrescono le possibilità e i desideri di molti lettori, che sempre ci scrivono perchè pubblichiamo ricevitori a galena o a diodi di germanio.

Come funziona un ricevitore a galena

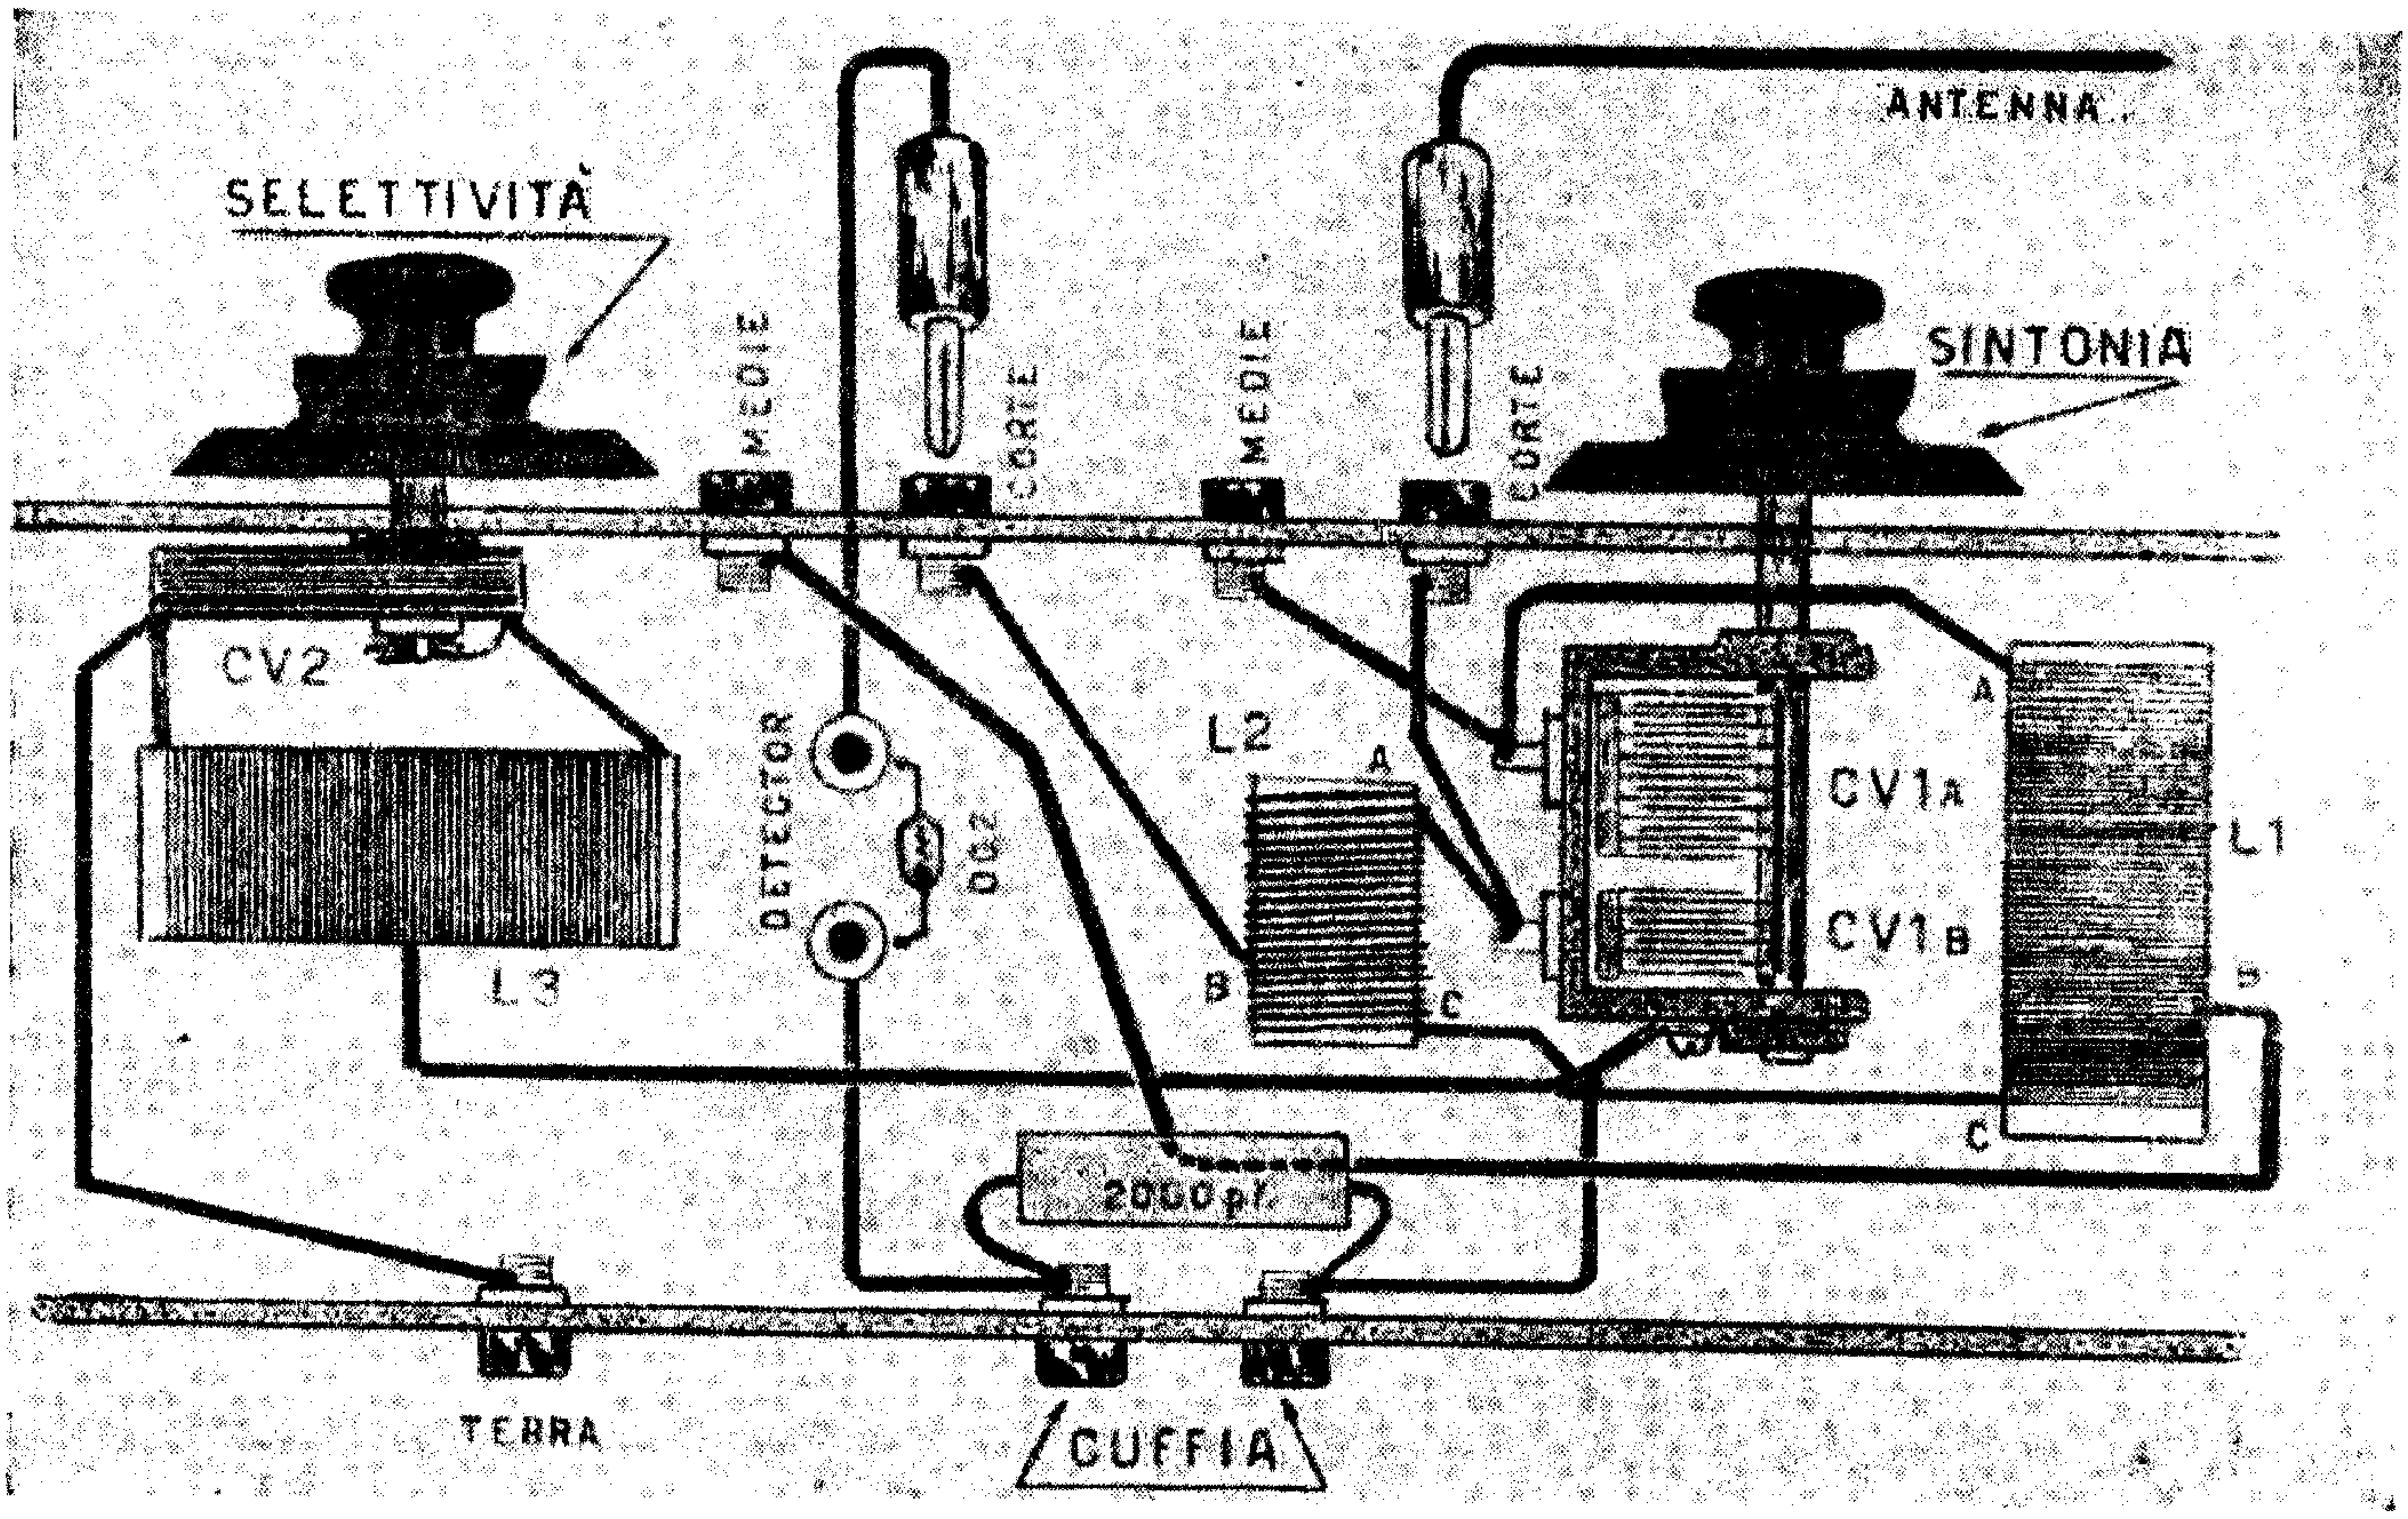
Bisogna ben comprendere che una radio a galena, contrariamente alla radio a valvole termoioniche, non ha nessun dispositivo amplificatore; la sola antenna captando le emissioni le invia ad un circuito oscillante dove, per mezzo del piedistallo, viene rettificato. Occorre però, oltre a captare l'emmissione desiderata, selezionarla ed escluderla da tutte le altre. Questa selezione si opera sempre per mezzo di un condensatore variabile e di una bobina d'antenna. Quando si hanno due o tre stazioni locali, è necessario ottenere una maggior selettività e questa può essere data solo da un buon circuito filtro composto da una seconda bobina e da un secondo condensatore variabile.

La galena o il diodo di germaio, posto come rettificatore, ha il compito di lasciare passare le alternanze di un solo senso; sono queste alternate che mettono poi in movimento le membrane della cuffia riproducendo fedelmente ogni suono. Che occorre fare per ricevere meglio le stazioni trasmittenti con una radio a galena?

Prima cosa: per ricevere bene, occorre installare un buon captatore di onde, vale a dire una buona antenna e preparare una buona presa di terra, poichè l'una non vale se non è buona l'altra. Poi occorrono dei buoni collegamenti, corti e perfettamente saldati specialmente, come nel nostro caso, se si desidera ricevere le onde corte. Infine occorre una buona cuffia abbastanza sensibile. Il « Fido » che proponiamo è il ricevitore che abbiamo studiato e provato per Voi perciò il risultato è sicuro e difficilmente si avranno insuccessi.

Il sistema di accordo è semplice e dopo tante prove è stato l'unico che ci ha dato il massimo di sensibilità. La selettività, grazie al circuito e filtro L3 e C2, è eccellente, tanto da poter selezionare completamente anche più di una stazione locale. Veniamo dunque a parlare un po' della presa d' antenna sulle bobine L1 e L2. La presa da noi effettuata è quella che ci ha dato migliori risultati. Chi avrà un po' di tempo disponibile, oppure chi trova diletto a sperimentare potrà provare di spostare la presa B cercando di ottenere, con la antenna usata, un rendimento migliore. Qualche lieve miglioramento si avrà pure modificando leggermente il numero delle spire delle bobine per le onde medie. Infatti coloro che desiderano, o che sono costretti ad ascoltare le stazioni tra i 400 e 500 metri, otterranno, con qualche spira in più nella bobina L1, un aumento di selettività e di potenza Questo ricevitore, oltre alla gamma delle onde medie, è pure previsto per la ricezione della gamma delle onde corte. Il passaggio delle onde viene effettuato per mezzo di una spinetta a banana, e due boccole da galena. Questo semplifica di molto il ricevitore rendendolo così adatto pure al principiante. Anche per l'antenna si usa il solito sistema delle due boccole da galena e della spinetta a banana. Per cambiare le onde è sufficiente inserire la spina dell'antenna sulla boccola che va alla presa media o corta della bobina sintonia cotemporaneamente alla presa del rivelatore a galena. Per ascoltare le onde medie l'antenna andrà inserita sulla presa B della bobina L1, e la galena sulla presa A sempre della bobina L1. Mentre per le onde corte, l'antenna andrà inserita sulla presa B della bobina L2 e la galena sulla presa A della bobina L 2. Per non usare due variabili, necessari per ascoltare le due gamme d'onda, abbiamo usato un variabile a due sezioni, uno con una capacità di 465 pF CV 1 A e uno con la capacità di 100 pF CV1B. Con questo sistema abbiamo ridotto, oltre allo spazio, il prezzo, poichè il variabile menzionato costa solo 100 lire in più di quanto costa un solo variabile. Quello che noi abbiamo adottato costa infatti L. 850. Dopo la parte Alta Frequenza composta dalla bobina e dai variabili di sintonia abbiamo il rivelatore a cristallo, che può essere convenientemente sostituito, ottenendo una maggiore sensibilità ed eliminando nello stesso tempo lo sgradevole inconveniente di cercare il punto sensibile del detector, da un diodo di germanio. Per chi ancora non lo sapesse nel diodo di germaio non c'è bisogno di cercare nessun punto sensibile così in luogo del detector sarà molto più conveniente usare un diodo di germaio tipo DG2 - OA5O - IN34 ecc. Per il diodo di germanio, non è necessario pure nessuna tensione di alimentazione per cui può essere perfettamente inserito nel nostro schema, apportandovi numerosi vantaggi. Al detector segue la cuffia di ricezione, la cui resistenza può essere compresa fra i 1000 e 4000 ohm. Questa cuffia viene shuntata da un condensatore da 2000 pF destinato a facilitare il passaggio della corrente Alta Frequenza che esiste dopo la rivelazione.

Terminata l'esposizione teo-



rica di questo nostro piccolo Fido. Ecco come noi andremo a realizzarlo praticamente. Su di un piccolo chassis delle dimensioni di centimetri 18 x 8 costruito in legno o faesite troverà posto tutto l'occorrente per la realizzazione. A destra monteremo il variabile doppio CV1A e CV1B a sinistra il variabile CV2. Nel centro del pannello, fisseremo pure le quattro boccole che ci serviranno per effettuare il cambio d'onda. A destra avremo le due boccole per l'antenna e a sinistra le due boccole per il detector. Uno sguardo al disegno pratico di montaggio chiarirà in modo più evidente la disposizione dei vari pezzi. Nel retro dello chassis fisseremo tre boccole, due serviranno per la cuffia e una per la presa di terra. Chi userà un detector a galena dovrà pure usare due boccole per quello; mentre chi userà il diodo di germanio potrà addirittura fissare internamente il diodo, sotto le due boccole dove andrebbe inserito il detector. Tutti i collegamenti andranno effettuati con fili di rame ricoperto di cotone. Tutte le giunte andranno saldate, con stagno e pasta salda; escludere nel modo più assoluto acido muriatico, che corroderebbe i fili. Per le bobine, si userà del tubetto bachelizzato (oppure di legno o di cartone) di diametro di 2 cm. Per L1 avvolgeremo 90 spire di filo da 0,18 mm. tipo smaltato. L'avvolgimento andrà effettuato a spire affiancate, la presa B per la bobina L1 andrà effettuata alla 30ª spira del lato C. Questa bobina servirà per le onde medie. Per le onde corte useremo una seconda bobina (L2). Le spire necessarie per costruire L2 sono 18 con presa B alla 6ª spira (p. dal lato di C) filo da 0,6 mm. coperto di cotone, su un tubetto dal diametro di 2 cm.

L' avvolgimento sarà effettuato a spire affiancate. Per L3 si userà sempre un tubetto del diametro di cm. 2. Su di esso si avvolgeranno 90 spire con presa centrale. Il filo sarà come per L1 di 0,18 mm. smaltato, spire affiancate.

Per i variabili si userà, come precedentemente detto, uno doppio ad aria da 465 pF e 100 pF (CV1A e CV1B) ed uno a mica o ad aria da 500 pf (CV2).

Per CV1, la sezione grande, cioè la parteA, verrà usata per le Onde Medie mentre la parte B, cioè quella con meno lamelle, per le Onde Corte. La massa metallica del variabile, cioè tutto il cestello che sostiene il variabile, servirà per saldarci il lato C delle due bobine (L1 e L2). Siccome molte volte questa presa, sul cestello metallico del variabile, non è sempre presente si potrà facilmente ottenerla avvitando in un qualsiasi foro sempre presente sul cestello, (carcassa) una vite, con una piccola linguetta di ottone per presa.

Il variabile CV1 sarà poi fissato con viti a ferro sullo chassis.

CV1 servirà per la sintonia, cioè per la ricerca delle stazioni trasmittenti, mentre CV2 servirà per la selettività, cioè per escludere una stazione disturbatrice.

Il diodo può essere inserito nel circuito da qualsiasi lato, poichè non c'è qui senso particolare. Appena montato tutto il circuito, se si è usato un diodo di germanio, il ricevitore funzionerà immediatamente, mentre se useremo un detector a galena, occorrerà cercare il punto sensibile del cristallo; e, a volte, per questa ricerca è necessario armarsi di pazienza. Per questo consigliamo tutti i giovani di abbandonare la galena e di usare in sua vece il diodo che non presenta, come la galena, i difetti sopra accennati. Occorre tener ben presente che non installando una buona antenna difficilmete si otterranno dei buoni risultati sulle Onde Corte. Così per le onde non in tutte le zone si potranno ascoltare programmi a tutte le ore. Così in certi luoghi ci sarà chi ascolterà bene le Onde Corte supponiamo alla mattina. Ci sarà chi, invece, la massima ricezione, sulle Onde Corte, la avrà la sera. Assicuriamo invece che le Onde Medie saranno ascoltate sempre e ottimamente a tutte le ore e con una ottima selettività.

PREZZO DEI COMPONENTI

Diodi di germanio .	L.	750
Variabili CV1 a due sezioni	»	850
Variabile CV2 a mica	»	250
7 boccole e 2 banane	»	150
Cuffia	»	1200
3 bobine	»	250

Apresentação

Durante nossa longa carreira como escritor de artigos e livros técnicos, por diversas vezes abordamos o tema "coletânea de circuitos", incluindo também informações. Assim, anteriormente, abordando este tema, publicamos as séries "Circuitos e Informações" (7 volumes) e "Circuitos e Soluções" (5 volumes) contendo centenas de circuitos úteis e informações técnicas de todos os tipos.

As séries se esgotaram, o tempo passou, mas os leitores ainda nos cobram algo semelhante atualizado e que possa ser usado ainda em projetos de todos os tipos. De fato, circuitos básicos usando componentes discretos comuns, de transistores a circuitos integrados, são ainda amplamente usados como solução simples para problemas imediatos, parte de projetos mais avançados e até com finalidade didática atendendo à solicitação de um professor que necessita de uma aplicação para uma teoria. Assim, voltamos agora com esta série, mas com uma estrutura diferenciada, novos projetos e nova abordagem. O diferencial na abordagem será dividir os diversos volumes da série por temas. Assim, no nosso primeiro volume tivemos circuitos de áudio, depois circuitos de fontes e seguindo a série neste sexto teremos circuitos de rádios, transmissores aplicações semelhantes como boosters e filtros.

Em nosso estoque de circuitos, coletados de todas as fontes possíveis, já temos mais de 5000 deles, muitos dos quais podendo ser acessados de forma dispersa no site. A vantagem de se ter estes circuitos organizados em volumes, além do acesso em qualquer parte, está na fácil localização de um circuito. As informações, por outro lado, serão agregadas aos circuitos, com links internos, o que só é possível numa publicação digital. A maioria destes circuitos, colhidos em publicações que, em alguns casos, pode não ser muito atuais, recebe um tratamento especial com comentários, sugestões e atualizações que viabilizam sua execução mesmo em nossos dias. Enfim, com esta série, damos aos leitores a oportunidade de ter em seus tablets, Iphones, Ipads, PCs, notebooks e outras mídias uma fonte de consulta de grande importância tanto para seu trabalho, como para seus estudos ou simples como hobby.

Newton C. Braga

Introdução

Depois do sucesso do Banco de Circuitos no meu site e das coleções esgotadas de Circuitos e Informações e Circuitos e Soluções, levo aos meus leitores uma coletânea de circuitos selecionada de minha enorme coleção disponível. Durante minha vida toda colecionei praticamente todas as revistas técnicas de eletrônica estrangeiras, dos Estados Unidos, França, Espanha, Itália, Alemanha, Argentina e até mesmo do Japão, possuindo assim um enorme acervo técnico.

Não posso reproduzir os artigos que descrevem os projetos que saem nessas revistas, por motivos ditados pela lei dos direitos autorais, mas a mesma lei permite que eu utilize uma figura do texto, com citação, comentando seu conteúdo para efeito de informação ou complementação de um conteúdo maior. É exatamente isto que faço na minha seção no site e também disponibilizo neste livro. Estou selecionando os principais circuitos destas publicações, verificando quais ainda podem ser montados em nossos dias, com a eventual indicação de componentes equivalentes, fazendo alterações que julgo necessárias e disponibilizando-os aos nossos leitores. Para o site já existem mais de 5 000 circuitos, no momento que escrevo este livro, mas a quantidade aumenta dia a dia.

Frequente o site, que ele poderá lhe ajudar a encontrar aquela configuração que você precisa para seu projeto. Os 100 circuitos selecionados para a primeira edição desta série e depois mais 100 para a segunda e mais 100 para cada uma seguinte, são apenas uma pequena amostra do que você vai encontrar no site. Para esta edição escolhemos 100 circuitos de rádios e transmissores experimentais com componentes comuns e de fácil obtenção na maioria dos casos.

Volumes Anteriores:
Volume 1 - 100 Circuitos de áudio
Volume 2 – 100 Circuitos de fontes
Volume 3 – 100 Circuitos osciladores
Volume 4 - 100 Circuitos de potência
Volume 5 - 100 Circuitos com LEDs e Displays

Banco de Circuitos – Volume 6
Rádios e Transmissores

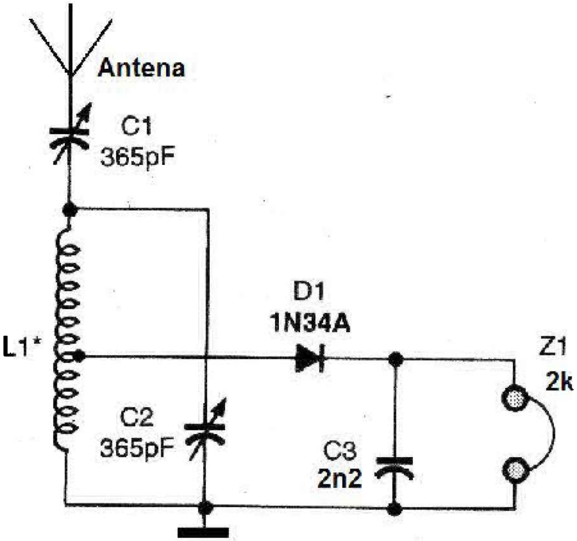
Neste volume teremos uma coletânea de circuitos de receptores de rádio elementares para as faixas de ondas médias, curtas, FM e VHF usando componentes comuns, além de transmissores de baixa potência para as mesmas faixas dos receptores. Lembramos que a operação de transmissores com alcances maiores e potências mais altas que os indicados neste livro está sujeita a restrições legais. Assim, a finalidade dos circuitos apresentados é experimental e didática.

Receptores

O desempenho dos receptores descritos (sensibilidade e seletividade) tanto depende do grau de sofisticação dos circuitos, lembrando que a maioria é experimental, como da habilidade do próprio montador e das condições locais de recepção. As bobinas, em especial são componentes críticos, assim como a antena. Em muitos casos, a localização em ambientes com muitas interferências e ruídos também afeta o desempenho destes circuitos.

1. Rádio Elementar

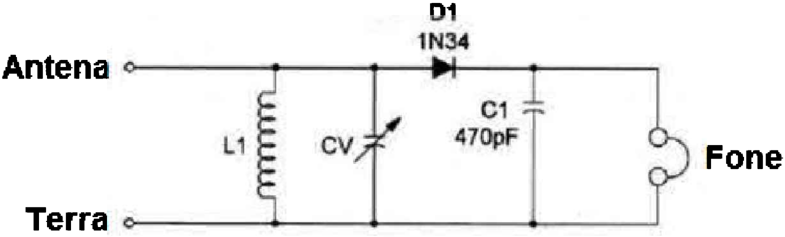
Este circuito foi publicado numa Poptronics do ano 2000, mas pode ser montado com facilidade ainda hoje. A bobina consta de 20 + 80 espiras de fio 28 ou próximo, num bastão de ferrite de 1 cm de diâmetro por 20 ou mais centímetros de comprimento. A posição da tomada pode ser alterada para se modificar a seletividade e a sensibilidade. O fone deve ser de alta impedância ou piezoelétrico com um resistor de 100k em paralelo. Os capacitores de sintonia podem ser obtidos de rádios AM fora de uso. A antena consiste num fio estendido de pelo menos 5 metros de comprimento. Veja que este circuito tem dupla sintonia e exige uma antena bem longa para funcionar bem. A ligação à terra, que pode ser feita num objeto grande de metal, é importante para o melhor desempenho.



Antena
C1
365pF
L1*
D1
1N34A
Z1
2k
C2
365pF
C3
2n2

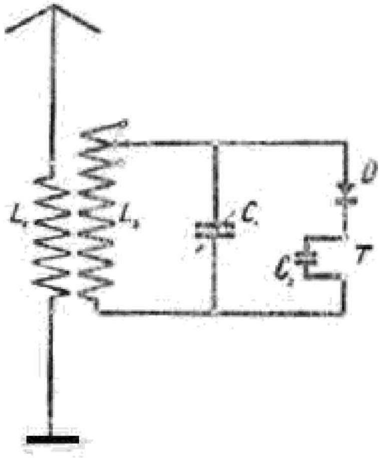
2. *Rádio de Cristal*

Este circuito usa um diodo de germânio como detector e o fone pode ser magnético de alta impedância ou ainda de cristal com um resistor de 100k em paralelo. L1 consta de 100 espiras de fio 28 num tubo de PVC ou papelão de 2,5 cm de diâmetro e CV é um capacitor variável de rádio AM comum. A antena deve ser longa, com pelo menos 5 m de comprimento, e a conexão à terra é importante. O circuito é do livro Fun Projects for the Experimenter de Newton C. Braga, publicado nos Estados Unidos.



3. Receptor de Cristal de 1926

Este circuito foi encontrado numa publicação alemã de 1926. Trata-se de um receptor de cristal ou galena (D). O cristal (D) pode ser substituído por um diodo de germânio. O fone deve ser magnético, ou se for de cristal deve ter um resistor de 22 k em paralelo. L1 é formada por 10 espiras sobre L2, e L2 por 65 espiras de fio de 0,5 mm (pode ser o 28) num tubo de papelão de 8 cm de comprimento e 1 polegada de diâmetro. C2 era especificado na época em centímetros (!), mas um capacitor de 1 nF cerâmico serve. Da mesma forma, C1 pode ser um capacitor variável de rádio transistorizado antigo. A antena deve ser longa. Na figura a página em alemão da publicação original.



Kristalldetektor-Empfänger mit aperiodischer Antennenkopplung.

- L 1 10–12 Windungen 0,7 mm umsp. Draht über oder neben L 2 gewickelt
- L 2 65 Windungen 0,5 mm umsp. Draht auf Spulenkörper von 8 cm Durchmesser. Anzapfungen bei der 25., 35., 45., 55. Windung.
- C 1 Drehkondensator 500—1000 cm
- D Kristalldetektor
- C 2 Blockkondensator 2000 cm
- T Telefonsteckbuchsen

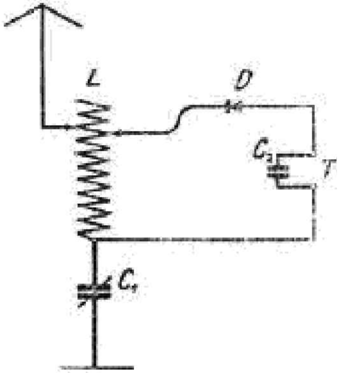
Durch die aperiodische Antennenkopplung wird eine große Abstimmschärfe erzielt. Diese Kopplungsart ist besonders bei langer Antenne vorteilhaft. Bei kurzer Antenne ist ein Empfänger nach Schaltbild 5 vorzuziehen.

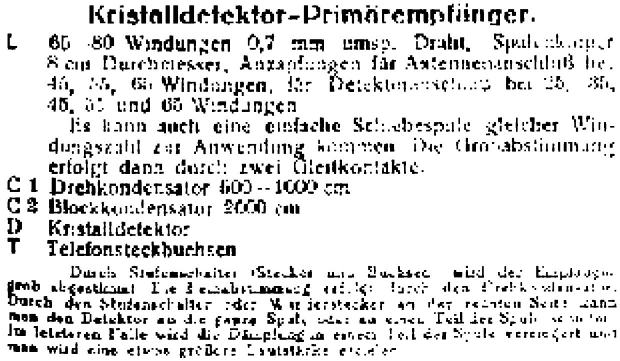
Die Grobabstimmung erfolgt durch den Stufenschalter, die Feinabstimmung mittels des Drehkondensators.

Will man die Antenne abstimmen, so schalte man eine Schiebespule von etwa 40 Windungen auf Spulenkörper von 6 cm Durchmesser zwischen Antenne und Empfänger.

4. Radio de Galena de 1926 (2)

Esta raridade é de uma publicação de 1926. O detector de galena (D) pode ser substituído numa versão moderna por um diodo 1N34 ou equivalente. A sintonia é em série e C1 pode ter 1 nF já que na época os capacitores de construção caseira eram especificados em centímetros. O capacitor variável pode ser obtido num rádio AM antigo. A bobina pode ser enrolada com 60-80 espiras de fio 28 num tubo de 2,5 cm de diâmetro (papelão ou PVC). Abaixo a página original da publicação em 1926.





Kristalldetektor-Primärempfänger.

L 60–80 Windungen 0,7 mm umsp. Draht, Spulenkörper 8 cm Durchmesser, Anzapfungen für Antennenanschluß bei 45, 55, 65 Windungen, für Detektoranschluß bei 25, 35, 45, 55 und 65 Windungen.

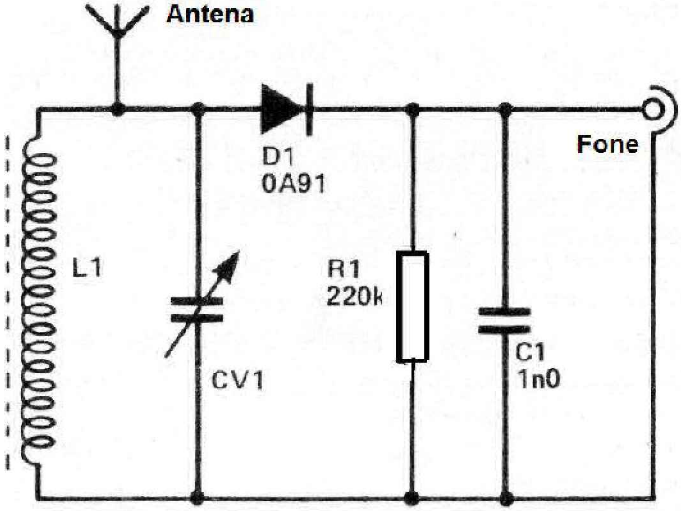
Es kann auch eine einfache Schiebespule gleicher Windungszahl zur Anwendung kommen. Die Grobabstimmung erfolgt dann durch zwei Gleitkontakte.

C 1 Drehkondensator 600–1000 cm
C 2 Blockkondensator 2000 cm
D Kristalldetektor
T Telefonsteckbuchsen

Durch Stufenschalter (Stecker und Buchsen) wird der Empfänger grob abgestimmt. Die Feinabstimmung erfolgt durch den Drehkondensator. Durch den Stufenschalter oder Wanderstecker an der rechten Seite kann man den Detektor an die ganze Spule oder an einen Teil der Spule schalten. Im letzteren Falle wird die Dämpfung in einem Teil der Spule verringert und man wird eine etwas größere Lautstärke erzielen.

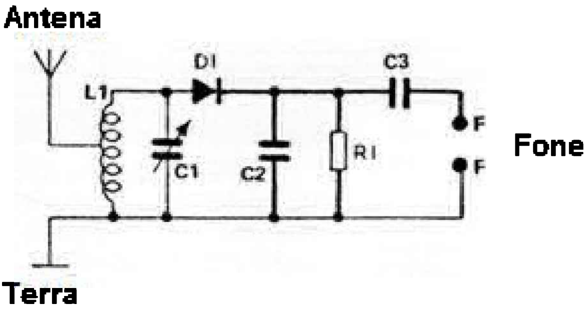
5. Rádio de Cristal (2)

Este circuito tradicional de rádio de cristal foi obtido numa documentação de 1990. O diodo pode ser o 1N34 ou qualquer outro de germânio que ainda possa ser encontrado. A bobina é formada por 100 espiras de fio 28 num bastão de ferrite e o capacitor variável pode ser obtido num rádio antigo de ondas médias. O fone é de cristal ou piezoelétrico e a antena deve ser bem longa, com pelo menos 5 metros de comprimento. Recomenda-se uma conexão à terra para maior desempenho.



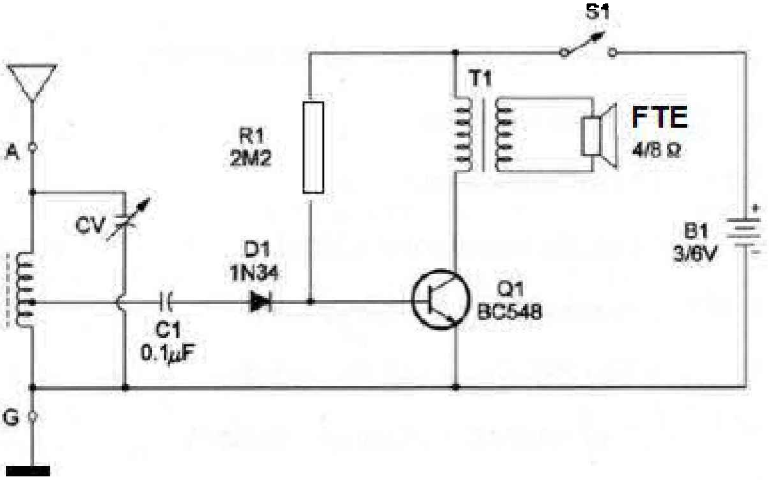
6. Rádio de Cristal (3)

A bobina consiste em 100 espiras de fio 28 num tubo de madeira ou PVC de 2 cm a 2,5 cm de diâmetro com tomada na 50ª espira. O diodo pode ser o 1N34 ou qualquer um de germânio. A antena deve ser longa, com pelo menos 10 metros de comprimento, C1 é um capacitor variável de rádio AM, C2 de 10 nF e C3 de 100 nF. O fone deve ser de cristal ou cerâmico. A ligação à terra é importante. R1 é de 10 k ohms.



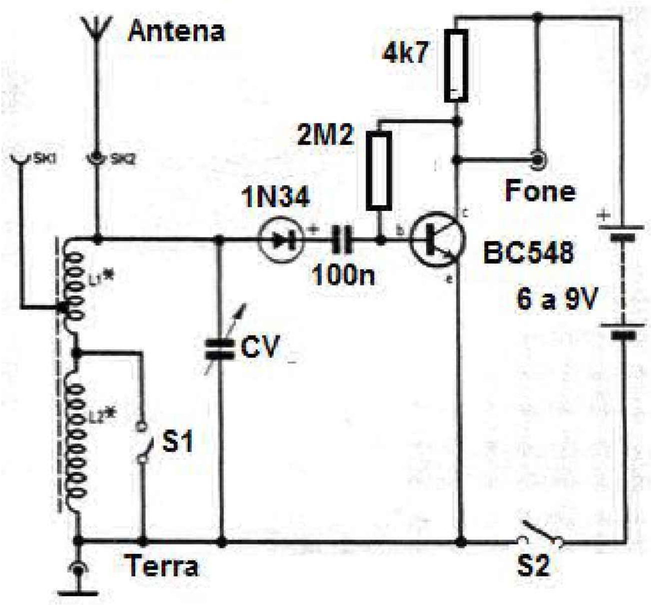
7. Micro Rádio AM

Este simples receptor capta as estações locais de AM com reprodução num pequeno alto-falante. A antena deve ter pelo menos uns 3 metros de comprimento. A bobina é formada por 30 + 50 espiras de fio 28 num bastão de ferrite. A ligação à terra é importante e o transformador deve ser obtido num rádio transistorizado antigo. Pode ser usado qualquer transistor de uso geral em lugar do original. O receptor é do livro Fun Projects for the Experimenter de Newton C. Braga, publicado nos Estados Unidos.



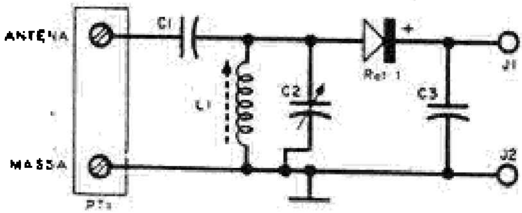
8. Rádio AM de 1 Transistor

Este circuito de rádio AM experimental foi encontrado numa revista inglesa de 1979. Ele pode ser montado com um BC548, alimentando um fone de cristal ou piezoelétrico. A antena deve ser longa e a ligação à terra é importante. A bobina consta de 10 + 20 espiras de fio 28 num bastão de ferrite para L1, e L2 consiste em mais 70 espiras do mesmo fio no mesmo bastão. O capacitor variável pode ser obtido de um rádio AM fora de uso. S1 seleciona a faixa de sintonia e S2 liga ou desliga o aparelho. SK1 é uma entrada opcional para a antena, conforme a faixa sintonizada. A alimentação é de 6 a 9 V e o consumo muito baixo.



9. Rádio de Cristal (3)

Este receptor foi obtido numa revista de 1961. A revista não mais é publicada, mas o circuito pode ser montado utilizando-se qualquer diodo de germânio, fone de cristal ou de alta impedância e para a bobina, 100 espiras de fio 28 num bastão de ferrite. A antena deve ser longa e a ligação à terra é importante. C2 é um capacitor variável obtido de um rádio de ondas médias fora de uso e C3 é de 1nF, assim como C1, os quais devem ser cerâmicos. O diodo pode ser de qualquer tipo de germânio como o 1N34 ou 1N60. Para a conexão da antena e massa (terra) é usada uma ponte de dois terminais com parafusos.



10. Rádio AM com FET

Este circuito foi publicado numa Poptronics de janeiro de 2000, mas pode ser montado com facilidade ainda hoje. A bobina consta de 20 espiras para L1 e 80 espiras de fio 28 ou próximo, para L2, as duas num bastão de ferrite de 1 cm de diâmetro por 20 ou mais centímetros de comprimento. O fone deve ser de alta impedância ou piezoelétrico com um resistor de 10k em paralelo. Os capacitores de sintonia podem ser obtidos de rádios AM fora de uso. A antena 1 consiste num fio estendido de pelo menos 5 metros de comprimento e a Antena 2, mais curta. O FET pode ser o BF245.

11. Rádio AM com FET (2)

Este circuito é de uma publicação americana de 1987 chamada Electronics Handbook. O circuito ainda pode ser montado com facilidade, pois todos os componentes são comuns. O transistor pode ser o BF245 ou MPF102 (FET). L2 é formada por 100 espiras de fio 28 num bastão de ferrite e L2, por 20 espiras do mesmo fio no mesmo bastão. C1 pode ser um capacitor de sintonia de um rádio AM comum. Os fones podem ser piezoelétricos ou magnéticos de 1k ou mais de impedância. O controle de volume é opcional, podendo o fone ser ligado diretamente ao capacitor C3.

12. Receptor AM Experimental

Este receptor foi obtido numa publicação de 1970, podendo ser montado com transistores mais modernos como o BC558, já que no original era utilizado um transistor de germânio. A bobina é formada por 15 + 20 + 70 espiras de fio 28 num bastão de ferrite e o capacitor C pode ser retirado de um rádio antigo. XRF é de 10 a 100 mH e os diodos são 1N34 ou equivalentes. O fone deve ter impedância entre 600 e 5000 ohms ou ser usado um fone de cristal com um resistor de 2k2 em paralelo. Os pontos da bobina são para a conexão alternativa da antena, conforme a estação captada. Observe a polaridade da alimentação que também pode ser de -6 V.

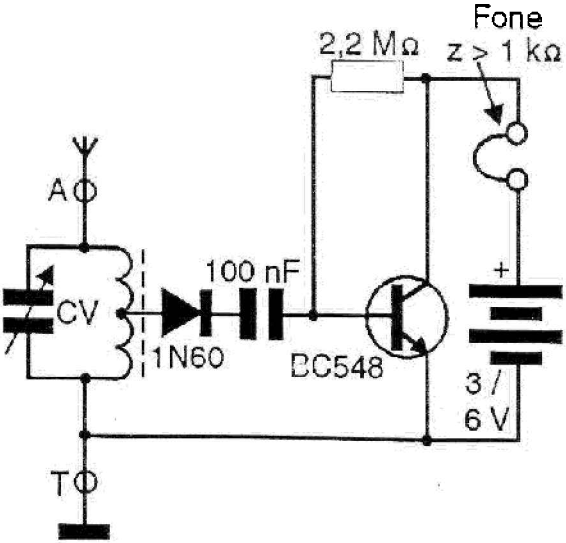
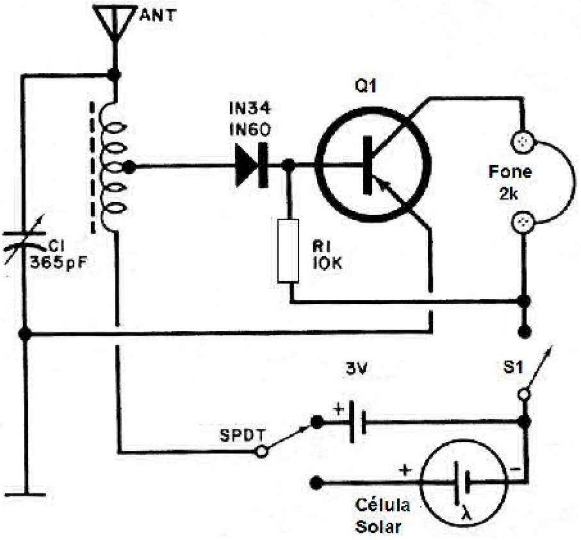
13. Micro Rádio AM

Este pequeno rádio experimental sintoniza as estações AM locais proporcionando escuta em fone de 1k a 2k. Pode ser usado fone de cristal ou um transdutor piezoelétrico, bastando que seja ligado um resistor de 2k2 a 4k7 em paralelo. A bobina consta de 20 + 80 espiras de fio 28 num bastão de ferrite e CV é capacitor variável obtido de um rádio AM fora de uso. A alimentação pode ser feita com duas ou quatro pilhas e a antena consiste num pedaço de fio de 3 a 10 metros de comprimento. A conexão à terra, num objeto de metal de grande porte, é importante para se obter maior sensibilidade. O circuito também funciona com transistores PNP, bastando inverter a polaridade de alimentação.



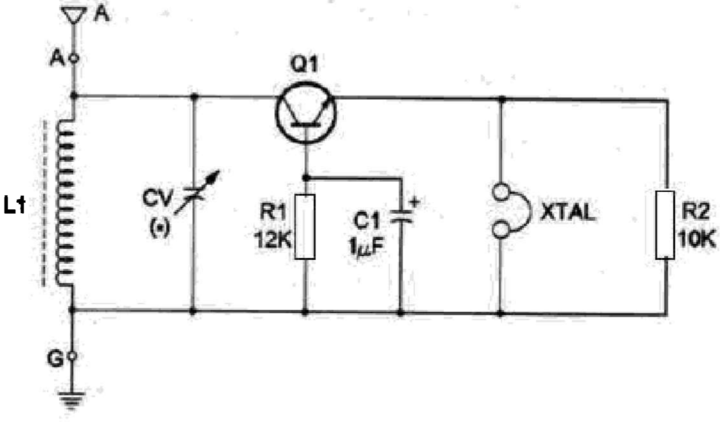
14. Rádio Solar

Este simples receptor AM alimentado por energia solar foi obtido numa Popular Electronics de 1974. O transistor pode ser o BC558, mas transistores de germânio obtidos de rádios antigos proporcionam melhores resultados com células de menor rendimento. A célula solar pode ser de qualquer tipo de 1,5 a 6 V, por exemplo, do tipo encontrado em calculadoras e outros aplicativos. A bobina consiste em 30 + 50 espiras de fio 28 num bastão de ferrite e o capacitor variável é do tipo encontrado em rádios AM antigos. A antena deve ser longa e o fone magnético de pelo menos 600 ohms. Para fones de cristal ou piezoelétricos ligue em paralelo um resistor de 2k2. A chave SPT comuta a alimentação para duas pilhas comuns. O consumo do circuito é muito baixo e a ligação à terra é importante para maior rendimento.



15. Rádio com Energia Grátis

O transistor deste rádio é alimentado com a própria energia do sinal, produzindo sua amplificação. Deve-se dar preferência a um transistor de germânio antigo NPN, pois é mais sensível. L1 consta de 80 espiras de fio 28 num bastão de ferrite, a antena deve ser bem longa e o capacitor variável pode ser aproveitado de um rádio fora de uso. A ligação à terra é importante para se ter o melhor desempenho. Dada a baixa tensão que se obtém na prática, os transistores de germânio proporcionam melhores resultados. Consiga um num velho rádio transistorizado fora de uso. Tipos como o 2SB75 são bastante interessantes. A antena deve ser bem longa, pois ela capta também a energia que o receptor precisa para funcionar. O circuito é do livro Fun Projects for the Experimenter de Newton C. Braga, publicado nos Estados Unidos.



16. Receptor AM com FET (3)

Este circuito foi encontrado numa Elementary Electronics de 1979. Ele pode ser montado com facilidade utilizando-se um JFET BF245 ou equivalente. L1 é uma bobina formada por 100 espiras de fio 28 num bastão de ferrite e L2 um choque de RF. O fone deve ser do tipo magnético de alta impedância ou então piezoelétrico com um resistor de 22 k em paralelo. C7 controla o ganho de RF e C3 faz a sintonia. L2 pode ser um choque comercial de 2,2 a 4,7 mH, já que o valor 2,4 mH indicado no original não é fácil de obter. O circuito sintoniza a faixa de ondas médias, mas pode ser alterado para a faixa de ondas curtas com menos espiras na bobina.

17. Rádio AM Regenerativo com FET

Este circuito foi publicado numa Poptronics de janeiro de 2000, mas pode ser montado com facilidade ainda hoje. A bobina L2 consta de 20 + 80 espiras de fio 28 ou próximo, num bastão de ferrite de 1 cm de diâmetro por 20 ou mais centímetros de comprimento ou mesmo num tubo de 2 cm sem núcleo. L1 é formada por 20 espiras do mesmo fio sobre L1. O fone deve ser de alta impedância ou piezoelétrico com um resistor de 10k em paralelo. Os capacitores de sintonia podem ser obtidos de rádios AM fora de uso. A antena consiste num fio estendido de pelo menos 5 metros de comprimento. O FET pode ser o BF245. Se a sensibilidade for reduzida, inverta a ligação de L1.

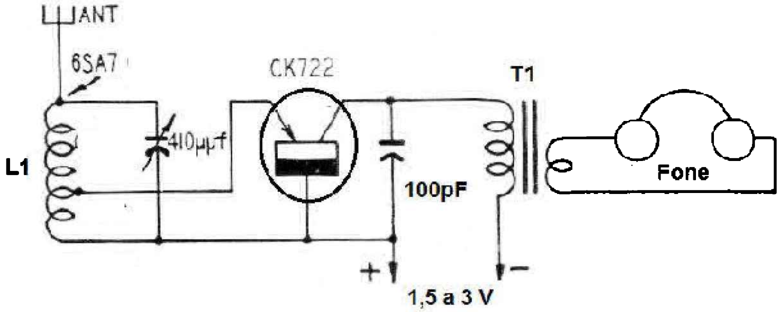
18. Rádio Alternativo com o CK722

Este circuito é de uma revista Radio Electronics de dezembro de 1954. Nele se mostra numa montagem experimental como o transistor, que então era novidade, pode ser usado num receptor capaz de funcionar com tensões a partir de 1,5 V, por exemplo, de uma pilha feita com moedas ou uma célula solar. O transformador é do tipo então encontrado em rádios transistorizados e o circuito deve funcionar com qualquer transistor PNP de germânio de uso geral. A bobina consta de 30 + 60 espiras de fio 28 num bastão de ferrite ou num tubo de papelão de 1 a 2 cm de diâmetro. O circuito capta as estações AM locais. O fone é de baixa impedância, podendo até ser usado um pequeno alto-falante se a antena for longa. No original foi usada uma bobina osciladora para a válvula 6SA7.



19. Rádio AM de Dois Transistores

Este simples rádio AM foi encontrado numa publicação de 1975, mas pode ser montado com transistores BC548. O fone também pode ser uma cápsula cerâmica piezoelétrica. O circuito pode ser alimentado com 3 ou mesmo 4 pilhas. L1 consiste em 80 espiras de fio 28 num bastão de ferrite e L2 é formada por 20 espiras do mesmo fio no mesmo núcleo. Uma antena pode ser ligada a L1. Uma antena pode ser ligada ao circuito em L1 para maior sensibilidade.

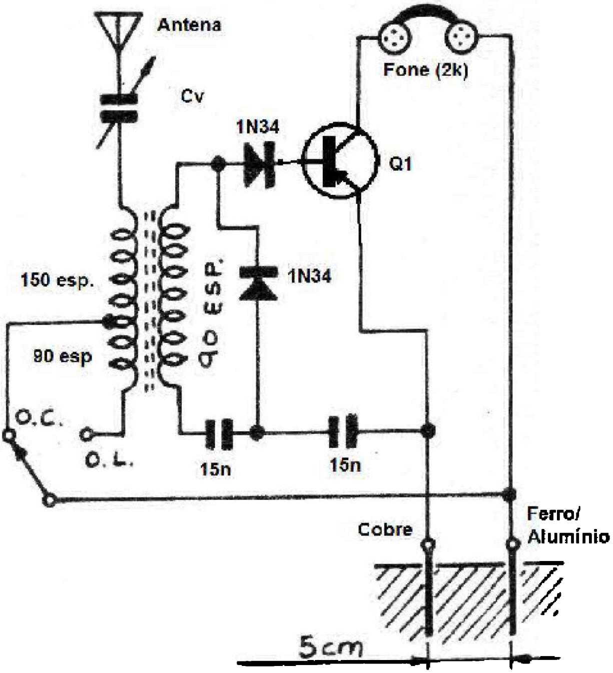
20. Receptor AM com Pilha Galvano Telúrica

Este circuito, de uma publicação da década de 70, utiliza um tipo de alimentação diferente que já havíamos sugerido em artigo anterior na revista Eletrônica Popular. Duas placas de metais diferentes enterradas formam uma pilha telúrica capaz de gerar perto de 1 V para alimentar o circuito. A bobina é enrolada em ferrite com fio 28 e o transistor para melhores resultados deve ser de germânio. O capacitor variável pode ser aproveitado de um velho rádio AM e a antena deve ser longa. As placas devem ter de 10 x 10 a 30 x 30 cm de dimensões com a separação indicada na figura. O circuito capta estações da faixa de ondas médias e longas (em uso para poucas aplicações em nosso país). Pode ser usado um fone piezoelétrico com um resistor de 2k2 em paralelo.



21. Simples Rádio AM Experimental

Este circuito capta as estações locais de ondas médias com escuta numa cápsula piezoelétrica ou fone de cristal. O transistor pode ser um PNP de germânio ou silício como o 2SB75, BC558, etc. CV é um capacitor variável retirado de um velho rádio de ondas médias transistorizado. L1 consta de 20 ou 30 espiras de fio 28 mais 80 espiras num bastão de ferrite. A antena é um pedaço de fio de 3 a 20 metros esticado e a ligação à terra é importante para se obter mais sensibilidade. O circuito é do livro Science Fair Projects de Newton C. Braga, publicado nos Estados Unidos.

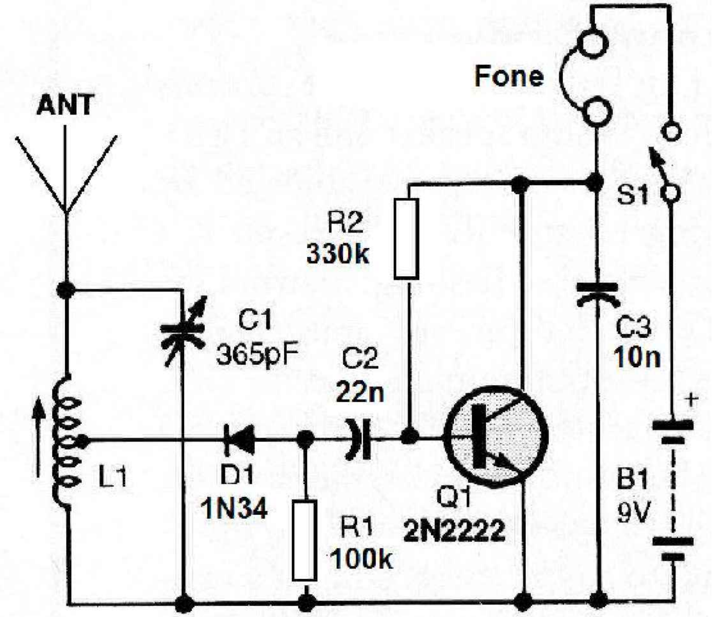
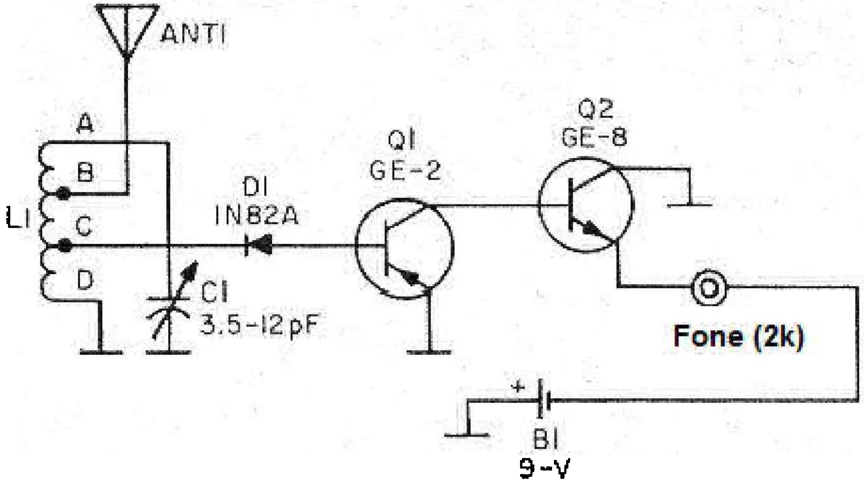
22. Rádio AM de 1 Transistor

Este rádio experimental para a faixa de ondas médias foi encontrado numa Poptronics de novembro de 2001. O transistor também pode ser um BC548 e o fone deve ser magnético de alta impedância, com pelo menos 2k ohms de impedância. Pode ser usado um fone piezoelétrico com um resistor de 4k7 em paralelo. A bobina consta de 30 + 70 espiras de fio 28 enroladas num bastão de ferrite e a antena deve ter pelo menos uns 5 metros de comprimento. Com um diodo de germânio o receptor será mais sensível. Uma ligação à terra feita no negativo da alimentação ajuda a obter mais sensibilidade. O resistor R3 pode ser alterado no sentido de se obter melhor rendimento.



23. Simples Receptor de VHF

Se você mora perto de um aeroporto ou outro local em que opere um transmissor de VHF na faixa de 50 a 150 MHz, pode captar seus sinais com este simples receptor. Este circuito foi indicado em artigo da revista americana Electronics Hobbyst do inverno de 1971. A revista não existe mais, mas o projeto pode ser montado com a utilização de equivalentes para o diodo e transistores. Para o diodo pode ser usado o 1N34, para Q1 e Q2 BC558. Dada a baixa tensão de alimentação, o circuito funcionará melhor com transistores de germânio antigos, como os originalmente indicados. O fone pode ser magnético do tipo de 2k, muito difícil de obter em nossos dias ou uma cápsula piezoelétrica de telefone em paralelo com um resistor de 2k2. A alimentação vem de uma bateria de 9 V. Os sinais devem ser fortes o bastante para levar o transistor à condução. A antena é telescópica de pelo menos 2 metros de comprimento. A bobina é formada por 8 espiras de fio comum sem núcleo e diâmetro de 1 cm, com tomadas de 2 em 2 espiras. Com uma antena maior e uma conexão à terra, o circuito terá melhor rendimento.



24. Rádio AM de Dois Transistores

Encontramos este circuito numa revista Hobby Electronics de fevereiro de 1981. No entanto, pelos componentes que utiliza, o circuito é perfeitamente viável ainda hoje. Os transistores podem ser os BC549 e o diodo 1N34. A bobina é enrolada num bastão de ferrite. O primário, ligado a VC1 consiste em 80 espiras de fio 28 AWG e o secundário 20 espiras. O núcleo é um bastão de ferrite de 12 a 20 cm de comprimento. O fone pode ser de cristal ou piezoelétrico de alta impedância. O consumo é muito baixo, o que significa que uma bateria de 9 V deve durar muito. O receptor não necessita de antena.

25. Rádio AM Simples de 2 Transistores

Originalmente, este circuito é de uma revista inglesa, mas encontrei-o na Revista Radio Chassis Television da Argentina, numa edição de 1978. A bobina consta de 80 a 100 voltas de fio 28 num bastão de ferrite e na saída tanto podemos ligar um fone de cristal como a entrada de um amplificador. Para estações mais fracas use uma antena. A ligação do variável na bobina da forma indica resulta numa baixa seletividade. Veja o circuito 26 para maior seletividade. O equivalente ao BC108, usado originalmente é o BC548 já indicado no diagrama.

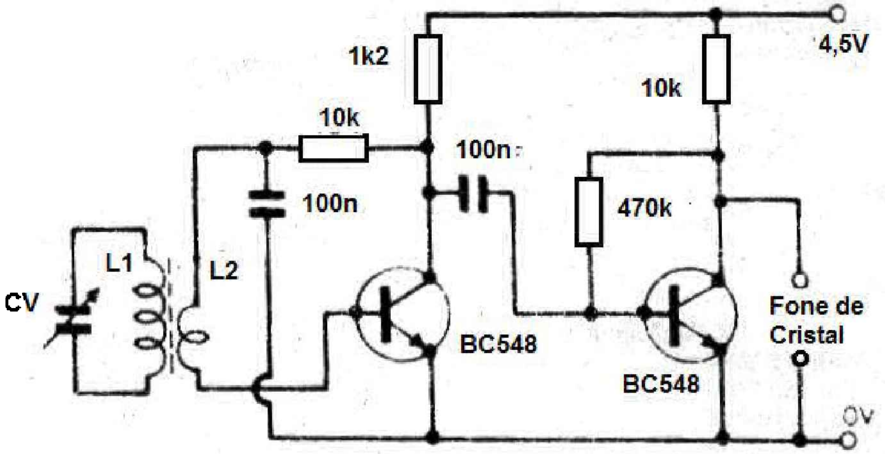
26. Rádio AM Simples de 2 transistores (2)

Originalmente, este circuito é de uma revista inglesa, mas encontrei-o na Revista Radio Chassis Television da Argentina, numa edição de 1978. A bobina L1 é formada por 10 espiras de fio 28 sobre L2 e L2 consta de 80 a 100 voltas de fio 28 num bastão de ferrite. Na saída tanto podemos ligar um fone de cristal como a entrada de um amplificador. Para estações mais fracas use uma antena. A ligação do variável na bobina da forma indica resulta numa melhor seletividade em relação ao projeto 25. Use os BC548 em lugar dos originalmente recomendados que eram os BC108. A antena pode ser ligada à base do transistor.



27. Rádio AM Simples de 2 transistores (3)

Originalmente, este circuito é de uma revista inglesa, mas encontrei-o na Revista Radio Chassis Television da Argentina, numa edição de 1978. L2 consta de 80 a 100 voltas de fio 28 num bastão de ferrite. Na saída tanto podemos ligar um fone de cristal como a entrada de um amplificador. Para estações mais fracas use uma antena. A antena pode ser ligada à base do primeiro transistor. O uso de três transistores num circuito com realimentação proporciona grande sensibilidade e seletividade. Use os BC548 em lugar dos BC108 que foram indicados na publicação original.

28. Rádio AM simples com ZN414

Originalmente, este circuito é de uma revista inglesa, mas encontrei-o na Revista Radio Chassis Television da Argentina, numa edição de 1978. L1 consta de 80 a 100 voltas de fio 28 num bastão de ferrite. Na saída tanto podemos ligar um fone de cristal como a entrada de um amplificador. Para estações mais fracas use uma antena. O integrado é o elemento critico do circuito, já que é difícil de obter atualmente. O capacitor de sintonia CV pode ser obtido em qualquer rádio de ondas médias fora de uso. Use o BC548 em lugar do transistor original que é o BC108, já trocado no nosso desenho. Observamos que o circuito integrado ZN414 é raro em nosso mercado, por não ser mais fabricado.

29. Receptor ZN414

Este circuito foi obtido numa Hands On Electronics, revista americana de janeiro de 1987. O ZN414 não é muito fácil de obter, mas se o leitor conseguir pode montar um excelente radinho de ondas médias para escuta em fone. A alimentação é feita por uma pilha e a bobina consta de 80 a 100 voltas de fio de 32 a 28 num bastão de ferrite. O capacitor de sintonia pode ser obtido num radinho transistor fora de uso. Este circuito tem uma etapa amplificadora que pode ser elaborada com os transistores BC558 e BC548.

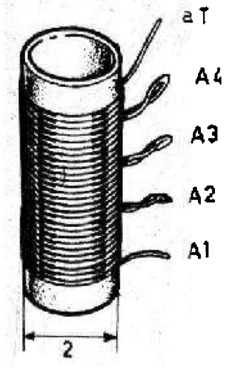
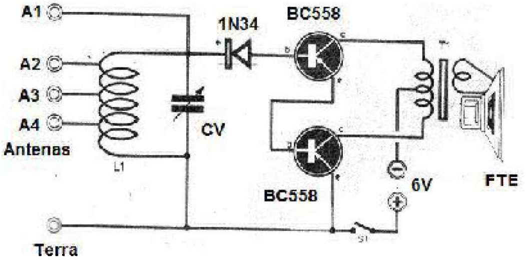
30.Receptor de Ondas médias (dois transistores)

Este simples receptor de ondas médias foi encontrado numa revista Técnica Prática da Itália do ano de 1965. O projeto é ainda atual se trocarmos os transistores pelos BC558, como já indicados na figura. O transformador de saída é obtido de um rádio transistorizado fora de uso. A bobina é formada por 75 espiras de fio 28 num tubo de 2 cm de diâmetro. As tomadas são feitas de 15 em 15 espiras. A antena deve ser longa e a ligação à terra é importante. CV pode ser obtido num rádio AM fora de uso. O circuito admite diversas melhorias. Uma delas consiste em se ligar de L1/C1 Para terra com um resistor de 47k em paralelo com um capacitor de 100 nF.





31. Receptor Experimental de FM

Encontrei este circuito numa revista de 1975, mas ele pode ser montado com facilidade utilizando-se um transistor BF494 ou BC548 em lugar do original. A saída deve ser ligada a um fone de cristal ou à entrada de um amplificador. A antena pode ser do tipo telescópica ou uma antena externa de TV. L1 tem 8 espiras de fio 28 numa forma de 1 cm e L2 de 2 a 4 espiras do mesmo fio ao lado de L1. Os choques L3 e L4 são de 1 mH a 2,2 mH. O circuito funciona com 9 V e a sintonia ajustada ao mesmo tempo em C1 e C2, que podem ser pequenos capacitores variáveis obtidos de rádios FM fora de uso.

32. Sintonizador AM

Encontrei este artigo de meu amigo A. Fanzeres numa revista uruguaia Corriente Alterna de julho de 1972. O artigo descreve um simples sintonizador de AM que pode ser ligado na entrada de qualquer amplificador de áudio para receber as estações AM locais. O artigo dá os detalhes da construção da bobina de antena. Mantivemos o formato original pelo valor histórico e como homenagem ao nosso amigo, já falecido, um grande nome da eletrônica em nosso país e no exterior.

Muy sencillo pero eficiente, este sintonizador permite captar las estaciones de radio en la banda de los 520 hasta 1600 Khz. Tiene una razonable selectividad y buena sensibilidad. Asociado a un amplificador, permite recepción de estaciones locales.

Si no se encuentra el bastón de ferrite con diámetro de 6 cms., puede ser utilizado otro diámetro, pero hay que modificar la cantidad de vueltas del alambrado, pero manteniendo la proporción de la derivación, o sea, 10 %.

33. Receptor Regenerativo com FET

Este circuito foi obtido numa revista inglesa de 1974. O circuito pode ser montado com facilidade com qualquer JFET como o BF245 e TR2 pode ser um BC548. A saída é para fone de cristal ou piezoelétrico. L1 é formada por 100 espiras de fio 28 num bastão de ferrite de 12 a 20 cm de comprimento e L2 por 5 espiras do mesmo fio. Inverta a ligação de L2 se o circuito apresentar baixo rendimento. C1 pode ser retirado de um velho rádio transistor fora de uso.

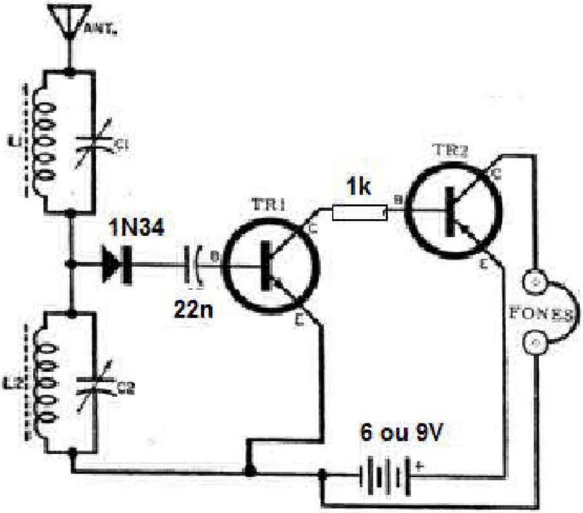
34. Rádio AM de Dupla Sintonia

Encontrei este circuito numa publicação de 1964, mas ele pode ainda ser montado. Com transistores de germânio obtém-se maior sensibilidade, mas ele também funciona com os BC558 e BC548 (PNP e NPN). Os dois circuitos de sintonia permitem obter mais seletividade. As bobinas são formadas por 100 espiras de fio 28 num bastão de ferrite e os capacitores variáveis obtidos de rádios transistores fora de uso. O fone deve ter 1k ou mais ou então ser um de cristal com um resistor de 4k7 em paralelo. O diodo pode ser o 1N34 e a antena deve ter pelo menos 3 metros de comprimento. Uma conexão à terra dota o circuito de maior sensibilidade.



35. Rádio OM e OC com FET

Este receptor experimental foi encontrado numa publicação inglesa de 1979. Ele pode receber sinais de ondas médias até a faixa de ondas curtas até uns 30 MHz, dependendo da bobina. Essa bobina deve ter de 20 a 100 espiras de fio 28 num bastão de ferrite com tomadas obtidas em posições diversas, de modo a se obter maior rendimento. O fone deve ser de alta impedância ou então piezoelétrico com um resistor de 4k7 em paralelo. Os FETs podem ser os BF245 ou MPF102.

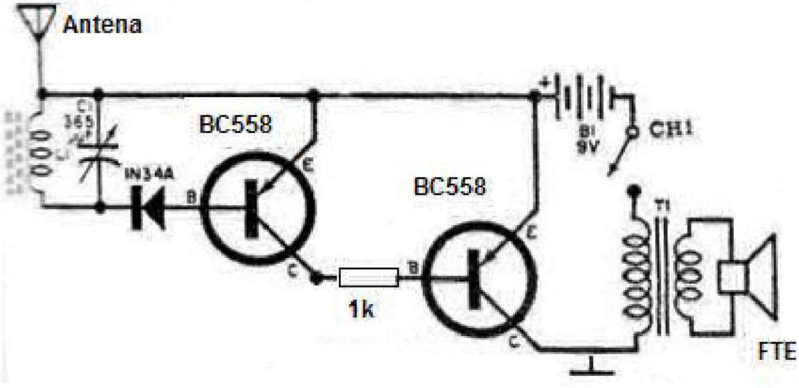
36. Rádio AM Experimental

Este circuito foi obtido numa revista de 1964 e tem algumas características interessantes como a polarização de entrada do primeiro transistor feita pelo próprio sinal. Deve-se tomar cuidado para não inverter o diodo. O resistor deve ser obtido experimentalmente para maior rendimento do resistor na faixa de 1k a 10k. A bobina consta de 100 espiras de fio 28 num bastão de ferrite e os transistores podem ser os BC558. O transformador é do tipo de saída para rádios transistorizados. O circuito funciona com 6 a 8 V de alimentação. O capacitor de sintonia pode ser obtido num rádio transistorizado AM fora de uso. A antena deve ser longa e uma boa conexão à terra é importante para se obter maior sensibilidade, já que um bom sinal é necessário para se excitar o alto-falante.



37. Rádio AM CMOS

Encontrei este circuito numa revista americana Hands On de 1986. Esta revista americana não mais existe, mas o circuito pode ainda ser montado com facilidade, pois seus componentes são comuns. O circuito fornece saída para fone ou para um amplificador e deve ser usada uma boa antena. A bobina L1 é formada por 80 a 100 voltas de fio AWG 28 num bastão de ferrite de 10 a 15 cm de comprimento e L2 é formada por 10 a 12 espiras do mesmo fio sobre L1. C2 é um capacitor variável obtido de um rádio AM comum. A alimentação pode ser feita com tensões de 9 a 12 V e o potenciômetro ajusta o ponto de funcionamento. C7 pode ser necessário para se obter melhor desempenho.

38. Rádio AM Simples

Este sensível Rádio AM não precisa de antena externa, podendo captar com facilidade as estações locais. A escuta é em fone de ouvido que tanto pode ser do tipo de cristal como um transdutor piezoelétrico do tipo encontrado em telefones. O circuito é alimentado por uma bateria de 9 V e tem um consumo muito baixo. A bobina L1 é formada por 100 espiras de fio esmaltado 26 ou 28 AWG num bastão de ferrite de 0,8 a 1 cm de diâmetro e de 12 a 20 cm de comprimento. Os bastões maiores proporcionarão maior sensibilidade.

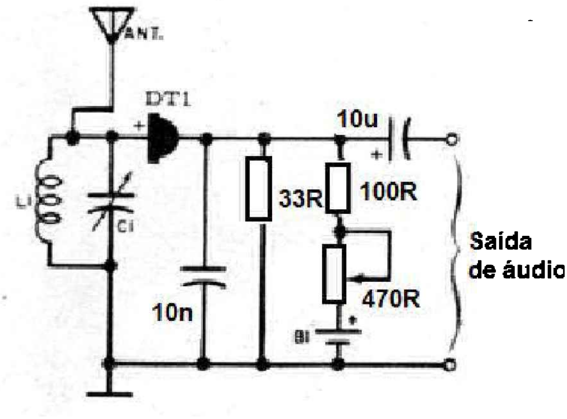
39. Receptor com Diodo Tunnel

Este circuito é de uma publicação de 1964. O circuito aproveita as características de resistência negativa do componente para detectar sinais de rádio. A bobina consta de 100 espiras de fio 28 num tubo de PVC de 2 cm de diâmetro para operação na faixa de ondas médias. O potenciômetro ajusta o ponto de funcionamento do circuito. A saída pode ser aplicada a um fone ou a um amplificador de áudio. A alimentação (B1) consiste numa pilha de 1,3 V a 1,5 V. A antena deve ser longa e a conexão à terra é importante para se obter maior sensibilidade.



40. Receptor AM Simples

O circuito apresentado foi obtido numa Radio Elettronica italiana de 1976, mas pode ser montado com facilidade utilizando-se transistores BC548, troca que já fizemos ao redesenhar o esquema. A saída deve ser feita em fone magnético de alta impedância ou piezoelétrico com um resistor de 2k2 em paralelo. O circuito é alimentado por bateria de 9 V. L1 consta de 30 + 70 espiras de fio 28 num bastão de ferrite e L2, 20 espiras sobre L1. A antena deve ser longa e uma conexão à terra ajuda a obter melhor desempenho. Os capacitores variáveis podem ser obtidos em antigos rádios de ondas médias.

41. Rádio AM com 2 FETs

Este circuito foi publicado numa Poptronics de janeiro de 2000, mas pode ser montado com facilidade ainda hoje. A bobina L2 consta de 20 + 80 espiras de fio 28 ou próximo, num bastão de ferrite de 1 cm de diâmetro por 20 ou mais centímetros de comprimento ou mesmo num tubo de 2 cm sem núcleo. L1 é formada por 20 espiras do mesmo fio sobre L1. O fone deve ser de alta impedância ou piezoelétrico com um resistor de 10k em paralelo. Os capacitores de sintonia podem ser obtidos de rádios AM fora de uso. A antena 1 consiste num fio estendido de pelo menos 5 metros de comprimento e a Antena 2, mais curta. Os FETs podem ser os BF245. Uma conexão à terra é importante par se obter melhor recepção.

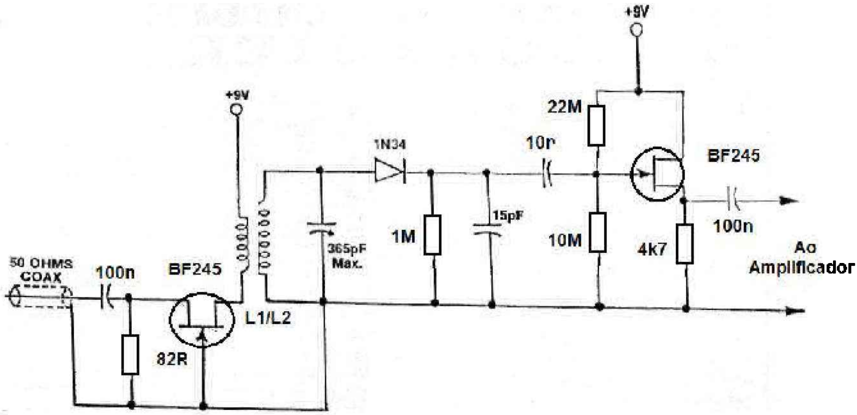
43. Rádio de Cristal

Este circuito saiu no Electronics Handobook Vol XIII de 1993, consistindo num rádio de galena ou cristal com diodo 1N34 e duas etapas de amplificação com FET. Uma delas é o amplificador de RF ou de antena com um transistor na configuração de gate comum de modo a baixar a impedância de entrada e a outra é o amplificador de áudio. Com isso o circuito pode ser alimentado a uma antena acoplada por cabo de 50 ohms. A saída da segunda etapa pode ser ligada a um amplificador de áudio externo. A bobina tem primário de 30 espiras de fio 28 ou 30 num cabo de vassoura ou tubo de PVC de 2,5 cm de diâmetro. Seu secundário, ligado ao variável consta de 100 espiras do mesmo fio. O primário deve ser enrolado sobre o secundário ou ao lado. O capacitor variável pode ser obtido num velho rádio de válvulas. O circuito tem muito baixo consumo, podendo ser alimentado por uma bateria de 9 V. O MPF102 pode ser substituído pelo BF245.



44. Rádio AM Mecânico

Este circuito foi encontrado numa revista inglesa de 1999, mas pode ser montado com facilidade com transistores BC548 ou qualquer NPN de uso geral. O circuito funciona com a energia gerada por um pequeno motor de corrente contínua que opera como dínamo. A energia carrega um capacitor e é usada para alimentar o rádio. L1 consta de 100 espiras de fio 28 num bastão de ferrite e CV é um capacitor variável obtido de um rádio AM fora de uso. Este projeto é interessante para demonstrar o funcionamento de fontes alternativas de energia, como o dínamo. O fone de cristal pode ser uma cápsula cerâmica piezoelétrica. O leitor deve fazer experiências com os motores que conseguir, pois o rendimento varia bastante de tipo para tipo.

45. Receptor Regenerativo de Ondas Médias e Longas

Encontramos este circuito numa Popular Electronics de maio de 1990. Com dois transistores e um fone de ouvido de alta impedância é possível receber as estações locais de ondas médias. Q1 e Q2 podem ser os BC548. L2 consta de 40 + 40 espiras de fio 28 num tubo de plástico ou papelão de 2 a 2,5 cm de diâmetro e L1 20 espiras do mesmo fio no mesmo tubo, ao lado de L2. O variável C1 pode ser obtido num rádio transistorizado fora de uso.

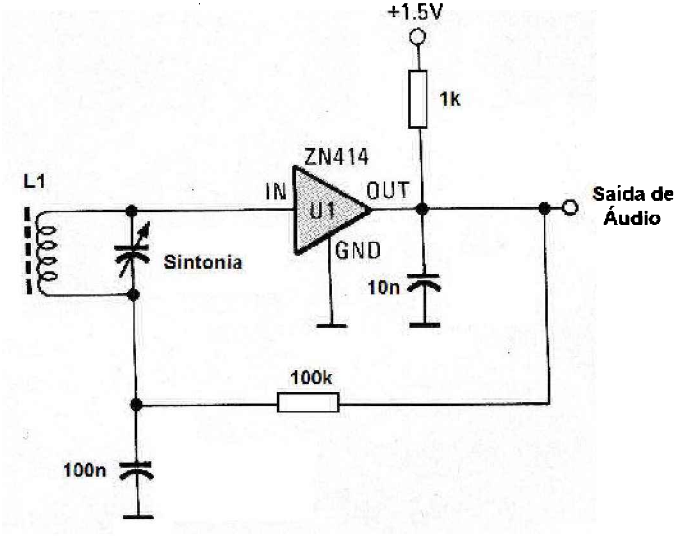
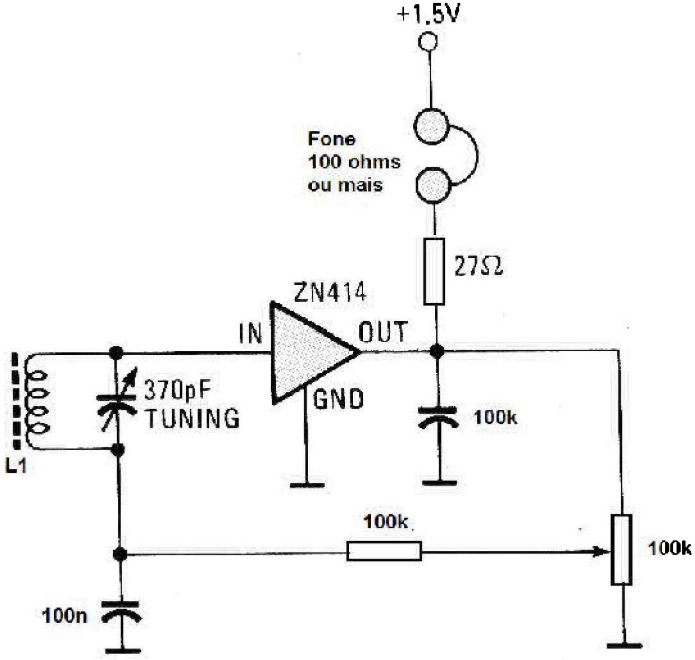
46. Rádio ZN414

Este circuito foi obtido numa Hands On Electronics, revista americana de janeiro de 1987. O ZN414 não é muito fácil de obter, mas se o leitor conseguir pode montar um excelente radinho de ondas médias para escuta em fone ou ainda um sintonizador aplicando a saída de áudio a um amplificador. A alimentação é feita por uma pilha e a bobina consta de 80 a 100 voltas de fio de 32 a 28 num bastão de ferrite. O capacitor de sintonia pode ser obtido num radinho transistor fora de uso. O circuito tem baixo consumo, podendo funcionar com fontes alternativas de energia como células solares e pilhas experimentais.



47. Rádio ZN414 (2)

Este circuito foi obtido numa Hands On Electronics, revista americana que não mais existe, edição de janeiro de 1987. O ZN414 não é muito fácil de obter, mas se o leitor conseguir pode montar um excelente radinho de ondas médias para escuta em fone. A alimentação é feita por uma pilha e a bobina consta de 80 a 100 voltas de fio de 32 a 28 num bastão de ferrite. O capacitor de sintonia pode ser obtido num radinho transistor fora de uso. Este circuito possui um controle de ganho e o resistor de 27 ohms nem sempre é necessário. O potenciômetro funciona como controle de ganho e, como o consumo é muito baixo, também pode ser usada na alimentação uma célula solar ou fonte alternativa.



48. Rádio Solar

Encontramos este circuito numa revista inglesa de 1983, mas ele pode ser montado com facilidade com o transistor BC548 em lugar do original, troca que já fizemos, e se o circuito integrado for encontrado. Na verdade, o circuito integrado em questão, que consiste num receptor completo é difícil de se obter atualmente no nosso mercado. A bobina é formada por 80 a 100 espiras de fio 28 num bastão de ferrite. Pode ser usada uma célula solar de calculadora ou ainda outras fontes alternativas de energia.

49. Receptor AM Reflex

Num receptor reflex o sinal de áudio detectado é aplicado de volta à entrada do circuito, de modo a receber nova amplificação. Neste receptor L1 é formada por 10 espiras de fio 28 num bastão de ferrite e L2 por 80 + 10 espiras do mesmo fio no mesmo bastão. O transformador de saída pode ser obtido de rádios transistorizados fora de uso e os transistores podem ser os BC548. O circuito foi obtido numa publicação internacional dos anos 80.

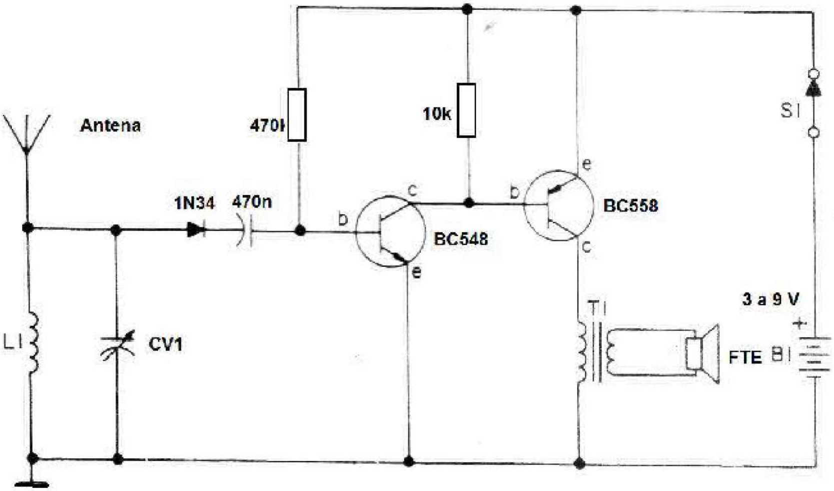
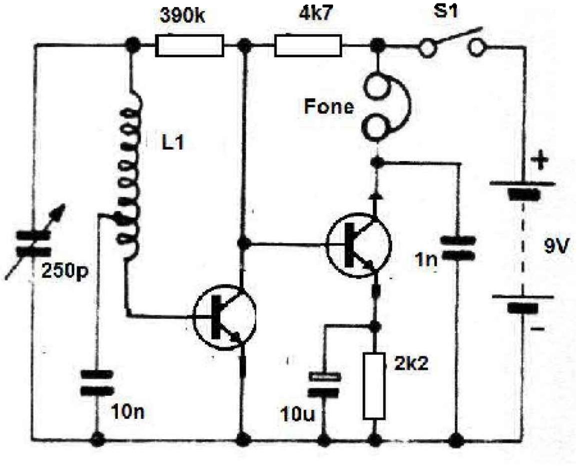
50. Rádio AM de Dois Transistores

Este circuito foi obtido na publicação 101 Electronics Projects de 1979. O circuito pode ser montado facilmente, pois todos os componentes são comuns. Este receptor capta as estações locais de ondas médias. O transformador pode ser obtido de um rádio AM antigo, assim como a bobina. Esta bobina também pode ser enrolada num bastão de ferrite sendo formada por 80 espiras de fio 28. O circuito também funciona com alimentação de 3 a 9 V. Os transistores podem ser o BC548 para Q1 e BC558 para Q2, já que os tipos indicados na publicação original não são fáceis de obter atualmente. A troca já foi feta ao redesenharmos o circuito. Uma boa antena externa e uma conexão à terra são importantes para se obter o melhor desempenho do circuito.



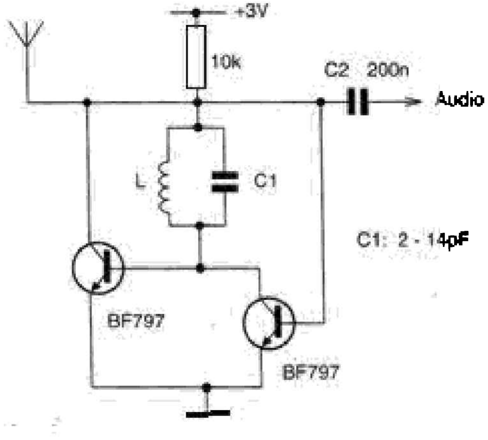
51. Rádio AM de 2 Transistores (2)

Este simples circuito de rádio AM de dois transistores foi obtido numa publicação argentina dos anos 1970. O circuito funciona com tensões de 3 a 12 V e a bobina consiste em 20 + 60 espiras de fio 28 num tubinho de papelão de 1 cm de diâmetro. O capacitor variável pode ser obtido de um rádio fora de uso e o fone deve ter de 600 ohms a 2k. Na sua falta use um transdutor piezoelétrico com um resistor de 2k2 em paralelo. Os transistores podem ser os BC548.



52.Receptor de FM de 2 Transistores

Este circuito foi obtido numa revista inglesa do ano 2000. Trata-se de um simples receptor de FM cujo sinal deve ser aplicado a um fone piezoelétrico ou à entrada de um amplificador. L consta de 4 espiras de fio 28 com diâmetro de 1 cm sem núcleo e C1 pode ser um capacitor variável retirado de rádio FM. A antena pode ser um pedaço de fio rígido de 40 cm a 1 metro. Podem ser usados os transistores BF494. Deve ser usada uma pequena antena telescópica. O sinal de áudio deve ser aplicado à entrada de um bom amplificador.



53.Rádio AM de 2 Transistores (3)

Este receptor foi encontrado numa revista Radio Elettronica de 1976. A revista italiana não mais existe , mas o receptor pode ser montado com transistores BC548 e 2N2222. Em lugar do 2N2222 também podemos usar o BD135. A bobina consta de 100 espiras de fio num bastão de ferrite com tomada na 30ª espira. A alimentação pode ser feita com bateria ou pilhas e tensões entre 6 e 12 V. Recomenda-se uma boa antena e a ligação à terra aumenta a sensibilidade. A tomada pode ser alterada para se modificar a sensibilidade e seletividade.

55. Receptor AM Solar

O circuito que apresentamos foi encontrado numa revista inglesa de 1974. Salvo o circuito integrado ZN414 que é pouco comum, os demais componentes podem ser obtidos com facilidade, pois o transistor pode ser trocado pelo BC548. O fone deve ser magnético de alta impedância ou piezoelétrico com um resistor de 4k7 em paralelo. L1 é formada por 100 espiras de fio 28 num bastão de ferrite e o capacitor variável obtido de um velho rádio AM fora de uso. As células solares podem ser obtidas de calculadoras que as utilizem, ou podem ser de outro tipo. O circuito funcionará com tensões de 1,3 V a 6 V.

56. Rádio AM de dois transistores (4)

Este simples radinho AM não precisa de antena externa para captar as estações locais. Ele foi encontrado numa documentação técnica de 1979, podendo ser montado com os transistores BC548 ou equivalentes mais modernos dos tipos indicados no original, que eram os BC108. A bobina é enrolada num bastão de ferrite de 20 a 25 cm de comprimento e o fio pode ser o 22 AWG. A tomada é feita na oitava espira, como indicado no diagrama. O fone deve ser magnético de baixa impedância. Se for cerâmico ou de cristal ligue em paralelo um resistor de 1k a 2,2 k. O diodo pode ser o 1N34. O consumo é baixo.

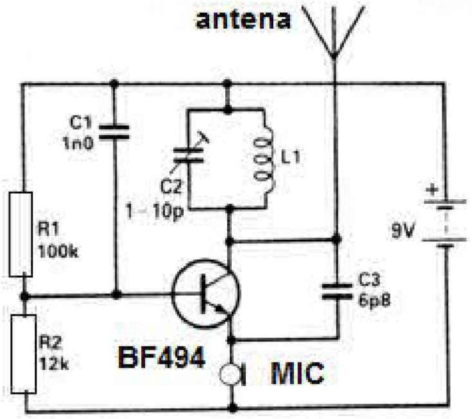
Transmissores

Os transmissores que descrevemos são todos do tipo experimental simples de baixa potência, já que, para operar transmissores potentes é preciso ter permissão especial. Na montagem de transmissores é muito importante que os capacitores das etapas de RF sejam cerâmicos e especial cuidado deve ser tomado com a confecção das bobinas.

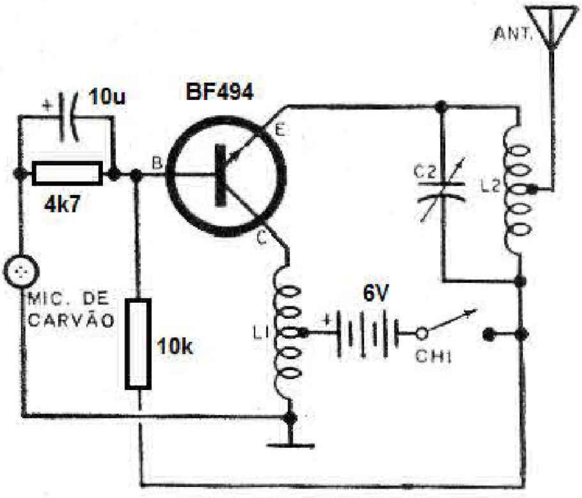
57. Micro Transmissor de FM

Este circuito é utilizado com microfones de baixa impedância como, por exemplo, pequenos alto-falantes, cápsulas magnéticas de fones até 600 ohms. O circuito é de uma publicação de 1989, mas pode ser montado com um transistor BF494. A bobina consta de 4 espiras de fio 24 ou 26 em forma de 1 cm sem núcleo. A antena pode ter de 10 a 40 cm de comprimento e o alcance pode chegar a algumas centenas de metros. Os capacitores devem ser cerâmicos. O trimmer não é crítico admitindo valores com capacitâncias máximas até 33 pF.



58. Mini Transmissor AM

Este circuito foi encontrado numa revista de 1964, que não existe mais. Trata-se de um pequeno transmissor ou microfone sem fio que envia seus sinais a um rádio AM a alguns metros de distância. O microfone deve ser obrigatoriamente de carvão ou magnético de baixa impedância. As bobinas são formadas por 40 + 40 espiras de fio 28 num bastão de ferrite e a antena é telescópica de 40 a 120 cm de comprimento. A alimentação é feita com 6 ou 9 V e o transistor pode ser o BC558. R1 é de 10k, R2 de 22k, C1 de 10 uF e 2 um variável de rádio AM antigo. Uma alteração consiste em se ligar o resistor de 4k7 e o capacitor de 10u à terra e usar um microfone piezoelétrico em paralelo com estes componentes.



59. Pequeno Transmissor de AM

Este pequeno transmissor AM experimental ou microfone sem fio foi obtido numa antiga publicação latina, dos anos 70. Seu alcance é da ordem de alguns metros com uma pequena antena e o microfone pode ser de qualquer tipo. A alimentação é feita com bateria especial de 15 V para maior alcance, mas ele funcionará com 9 V utilizando-se um transistor BC558. L1 consta de 40 + 40 espiras de fio 28 e O capacitor de 2-20 pF ou mais pode ser um pequeno variável para se obter sintonia, o que no circuito original não existe.

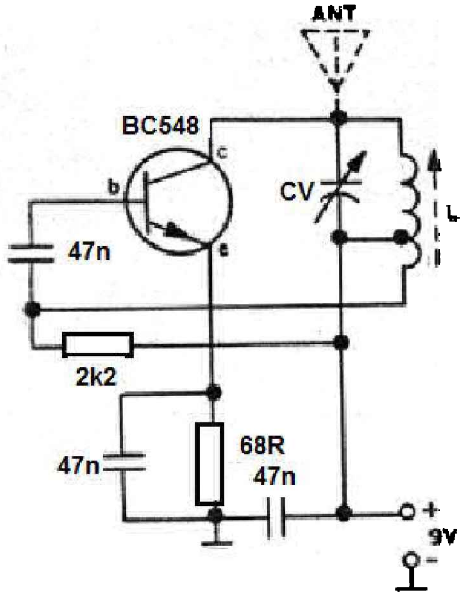
61. Transmissor de Onda Contínua (CW)

Este circuito foi indicado em artigo da revista americana Electronics Hobbyst do inverno de 1971. A revista não existe mais, mas o projeto pode ser montado com as modificações feitas e a utilização de um transistor BC548 ou BF494. Para a faixa de ondas curtas de 3 a 10 MHz enrole 30 espiras de fio 28 AWG num bastão de ferrite de 10 a 15 cm de comprimento com tomada na 10ª espira a partir do ladro de terra (R1). A antena pode ser telescópica e a alimentação tanto feita com 4 pilhas como bateria de 9 V. C2 é um variável comum tirado de um rádio AM. Os capacitores devem ser cerâmicos. O manipulador para envio de sinais telegráficos pode ser intercalado à fonte de alimentação.



62. Microfone sem fio de FM

Este circuito foi indicado em artigo da revista americana Electronics Hobbyst do inverno de 1971. A revista não existe mais, mas o projeto pode ser montado com a utilização de transistores equivalentes. Para Q1 podemos usar o BC558 e para Q2 o BC558 e se não oscilar qualquer PNP de RF. Os capacitores menores devem ser cerâmicos e a antena deve ter 15 cm ou mais. O microfone é piezoelétrico, mas pode ser usado um eletreto com um resistor de 10k ao positivo da alimentação.

63. Transmissor de Ondas Médias

Este circuito foi obtido na revista italiana Radio Elettronica de agosto de 1974. A revista não mais existe, mas o circuito pode ser montado mesmo em nossos dias com transistores equivalentes como os BC548 para TR1 e TR2, e BD136 para TR3. L1 é formada por 60 + 20 espiras de fio 28 num bastão de ferrite. Alterações nos resistores de polarização podem ser necesssárias para melhor desempenho. A antena pode ser telescópica com pelo menos 60 cm de comprimento. O alcance, dada a faixa de operação, é pequeno, da ordem de alguns metros apenas.

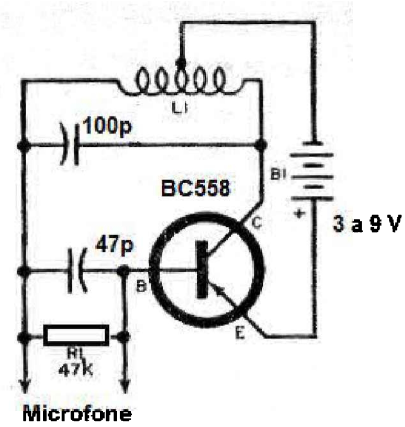
64. Microfone sem fio AM

Este artigo saiu numa Popular Electronics de julho de 1965. O artigo é atual exceto pelo transistor e também pelo seu alcance muito pequeno. O transistor pode ser um BC558. A bobina consiste em 50 + 50 espiras de fio 28 AWG num bastão de ferrite de 10 a 15 cm de comprimento. O microfone deve ser piezoelétrico. A alimentação pode ser feita com tensões de 6 a 9 V, obtidas de 4 pilhas pequenas ou uma bateria. Em lugar do capacitor fixo de 100 pF pode ser usado um capacitor variável para facilitar a sintonia, pois no original o ajuste é feito apertando-se e afastando-se as espiras da bobina. Uma antena no coletor do transistor aumenta o alcance. Alterando-se a bobina o circuito opera também na faixa de ondas curtas.



65. Microfone sem fio AM (2)

Este circuito foi encontrado numa revista de 1963, mas ainda pode ser montado com facilidade com alguns componentes atuais. Os transistores podem ser os BC558 e o transformador é obtido de um rádio transistorizado fora de uso. A bobina consta de 40 + 40 espiras de fio 28 num bastão de ferrite de 12 cm de comprimento aproximadamente. A antena tem de 30 a 50 cm e o alcance é de alguns metros na faixa de 550 a 1600 kHz. O resistor R3 de 100R a 1k deve ser obtido experimentalmente, para o melhor desempenho. Os capacitores devem ser cerâmicos.

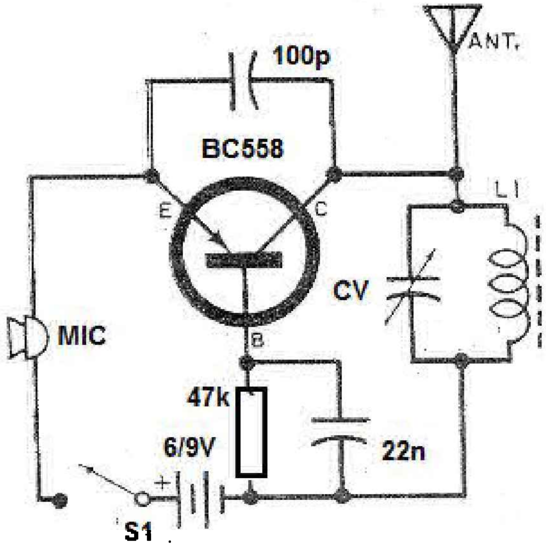
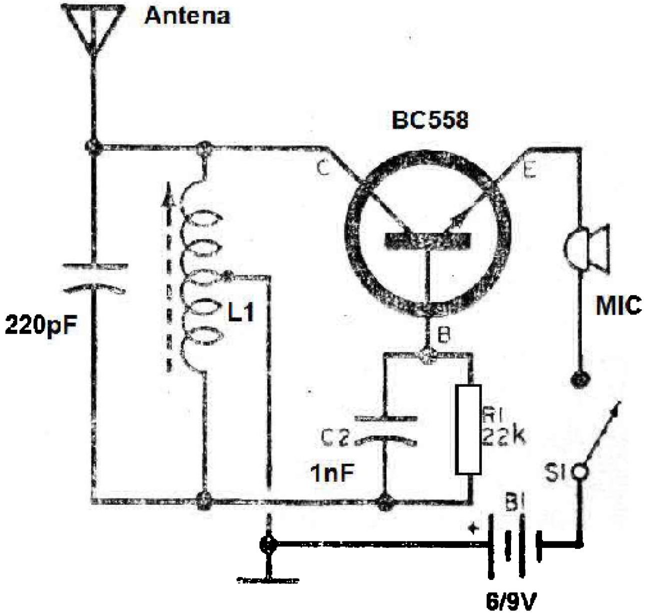
66. Microfone sem fio AM (3)

O microfone deste transmissor AM de curto alcance deve ser magnético de baixa impedância (um pequeno alto-falante) ou de carvão. L1 é formada por 80 espiras de fio 28 num bastão de ferrite e CV é um capacitor variável de antigo radio AM. O transistor pode ser o BC558 e a antena telescópica de 40 cm a 1,5 m de comprimento. A faixa de frequências está entre 500 e 1600 kHz. A bobina Poe ser alterada para operação na faixa de ondas curtas.



67. Micro Transmissor de AM

Este circuito foi obtido numa tradução de revista americana de 1965. A bobina é formada por 40 + 40 espiras de fio 28 num tubo de papelão que desliza sobre bastão de ferrite para ajuste de frequência. O microfone pode ser um pequeno alto-falante e a antena é do tipo telescópico. A alimentação pode ser feita com tensões de 6 a 9 V. O transistor pode ser o BC548 e a faixa de frequências de operação está entre 550 kHz e 1600 kHz. O alcance é de alguns metros. A bobina pode ser fixa, trocando-se o capacitor de 220 pF por um variável comum de rádio de ondas médias.



68. Transmissor de FM Alimentado por AC

Este circuito, de nossa autoria, publicado numa antiga edição de década de 90, é alimentado diretamente pela rede de energia. Os sons captados pelo microfone são enviados para um receptor a uma distância de algumas dezenas de metros e recebidos num rádio comum de FM. O circuito tem boa sensibilidade e baixo consumo. A bobina é formada por 4 espiras de fio rígido fino com diâmetro de 1 cm sem núcleo e a antena um pedaço de fio rígido de 12 a 20 cm de comprimento. Os capacitores devem ser cerâmicos, exceto C1 que é de poliéster para 400 V e C2 eletrolítico. O valor entre parênteses é para a rede de 220 V.

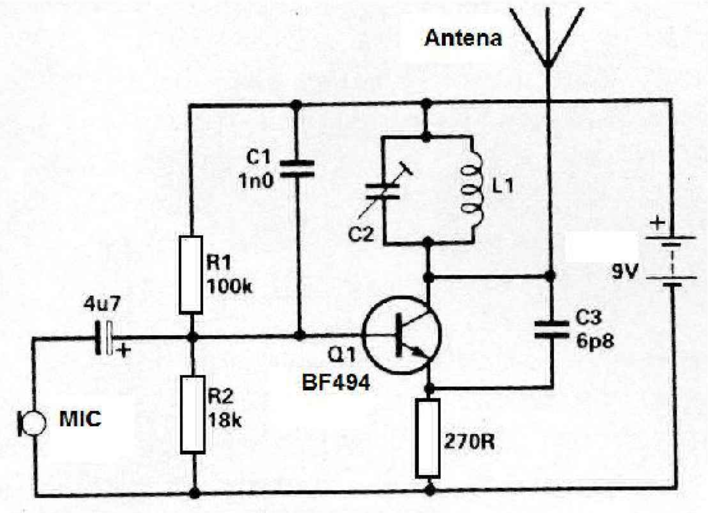
69. Micro Transmissor de FM (4)

Este circuito é utilizado com microfones de alta impedância como, por exemplo, cápsulas de cerâmica ou cristal. O circuito é de uma publicação de 1989, mas pode ser montado com um transistor BF494. A bobina consta de 4 espiras de fio 24 ou 26 em forma de 1 cm sem núcleo. A antena pode ter de 10 a 30 cm de comprimento e o alcance pode chegar a algumas centenas de metros. Os capacitores devem ser cerâmicos. O circuito também funciona bem com alimentação d 3 ou 6 V, mas com menor alcance. Para microfone de eletreto, ligue entre o positivo do eletreto e da alimentação um resistor de 4k7. C2 é um trimmer comum de 10 a 30 pF de capacitância máxima.



70. Micro Transmissor de FM (5)

Este circuito é utilizado com microfones de alta impedância como, por exemplo, cápsulas de cerâmica ou cristal. O circuito é de uma publicação de 1989, mas pode ser montado com um transistor BF494 e um BC548. A bobina consta de 7 espiras de fio 24 ou 26 em forma de 0,5 cm com núcleo ajustável. A antena pode ter de 10 a 30 cm de comprimento e o alcance pode chegar a algumas dezenas de metros. Os capacitores devem ser cerâmicos. A alimentação original é com uma pilha botão d 1,3 V (mercúrio) ou 1,5 V (comum), mas o circuito também funciona com alimentação de 1,5 V ou 3 V de pilhas AAA ou AA.

71. Transmissor de FM

O alcance deste pequeno transmissor de FM pode superar os 100 metros. L1 tem 4 espiras de fio 20 a 22 sem núcleo em forma de 1 cm. A antena é um fio rígido de 10 cm a 40 cm. Q1 pode ser um BC548 e Q2 um BF494 ou 2N2222. O microfone é de eletreto. O circuito também funciona com 6 V. C5 pode ser qualquer trimmer comum de 20 a 50 pF de capacitância máxima. Os capacitores menores devem ser todos cerâmicos, com especial atenção para C6 cujo valor pode necessitar de alteração na faixa de 4,7 pF a 10 pF.

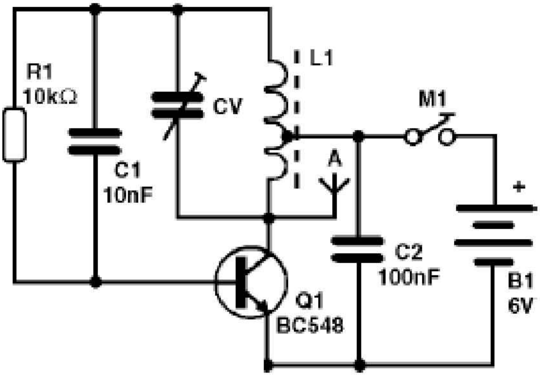
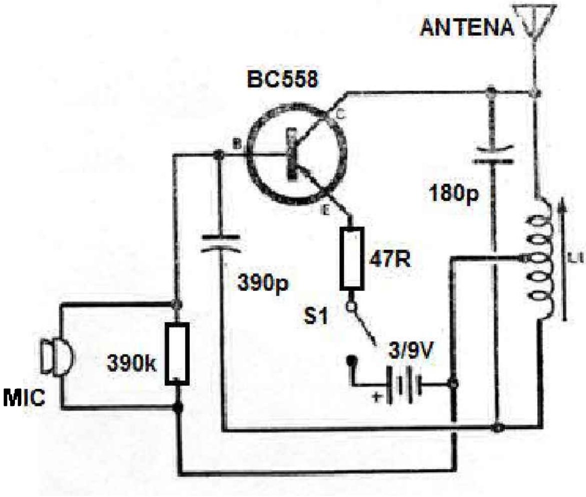
72.Micro Transmissor de Ondas Curtas

Este transmissor telegráfico de ondas curtas pode enviar seus sinais a um receptor a algumas dezenas de metros. L1 depende da faixa podendo ter de 10 + 10 a 20 + 20 espiras de fio 28 num bastão de ferrite para a faixa de 5 a 15 MHz. CV é um capacitor variável de rádio AM e a antena pode ter de 50 cm a 2 metros de comprimento. A alimentação pode ser feita com tensões de 6 a 9 V. Para 12 V use um transistor BD135. Os capacitores devem ser cerâmicos. O circuito é de um livro do autor publicado nos Estados Unidos.



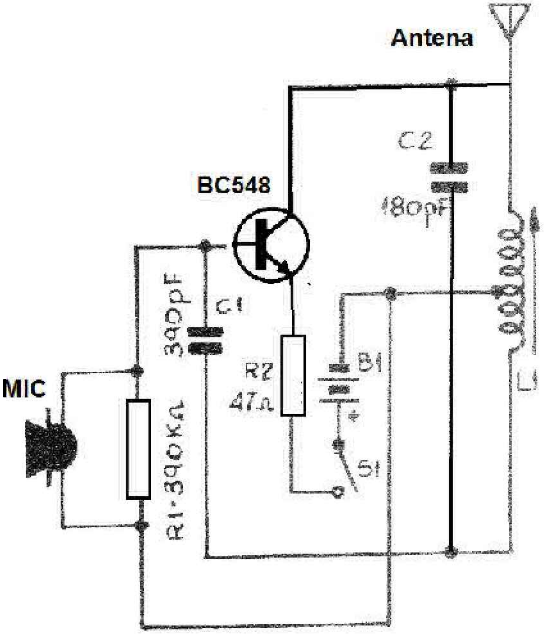
73. Microfone sem fio AM (4)

Este circuito foi obtido numa publicação de 1965, mas ainda pode ser montado com um transistor BC558 em lugar do original que era de germânio. L1 consta de 50 + 50 espiras de fio 28 num tubo de papelão que pode ser deslizado sobre um bastão de ferrite para ajuste da frequência. A antena é telescópica de 30 a 100 cm, e o microfone do tipo piezoelétrico. O alcance é de alguns metros.



74. Microfone sem fio AM (5)

Este pequeno transmissor AM de curto alcance foi obtido numa publicação argentina dos anos 1970. O circuito tem alguns metros de alcance, utilizando uma pequena antena telescópica e o microfone deve ser piezoelétrico (cerâmico). A bobina é formada por 40 + 40 espiras de fio 28 num bastão de ferrite e pode ser usado um transistor BC558 em lugar do original. A alimentação deve ser feita com 6 ou 9 V e a sintonia é feita deslocando-se o núcleo de ferrite dentro da bobina, que deve ser enrolada num tubinho de papelão. Pode-se ter a sintonia num capacitor variável de rádio AM ligado em paralelo, se a bobina for fixada no núcleo de ferrite.



75. Microfone sem fio de FM (2)

Este excelente circuito de microfone sem fio para a faixa de FM modulado por varicap saiu na revista Electronics Now &Radio Electronics de fevereiro de 1993, podendo ser montado com facilidade com um transistor 2N2222 ou BF494 em lugar do original. O microfone pode ser piezoelétrico e a bobina é formada por 4 espiras de fio 22 a 26 em forma de 1 cm sem núcleo. A antena tem de 10 a 30 cm de comprimento. Varicaps da série BB podem ser usados em lugar do original, que era de tipo pouco comum no nosso mercado de componentes. A troca já foifeita quando redesenhamos o circuito.

78. Micro Espião de FM

Este circuito foi encontrado numa Radio Elettronica (Itália) de abril de 1974. O circuito pode ser montado ainda hoje com o transistor 2N2222. Somente o circuito integrado original é mais difícil de ser obtido. O alcance é da ordem de algumas dezenas de metros e a bonina consiste em 4 espiras de fio 26 ou 28 com diâmetro de 1 cm sem núcleo. A antena deve ter de 10 a 40 cm se for usada, devendo ser ligada ao coletor de Q1. O problema maior deste circuito é encontrar o circuito integrado TAA320, que não mais é fabricado. Uma possibilidade consiste em substituir esta etapa por um estágio de um único transistor com mudanças no circuito, devido ao acoplamento do microfone.

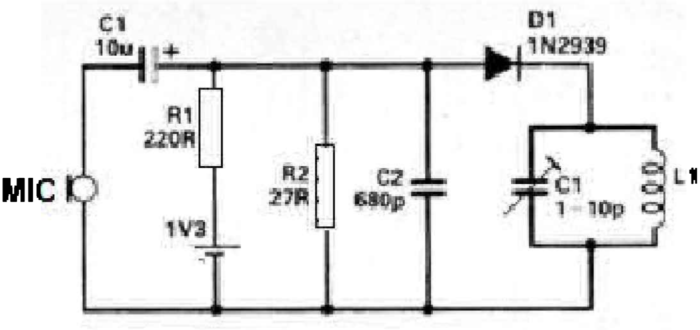
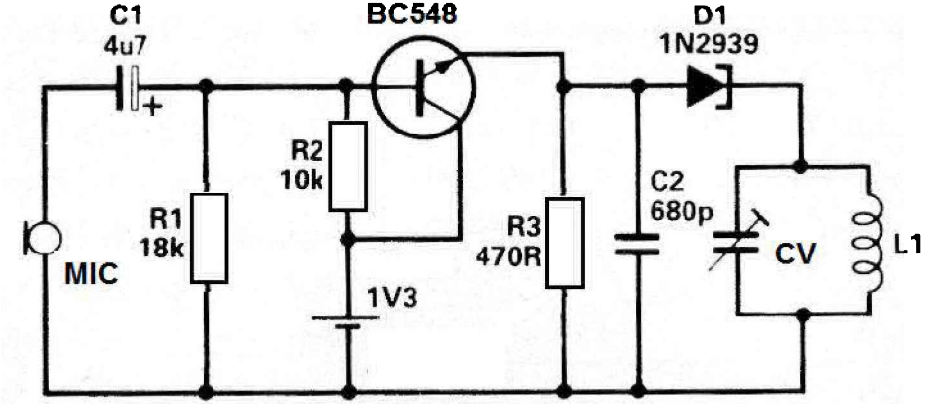
82. Transmissor de FM Com Diodo Tunnel

Este micro transmissor de FM utiliza um diodo tunnel como oscilador. Encontrei-o numa publicação inglesa de 1989. Veja que a alimentação é feita com uma bateria de mercúrio de 1,3 V. O circuito também funcionará com uma pilha botão ou AAA de 1,5 V. O microfone é uma cápsula cerâmica ultraminiatura ou mesmo magnética. O alcance é de apenas alguns metros, mas o circuito pode ter uma montagem extremamente pequena. L1 consiste em 5 espiras de fio 30 em forma de 0,5 cm sem núcleo.



83. Transmissor de FM com Diodo Tunnel (2)

Este micro transmissor de FM utiliza um diodo tunnel como oscilador. Encontrei-o numa publicação inglesa de 1989. Veja que a alimentação é feita com uma bateria de mercúrio de 1,3 V, mas pode ser usada uma pilha botão ou AAA. O microfone é uma cápsula cerâmica ultraminiatura ou mesmo magnética. O alcance é de apenas alguns metros, mas o circuito pode ter uma montagem extremamente pequena, servindo como espião ou localizador. L1 consiste em 5 espiras de fio 30 em forma de 0,5 cm sem núcleo. CV é um trimmer com capacitância máxima d 10 a 33 pF. O transistor pode ser o BC548 ou outro de uso geral.



84. Transmissor de Bips Sinalizador

Este transmissor opera na faixa de FM emitindo bips que podem ser captados num rádio comum a uma distância até mais de 100 metros em campo aberto. A antena é telescópica de 20 a 80 cm e a bobina é formada por 2 + 2 espiras de fio 28 numa forma sem núcleo de 1 cm de diâmetro. CV é um trimmer comum de 10 a 40 pF de capacitância máxima. O circuito é do livro Science Fair Projects de Newton C. Braga.

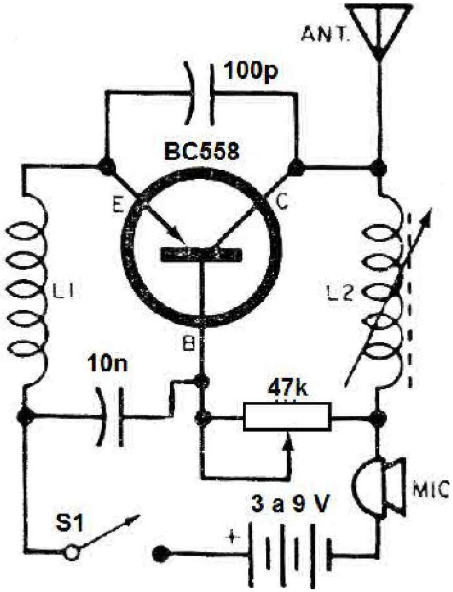
89. Microfone sem fio AM (6)

Encontrei este circuito numa publicação de 1964. O circuito ainda pode ser montado com facilidade com um transistor BC558 em lugar do original. O alcance é de alguns metros com uma antena telescópica de 40 a 100 cm. A bobina L2 consiste em 80 espiras de fio 28 num tubo de papelão que desliza sobre um bastão de ferrite para o ajuste de frequência. L1 é um choque de 2,5 mH. O microfone deve ser de baixa impedância, por exemplo, um pequeno alto-falante. A alimentação é feita por uma tensão de 3 a 9 V. A frequência de operação vai de 550 a 1600 kHz. O trimpot de ajuste é de 47k (será conveniente ligar um resistor de 4k7 em série, não dado na publicação original) e C1 é de 10 nF. C2 é de 470 pF.

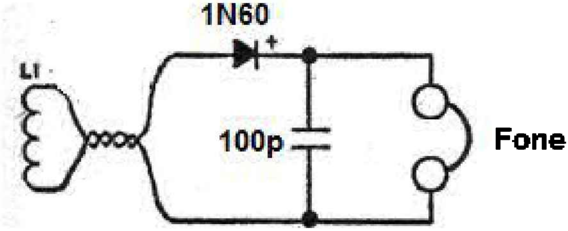


Circuitos Diversos

Damos a seguir uma seleção de circuitos que são utilizados tanto com receptores como transmissores. Neste grupo incluímos os reforçadores de sinais, comprovadores de transmissores, detectores de transmissores e muito mais.

90. Verificador de Transmissores AM

Este circuito foi indicado em artigo da revista americana Electronics Hobbyst do inverno de 1971. A revista não existe mais, mas o projeto pode ser montado com facilidade, pois os componentes são comuns. O fone pode ser de cristal ou uma cápsula piezoelétrica. A bobina consiste em 3 voltas de qualquer fio numa forma de 3 a 4 cm sem núcleo que deve ser aproximada da bobina de saída do transmissor em teste. O diodo pode ser o originalmente indicado 1N60 ou equivalente como o 1N34. O circuito também funciona com transmissores da faixa de ondas curtas e mesmo osciladores modulados.



91.Detector de RF

Na verdade, trata-se de um indicador de intensidade de campo com um amplificador operacional equivalente ao 741. Este circuito foi encontrado numa Popular Electronics de 1991, mas pode ser montado com facilidade ainda hoje. A antena é telescópica e o choque pode ser enrolado com 50 espiras de fio 32 num bastão de ferrite.

96.Reforçador AM (2)

Este circuito booster, encontrado numa publicação argentina da década de 1970, foi originalmente projetado para reforçar sinais de AM em rádios de carro. O circuito é do tipo aperiódico, ou seja, sem sintonia, reforçando sinais de toda a faixa. A alimentação é de 9 V e o consumo muito baixo. O transistor original de RF de germânio pode ser substituído pelo BF494 ou BF495.Os cabos de entrada e saída devem ser blindados.

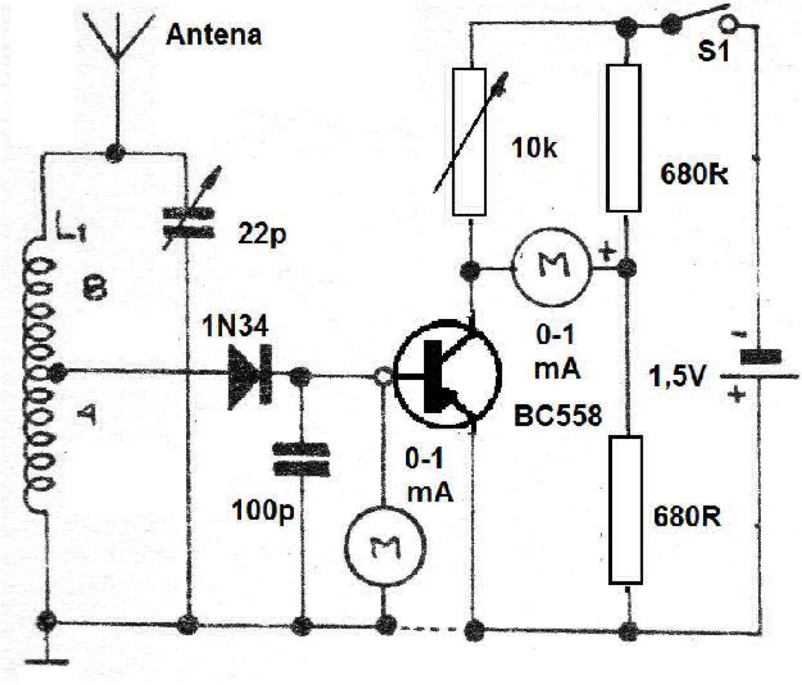
97. Medidor de Intensidade de Campo Para 27 MHz

Originalmente este circuito foi projetado para medir a intensidade de sinal de transmissores da faixa do cidadão, 27 MHz ou 11 metros, como também é conhecida. Mas, com alteração da bobina, pode ser usado com transmissores de outras faixas. O circuito foi obtido numa publicação argentina dos anos 1970. A bobina é formada por 4 mais 8 voltas de fio 26 num tubo de 1 cm de diâmetro e o trimmer é comum podendo também ser usado um variável de FM. O transistor pode ser o BC558 em lugar dos originais de germânio e a alimentação é feita com uma ou duas pilhas pequenas. O diodo pode também ser o 1N34.



98. Amplificador de Antena

Intercalado entre uma antena externa e a entrada de antena de um receptor este circuito proporciona melhor recepção. O circuito serve para receptores de ondas médias e curtas e com um pouco menos de ganho, para receptores de FM. As conexões de entrada e saída devem ser blindadas. Este circuito é de um livro de Newton C. Braga.

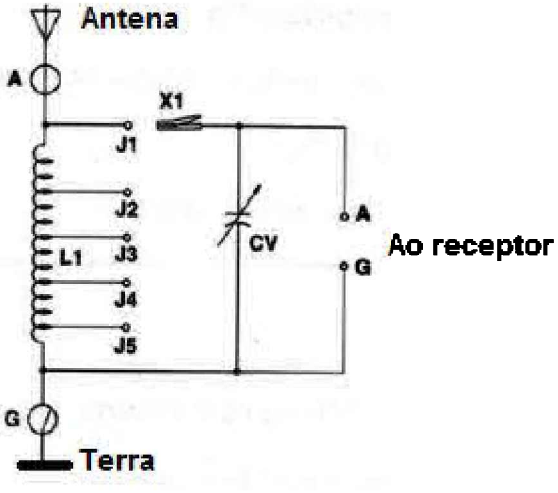
99. Pré-Seletor de Ondas Médias

Muitos ainda gostam de ouvir ondas médias, mas residem em locais de difícil recepção com muitas interferências e baixa intensidade de sinal o que exige o uso de antenas externas. A recepção nestes locais pode ser melhorada por um pré-seletor. A bobina consta de 100 espiras de fio 28 num tubo de papelão ou PVC de 1 polegada com tomadas de 20 em 20 espiras. O capacitor variável é de um rádio antigo de ondas médias. O circuito é ligado entre a antena e terra do receptor. Com uma boa antena externa e um receptor sensível, mais a ajuda deste circuito, estações muito distantes de ondas médias podem ser captadas, principalmente à noite. O circuito é do Fun Projects for the Experimenter, livro de Newton C. Braga.



100. Super Booster de OM

Este circuito é de uma Elementary Electronics de 1977. Ele pode ser montado com certa facilidade trocando-se Q2 por um BF494. Q1 pode ser substituído por qualquer MOSFET de comporta dupla. L1 consiste em 100 espiras de fio 28 num bastão de ferrite e L2 20 espiras sobre L1. O capacitor variável pode ser obtido de qualquer rádio AM fora de uso. A saída do circuito é ligada a umas 4 espiras de fio que envolvem a caixa do rádio AM, formando a bobina L2. O consumo é muito baixo, podendo ser usada uma bateria na sua alimentação.

PROBLEMAS CAUSADOS POR TRANSMISSORES DE FM

Recentemente aeroportos de grandes cidades como São Paulo, tiveram sérios problemas de interferências de emissoras clandestinas de FM, que afetando a operação dos sistemas de navegação fizeram com que pousos e manobras importantes de aproximação de aeronaves fossem abortadas.

Uma ação drástica contra essas emissoras está sendo feita pelas autoridades, pois o que está em jogo é a segurança do tráfego aéreo. É melhor prevenir um acidente grave agora do somente tomar as medidas cabíveis depois que acontecer algo.

O Problema

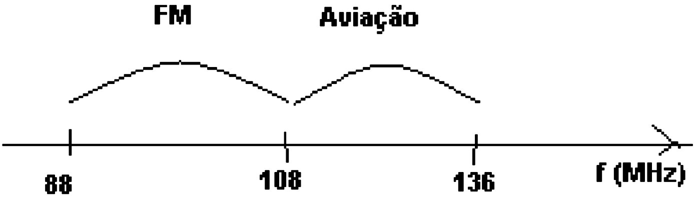
Com o falso rótulo de "Emissoras Comunutárias", muitas pessoas e entidades têm posto no ar emissoras de FM de potências muito acima do que a idéia da legislação inicial que existia sobre o assunto permitia.

Assim, os 5 W de potência máxima não são respeitados da mesma forma que a altura máxima da torres. Temos visto transmissores de até 500 W (!) com torres que chegam a 40 metros, na rota de aproximação de aeronaves no Aeroporto de Guarulhos!

Mas, não é somente a potência que causa problemas. Os transmissores usados não têm qualquer controle de qualidade, normalmente são montagens caseiras precárias que acabam por ter seu sinal espalhando por um espectro que se estende muito além da faixa de FM.

É justamente aí que temos o ponto crítico. A faixa destinada às comunicações entre torre e aeronaves e o sistema de balizamento dos aeroportos opera na faixa que vai dos 108 MHz a 136 MHz, ou seja, justamente acima da faixa de FM.

Assim, um transmissor de FM descalibrado, e não precisa ser muito potente, pode ter sinais espúrios na faixa de aviação, interferindo dos equipamentos de aproximação e comunicação das aeronaves, conforme mostra a figura 1.



E, para que um transmissor emita sinais espúrios e harmônicas não é preciso muito. Basta que os circuitos das etapas osciladora e de amplificação não sejam bem ajustados para que isso ocorra. A não existência de filtros de saída que eliminem harmônicas e espúrios também causa problemas e o próprio sistema de antenas e cabos mal dimensionados também é causa de problemas.

Montando Transmissores

Muitas vezes publicamos transmissores de FM, alguns até com potências elevadas. Sempre, entretanto, alertamos os leitores para as restrições legais que existem quanto ao seu uso, e principalmente os cuidados que devem ocorrer com sua instalação e montagem.

Em suma, montar e operar transmissores não são brinquedos. Justifica-se a utilização de um transmissor com alguma potência numa localidade isolada, como uma vila ou pequena cidade em que o serviço não existe.

Justifica-se a instalação de um pequeno transmissor num clube ou escola, desde que isso não afete qualquer tipo de serviço de comunicação que eventualmente possa existir no local.

Na verdade, essa é a filosofia básica da Emissora Comunitária que seria prestar um serviço no local em que ele não é disponível. No entanto, no momento em que esse tipo de equipamento pode causar problemas, e principalmente colocar em risco vidas humanas, sua presença não tem qualquer justificativa.

Instalar e operar indevidamente transmissores de FM em locais densamente povoados, podendo também causar interferências em TV e outros serviços, perto de aeroportos onde podem interferir nos equipamentos das aeronaves, é algo que deve ser combatido rigorosamente.

Transmissor sem Alcance

Montei um transmissor de FM, mas o seu alcance não vai além de uns 5 m. Me afasto do receptor de FM e o sinal some. O que está acontecendo?

Provavelmente você está sintonizando um sinal espúrio ou harmônica. Explicamos. O circuito de muitos pequenos transmissores produz um sinal mais forte na frequência para o qual está sintonizado e outros mais fracos, denominados espúrios ou harmônicas em frequências diversas. Estes sinais, por serem mais fracos, não têm alcance.

Se você em lugar de sintonizar o sinal principal do transmissor, sintonizar um destes sinais espúrios, o alcance será muito pequeno e ele some. O que você deve fazer é sintonizar novamente o transmissor e procurar o sinal mais forte. Deve fazer várias tentativas até encontrar este sinal que é o fundamental. Isso também ocorre com transmissores de controle remoto e outros.

QUANDO UMA MONTAGEM NÃO FUNCIONA

Dicas Para os Montadores

A experiência do autor de mais de 30 anos de publicação de montagens, além das aulas que dá mostram que os problemas de funcionamento dos aparelhos montados por leitores e alunos têm sempre as mesmas origens. É claro que não descartamos os casos em que os próprios diagramas ou placas podem conter erros introduzidos no processo de desenho e que às vezes escapam de nossa revisão.

Temos sempre o cuidado de montar os aparelhos publicados, muitos dos quais muitas vezes não funcionam sozinhos, pois suas configurações podem fazer parte de mais um projeto, o que nem sempre é compreendido por quem vê algo montado, aparentemente "igualzinho" ao original, mas que não funciona. Se isso acontecer, o que fazer? O que pode ter ocorrido?

Analisemos os casos mais comuns:

Confira sempre sua montagem pelo diagrama e depois pelo desenho da placa de circuito impresso.

Nos projetos que damos em nossas publicações e no site é comum colocarmos junto ao diagrama os valores dos componentes que são repetidos na lista de material com informações adicionais como tensão de trabalho para os capacitores, dissipação e código de cores para os resistores, etc.

Assim, se houver uma discrepância entre os valores o leitor pode ter um ponto de partida para uma eventual falha. Veja depois se os resistores e capacitores estão com os valores corretos na montagem.

É muito comum que um resistor de 1k seja colocado em lugar de 10k numa montagem. Marrom, preto, vermelho pode ser facilmente confundido com marrom, preto, laranja, principalmente se o vermelho do primeiro estiver desbotado. Para os capacitores, o problema é mais grave devido aos códigos utilizados.

É comum que se troque os valores de componentes como, por exemplo usar 4k7 = 4 700 pF em lugar de 4K7 = 4,7 pF numa montagem, o que a leva a não funcionar. Na figura 1 mostramos alguns códigos de capacitores cerâmicos que causam confusões.

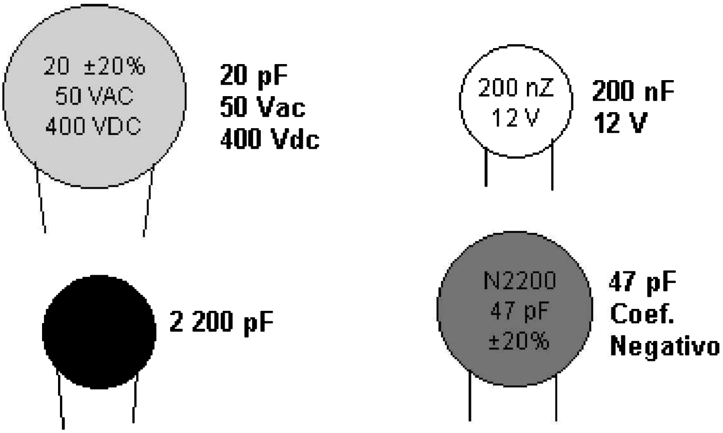


Figura 1 – Códigos de capacitores cerâmicos.

Conferir com uma lente os valores dos componentes numa montagem é fundamental, antes mesmo de se alimentar o circuito para um teste de funcionamento.

Tipos e especificações de componentes

O tipo de componente indicado para uma aplicação é fundamental para o seu funcionamento, principalmente nos casos mais críticos. Isso ocorre, por exemplo, nos circuitos de altas freqüências (transmissores, receptores, osciladores, etc.) onde existem funções em que o uso de capacitores cerâmicos é obrigatório. Se, na função indicada para um capacitor cerâmico for utilizado um de poliéster, mesmo que de mesmo valor que o pedido, o circuito poderá não funcionar.

Para os transistores, diodos, SCRs e outros semicondutores em alguns casos pode ser indicado um sufixo que significa uma característica adicional. Por exemplo, para os transistores a última letra pode significa tanto o ganho como a tensão de trabalho, e ela deve ser observada quando se adquirir o componente. Por exemplo, o TIP31A é diferente do TIP31 porque o "A" significa que este transistor suporta uma tensão maior, conforme mostra a figura 2.

	TIP31	TIP31A	TIP31B	TIP31C
Vcb (V)	40	60	80	100
Vce (V)	40	60	80	100
Ic (A)	3	3	3	3
Pmax (W)	40	40	40	40
ft min MHz	3	3	3	3
Hfe	10-50	10-50	10-50	10-50

Figura 2 – O sufixo está associado às características do componente.

Da mesma forma, o BC548B tem um ganho maior que o BC548.

Se usarmos um BC548 comum onde se recomenda um BC548B poderemos ter problemas de funcionamento no aparelho que está sendo montado. Existem ainda os casos em que são especificadas tensões e corrente mínimas. Para os capacitores é comum indicarmos a tensão de trabalho. Na figura 3 temos alguns capacitores com as indicações de suas tensões de trabalho.

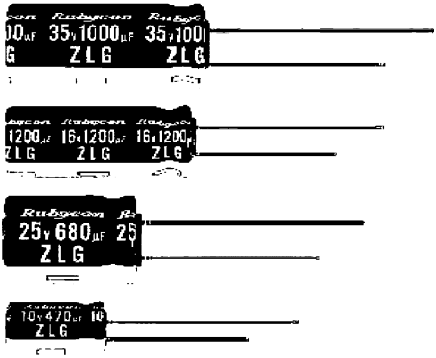

Figura 3 – Eletrolíticos com tensões de trabalho indicadas.

Esta é a tensão máxima que eles suportam e não a tensão que neles aparece quando em funcionamento. Assim, se num circuito temos tensões até uns 12 V, é comum utilizarmos capacitores de pelo menos 16 V (nos locais em que os 12 V podem aparecer), dando assim uma tolerância para funcionamento seguro.

Se um capacitor de menor tensão for utilizado, ele pode ter seu dielétrico rompido "queimando" e impedindo o funcionamento do aparelho. Para as correntes vale o mesmo. Num circuito em que tenhamos uma corrente menor do que 1 A podemos utilizar um diodo que suporte 1 A ou mais. Também é preciso estar atento às dissipações, ou seja, à quantidade de calor que o componente pode dissipar.

Se utilizarmos um resistor de 1/8 W onde se exige um de 1 W, ele esquentará demais e poderá queimar. Os resistores têm suas dissipações associadas ao seu tamanho, conforme mostra a figura 4.

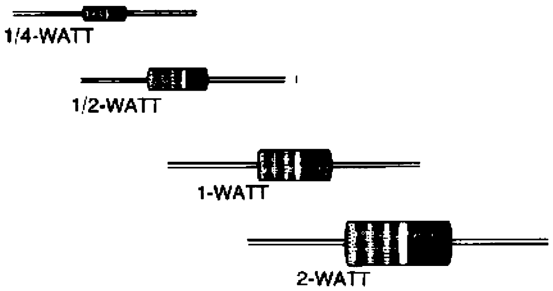

Figura 4 – Resistores maiores dissipam mais potência

Nesta relação devemos ainda incluir os componentes que devem ser "montados" em casa. É o caso das bobinas que são elementos extremamente críticos nos transmissores e receptores. Se o número de espiras, separação entre espiras, diâmetro e características do núcleo não forem obedecidas o circuito não vai oscilar na freqüência correta.

Posição de componentes polarizados

Diodos, transistores, capacitores eletrolíticos, SCRs e circuitos integrados possuem posições corretas para sua montagem. Se forem invertidos o aparelho certamente não funcionará e mais do que isso: o próprio componente pode queimar. Normalmente, nos desenhos das placas de circuito impresso são indicadas as posições dos componentes, mas para os casos em que o próprio leitor projeta a placa, ele deve conhecer o formato e a disposição dos terminais para saber como posicionar cada componente. Na figura 5 temos o modo como as posições dos componentes polarizados são indicadas.

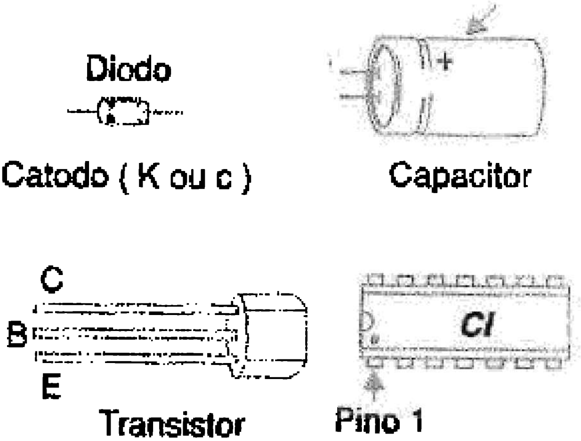

Figura 5 – Indicações de componentes polarizados ou com posição certa de montagem.

Soldas frias

Esta é, sem dúvida alguma, a maior causa de não funcionamento de aparelhos eletrônicos. Chamamos de "solda fria" aquela que "não pega". Aparentemente o componente está soldado, mas se examinarmos com uma lente veremos que ele está solto, que a solda não aderiu aos seus terminais ou à placa de circuito impresso. Resultado: a corrente não pode passar e com isso o aparelho não funciona.

O caso mais comum ocorre quando soldamos fios esmaltados de bobinas numa placa. Estes fios precisam ser raspados antes de serem soldados, pois a fina capa de esmalte que os recobre impede a aderência da solda. Na figura 6 temos alguns casos de soldas frias.

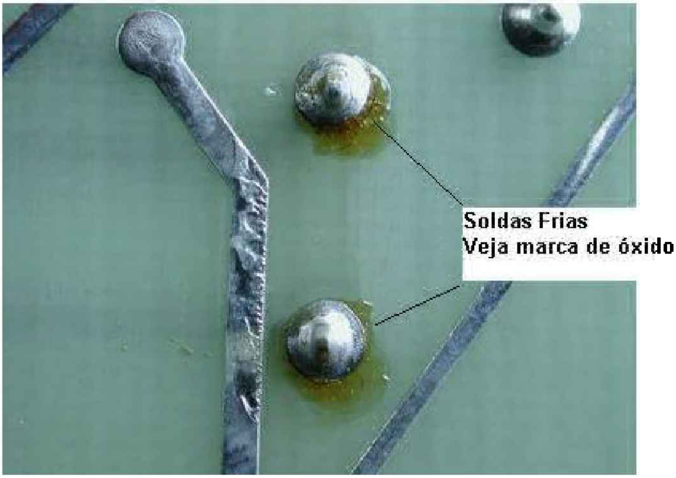

Figura 6 – Soldas frias (temperatura insuficiente do soldador ou placa suja)

Desenho de placa

Ao se elaborar uma placa de circuito impresso, diversos problemas podem ocorrer.

O primeiro é a interrupção e curto entre trilhas quando a placa é corroída. As interrupções podem ser reparadas com uma ponte de soldas e os curtos eliminados com um estilete. Na figura 7 temos algumas imperfeições na elaboração de placas de circuito impresso.

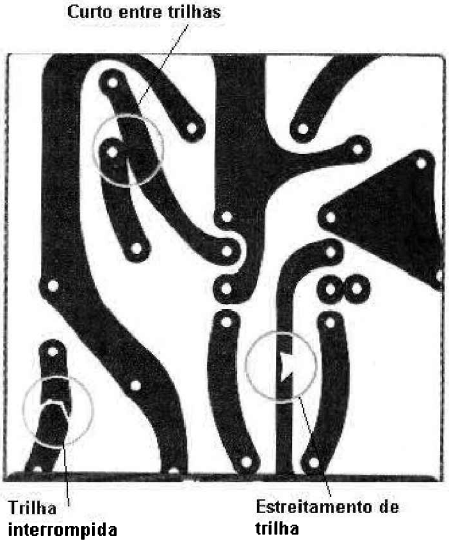

Figura 7 – Imperfeições de uma placa de circuito impresso.

De qualquer forma, antes de fazer a montagem, examine com uma lente todas as trilhas da placa para verificar se estão perfeitas. Outro problema que pode ocorrer é o projeto mal feito de uma placa. Trilhas "esquecidas" podem significar a falta de uma conexão entre componentes que vai impedir o funcionamento do aparelho.

Confira a montagem da placa com o diagrama e isso pelo menos duas vezes!

Existem também as montagens que são críticas quanto a disposição e largura das trilhas. As trilhas que trabalham com sinais de altas freqüências devem ser curtas e não podem ter curvas em ângulos retos (quinas). As trilhas que trabalham com correntes intensas devem ser largas.

Adota-se a regra geral de que para cada ampère de corrente a trilha deve ter 1 mm de largura. Numa fonte de 3 A, as trilhas que conduzem a corrente principal deve ter pelo menos 3 mm de largura.

Tolerâncias

Este é o fator que influi enormemente no funcionamento de certos aparelhos, principalmente os mais críticos. O controle sobre a ação das tolerâncias dos componentes é algo bastante difícil de fazer, principalmente quando os componentes utilizados são adquiridos em lojas comuns ou aproveitados de outros equipamentos.

O que ocorre é que, quando se projeta um circuito ou se faz a montagem de um protótipo utilizam-se componentes comuns que podem ter tolerâncias elevadas.

Por exemplo, os resistores podem ter tolerâncias de 5% a 20% enquanto que os capacitores eletrolíticos chegam a ter tolerâncias de até 40%. Isso significa que se somarmos os desvios dos valores de todos os resistores de um circuito, se por uma casualidade todos tiverem desvios no mesmo sentido o circuito poderá ser levado a uma condição em que o funcionamento se torna impossível.

Para os transistores o problema pode ser ainda mais grave. Um transistor BC548 pode ter ganhos entre 110 e 800. Se, casualmente o montador de um projeto experimental utilizar um transistor que esteja com ganho 500, portanto dentro da faixa e conseguir fazê-lo funcionar de um modo precário.

Outro montador que utilize o mesmo transistor, mas que esteja com ganho 200 (dentro ainda da faixa), não conseguirá fazer o mesmo circuito funcionar!

Existe ainda um fator agravante para o uso de transistores: um transistor de uso geral pode ser "recarimbado". Existem fornecedores desonestos que compram lotes de transistores que não passam nos testes de fábrica por estarem com suas características abaixo das exigidas e os recarimbam com designações de tipos de uso geral como BC548, 2N2222, 2N3904, etc. e os vendem.

Nas aplicações menos críticas eles funcionam, mas se for exigido um ganho maior o comprador "dança". O correto (normalmente fazemos isso nos nossos projetos) é calcular o circuito para o transistor na condição mínima de ganho.

De qualquer forma, diante de um circuito que não oscile, que tenha baixo ganho ou ainda apresente instabilidades uma possibilidade de se sanar o problema é a troca do transistor, mesmo que por um igual mas que pode estar com maior ganho...

Muitos multímetros possuem teste de transistores com indicação do ganho e existem também os provadores de transistores. Na figura 8 temos um provador de transistores.

BASE CURRENT CONTROL
TEST

Figura 8 – Um teste de transistor e diodos de baixo custo.

Será interessante ter um deles.

Fornecedor confiável, componentes confiáveis

Evidentemente, problemas de fornecimento de componentes com características diferentes das exigidas, de má procedência ou mesmo "recarimbados", podem ser evitados com um fornecedor de confiança.

Ajustes

Muitos projetos precisam de ajustes críticos para serem colocados no ponto de funcionamento. Se bem que em revistas destinadas a leitores que não tenham recursos para aquisição de instrumentos complicados a maioria dos ajustes possa ser feita sem instrumentos ou no máximo com um multímetro, existem certos cuidados a serem considerados.

O principal problema que ocorre com ajustes estão nos circuitos osciladores e de alta freqüência. É comum que o montador ajuste um circuito não para sua freqüência correta mas para uma freqüência múltipla, ou seja, uma harmônica. Quando isso acontece o circuito funciona, mas seu rendimento é bem menor que o esperado.

Num transmissor, por exemplo, o alcance ficará reduzido e o montador terá dificuldades em saber por quê. Num reconhecedor de tom de um controle remoto, por exemplo, o circuito se torna instável e começa a responder comandos indevidos, conforme mostra a figura 9.

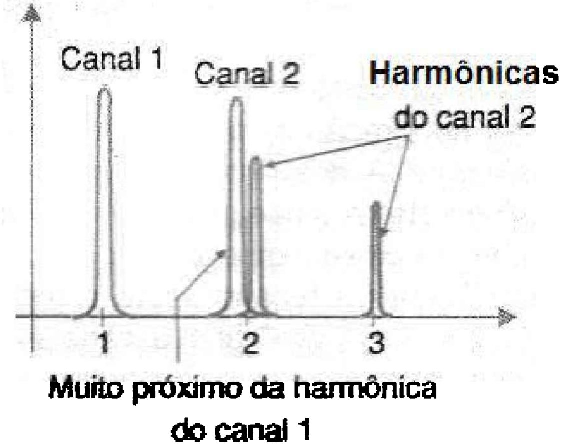

Figura 9 – Ajustes indevidos em reconhecedores de tom.

Finalmente temos até a perda de seletividade dos circuitos que começam a "misturar" estações. O melhor procedimento neste caso é tentar o reajuste em outra posição do elemento de controle (trimmer, trimpot, etc.).

Configurações semelhantes

Os circuitos eletrônicos seguem configurações que têm sempre a mesma disposição de componentes. Transistores, por exemplo, sempre têm elementos de carga (resistores, bobinas, etc.), resistores de polarização e capacitores de acoplamento e desacoplamentos, conforme mostra a figura 10.

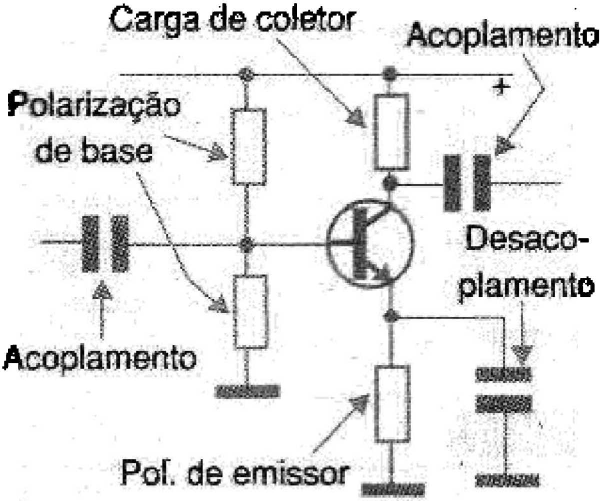

Figura 10 – Configuração comum.

Procure um circuito semelhante e veja se os valores estão compatíveis, se é daquele modo que a ligação deve ser feita, a polaridade da alimentação, etc. Se a configuração empregar um circuito integrado popular como o 555, verifique em outros artigos ou esquemas se as ligações são semelhantes para aquela função. Elas podem servir de referência, inclusive dando uma ordem de grandeza dos componentes utilizados.

Desconfiômetro

Uma outra "ferramenta" que é muito importante quando se monta algum circuito eletrônico e ele não funciona é o "desconfiômetro".

Se alguma coisa vai mal, desconfie de tudo.

Lembre-se que, pela Lei de Murphy, justamente aquilo que tem a menor possibilidade de falhar ou de estar errado é justamente o que está causando o problema na sua montagem...

Verifique tudo! Mesmo o que você tem certeza de que não é a causa do problema...

Procurando ajuda

Evidentemente, o primeiro lugar em que o leitor pensa para poder pedir ajuda é a nossa equipe técnica. No entanto, para que possamos ajuda sem ver a montagem (o que para nós é impossível – pois não temos condições de examinar um a um os projetos que eventualmente nos sejam enviados) é preciso que o leitor saiba explicar o que fez.

Muitos leitores nos enviam longas cartas descrevendo de forma imprecisa o que acontece com seus aparelhos o que dificulta bastante a possibilidade de darmos qualquer ajuda. Para que o leitor tenha sua consulta efetivamente respondida e de forma que possa ajudar proceda da seguinte forma:

Seja objetivo na sua consulta – ela deve ser curta e direta para facilitar nosso exame.

Indique sempre em que ponto do site se encontra o artigo que montou. De preferência dê o nome (ART003, PN002, etc.)

Explique de forma clara o que acontece com ele: não funciona, não dá ajuste, não tem alcance.

Indique se usou algum componente com especificação diferente da indicada na lista de materiais.

Indique se alterou valores de componentes

Se algum componente aquecer ou queimar indique qual.

Se tem um multímetro indique as tensões que pode medir nos principais pontos do circuito.

É importante também alertar que a nossa correspondência é volumosa.

Assim, não espere que uma consulta enviada pela manhã já tenha sua resposta à tarde. Precisamos de tempo para analisar o problema, localizar o artigo e, é lógico atender os leitores que estão na sua frente.

Também precisamos informar que não temos condições de alterar projetos publicados para atender às necessidades do leitor. "Como modificar o amplificador X, artigo Y para que ele se transforme numa máquina de fazer pipocas?"

Também não podemos dar opiniões sobre equipamentos comerciais ou indicar alterações. Isso ocorre porque alterações e modificações nem sempre são simples e possíveis. Mesmo quando são possíveis não podemos indicar alguma coisa ao leitor sem experimentar ou ter certeza de que funcione!

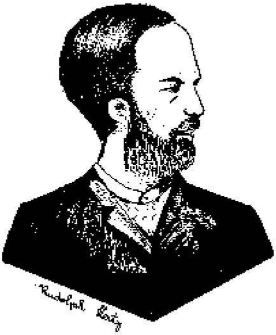
O RÁDIO

Houve época em que toda a eletrônica se traduzia numa palavra ”rádio”. De fato, naqueles tempos, o único aparelho que podia ser denominado eletrônico, e de uso comum, era o rádio. Presente em muitos lares permitia o “milagre”de ouvir vozes de pessoas distantes.

Com a evolução da eletrônica, novos equipamentos surgiram como os amplificadores para fonógrafos, gravadores, a TV e depois tudo que hoje conhecemos, uma infinidade de aplicativos a nossa disposição.

Assim, se quisermos ter uma visão da história da eletrônica, nada melhor do que usar o rádio como referência. A história do rádio está intimamente ligada a história da evolução de novas tecnologias.

Neste artigo tratamos um pouco do rádio, explicando sua origem, os diversos tipos de circuitos e algumas características importantes para projetos. Daremos até alguns circuitos práticos simples para os que desejarem fazer experimentos, ou demonstrações com finalidades didáticas.



Rudolf Hertz (desenho de Dyrce Braga)

O Início

Maxwell, através de equações matemáticas, previu a existência de ondas eletromagnéticas, da mesma natureza que as ondas de luz, que podiam se propagar no espaço com a velocidade próxima de 300 000 km/s, mas de freqüência muito mais baixa.

Lendo os trabalhos de Maxwell, um cientista alemão chamado H. R. Hertz, em 1887, realizou as primeiras experiências práticas que provaram a existência de tais ondas.

A prova foi simples, consistindo na montagem do primeiro transmissor do primeiro receptor de rádio. Produzindo faíscas elétricas num canto do laboratório, estas faíscas geravam ondas eletromagnéticas que, provocavam o aparecimento de outras num dispositivo colocado do outro lado do laboratório.

Esta experiência também serviu para a elaboração da primeira antena que consistia em placas de metal.

Guglielmo Marconi, lendo os trabalhos publicados por Hertz, relatando suas experiências, percebeu que estas ondas poderiam, ser usadas para levar mensagens, trabalhando a partir de então no aperfeiçoamento da descoberta.

Marconi desenvolveu então dispositivos capazes de gerar e receber ondas eletromagnéticas.

A partir de 1895, com apenas 21 anos de idade, Marconi deu início a uma série de experiências que culminaram com a transmissão com êxito de mensagens a navios situados a 20 km de distância da costa.

Depois, Marconi criou um sistema capaz de transmitir direcionalmente os sinais eletromagnéticos e, finalmente em 1901, um sistema capaz de transmitir sinais entre a Inglaterra e a Terra Nova, sendo essa a primeira transmissão através do Atlântico.

A primeira transmissão de radiodifusão documentada ocorreu em 1906, tendo sido realizada por R. Fessenden nos Estados Unidos.

Na véspera de natal de 1906, usando um alternador de radiofreqüência, que operava em 50 kHz, construído pela General Electric, foi realizada a primeira transmissão de radiodifusão.

O microfone usado para modular este primeiro transmissor era ligado diretamente à antena, controlando assim toda a potência aplicada. O resultado era que o microfone precisava ser refrigerado a água, tal o calor desenvolvido.

Landel de Moura

Da mesma forma que existe uma grande controvérsia em relação à invenção do avião, caso em que os americanos defendem os irmão Wright e nós Santos Dumont, podemos dizer que para o rádio existe também uma boa discussão sobre o assunto.

Os russos defendem Popov enquanto que "oficialmente", Marconi é o inventor do rádio. No entanto, existem provas de que muitos pesquisadores transmitiram e receberam ondas de rádio antes de Marconi.

É o caso do padre brasileiro Roberto Landel de Moura que enviou sinais de rádio entre pontos diferentes da cidade de São Paulo, antes de Marconi e também teria transmitido a voz e imagens na mesma época sem o devido reconhecimento.

Roberto Landel de Moura – Inventor do rádio

Somente agora suas descobertas estão sendo revistas com a atribuição do devido valor que possuem. Sugerimos aos leitores interessados que visitem o site de Luiz Netto sobre Landel de Moura em http://www.rlandell.hpg.ig.com.br/ ou ainda que leiam o livro de Hamilton Almeida, Padre Landel de Moura: um herói sem glória. O brasileiro que inventou o rádio, a TV, o teletipo...” (Editora Record).

Os Circuitos Receptores

A partir do primeiro receptor de Hertz, que consistia simplesmente numa espira com duas esferas separadas por uma distância muito pequena, onde era possível observar as faíscas, foi criado um dispositivo denominado “coesor”. O coesor era um tubinho cheio de limalha de metal, onde a presença de sinais de rádio fazia saltar faíscas, tornando-o condutor.

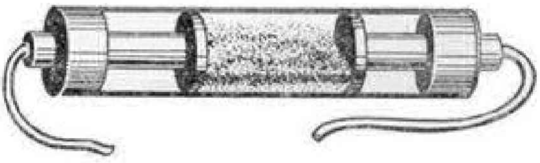


Figura 1 – o coesor de Branley, primeiro detector de sinais de rádio

Depois disso, diversos dispositivos foram criados para detectar as ondas de rádio, chegando às técnicas avançadas que hoje são utilizadas.

Rádio de Galena

Um dos primeiros tipos de rádio que existiu não utilizada nenhum dos modernos dispositivos eletrônicos que conhecemos como transistores ou circuitos integrados. Estes rádios tinham uma estrutura bastante simples, conforme mostra a figura 2.

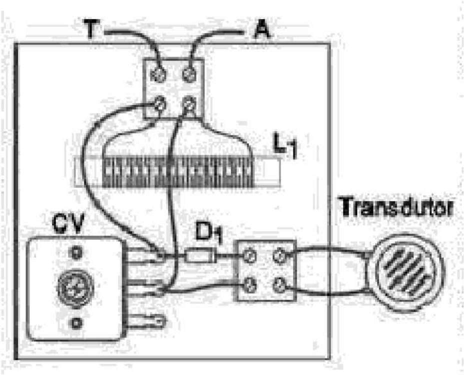

Figura 2 – Rádio de galena simples usando um diodo (D1) em lugar do cristal de galena.

Uma enorme antena (A), consistindo em fio estendido com comprimento de 10 a 50 metros de comprimento, captava o máximo de energia das ondas eletromagnéticas emitidas pela estação. Estas ondas induziam na antena correntes de alta freqüência que então eram levadas a um circuito seletor. O seletor mais simples que podemos descrever consiste numa bobina e num capacitor variável, ligados em paralelo, conforme mostra a figura 3.

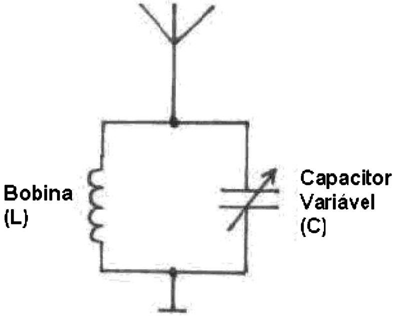

Figura 3 – Circuito de sintonia formado por uma bobina e um capacitor

Este circuito até hoje é usado na maioria dos receptores de rádio. O número de voltas de fio da bobina e a quantidade de placas do capacitor determinam a faixa de freqüências das estações que podem ser selecionadas.

Para o caso das estações de AM (amplitude modulada) de ondas médias onde as estações têm freqüência entre 530 e 1605 kHz,usando capacitores variáveis entre 270 e 465 pF, o número de voltas da bobina estará tipicamente entre 80 e 120.

Este circuito tem a propriedade de deixar passar para a terra as correntes de todas as freqüências captadas, exceto as da freqüência da estação que desejamos ouvir.

O sinal separado, da estação selecionada, é então levado a um detector de envoltória ou simplesmente detector. O detector nada mais é do que um retificador que conduz a corrente num único sentido de modo que, através de uma filtragem (filtro passa baixas), possamos separar a corrente de baixa freqüência da modulação (som) da corrente de alta freqüência que a transporta (portadora).

Isso ocorre porque o som do microfone na emissora é aplicado à "onda" que lhe transporta. A onda eletromagnética é, portanto apenas um meio de transporte para os sinais de freqüências menores que correspondem aos sons, conforme mostra a figura 4.

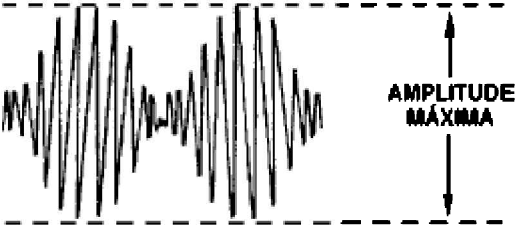

Figura 4 – Sinal de alta frequência transportando sinal de áudio (AM)

Atualmente temos componentes próprios que podem ser usados como detectores, como os diodos semicondutores. No entanto, antigamente, as coisas eram mais difíceis.

O detector tinha de ser fabricado com um cristal de galena, uma espécie de óxido de chumbo, que era montado numa base de material condutor. Um fio extremamente fino, chamado "bigode de gato", era usado para encontrar os pontos sensíveis do cristal.

O operador do rádio deveria, com muita calma e habilidade, encostar o bigode de gato em diversos pontos do cristal, até encontrar o "ponto sensível" que possibilitaria de detecção dos sinais de rádio. Sem dúvida, ouvir rádioi exigia habilidade naqueles tempos!

A corrente que temos depois do diodo já é de baixa freqüência, devendo ser filtrada antes de ser levada a um fone. O fone nada mais é do que um reprodutor de som.

Formado por uma bobina de fio fino, com a passagem da corrente é criado um campo magnético que, atuando sobre uma placa de metal chamada diafragma, a faz vibrar. Estas vibrações são transferidas para o ar na forma do som originalmente enviado a partir da estação, conforme mostra a figura 5.

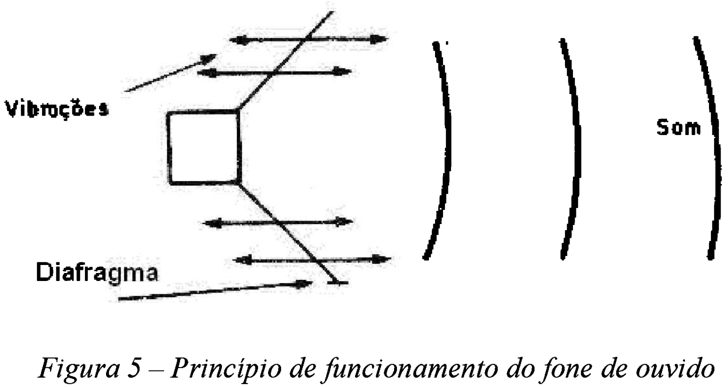

Figura 5 – Princípio de funcionamento do fone de ouvido

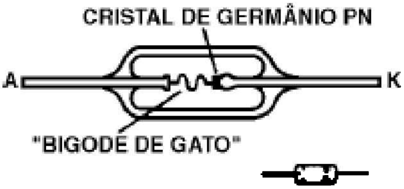
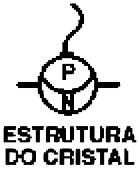
Veja que o princípio de funcionamento desse receptor é muito simples, mas apresenta muitos inconvenientes: toda a energia que vai para o fone deve ser captada pela antena. Assim, o volume do som depende da eficiência a antena na captação dos sinais.

Mesmo estações fortes ou próximas só podem ser ouvidas com o fone muito próximo do ouvido. O uso de um alto-falante é praticamente inviável com esse tipo de receptor.

Para os leitores que desejam experimentar com esse tipo de receptor, damos um circuito prático, onde a única modernização é a troca do cristal de galena (difícil de obter) por um diodo de germânio de qualquer tipo.

Esse tipo de componente já tem um "bigode de gato" interno soldado no ponto de máxima sensibilidade, evitando assim o inconveniente de se precisar encontrar o ponto sensível. O circuito é mostrado na figura 6.





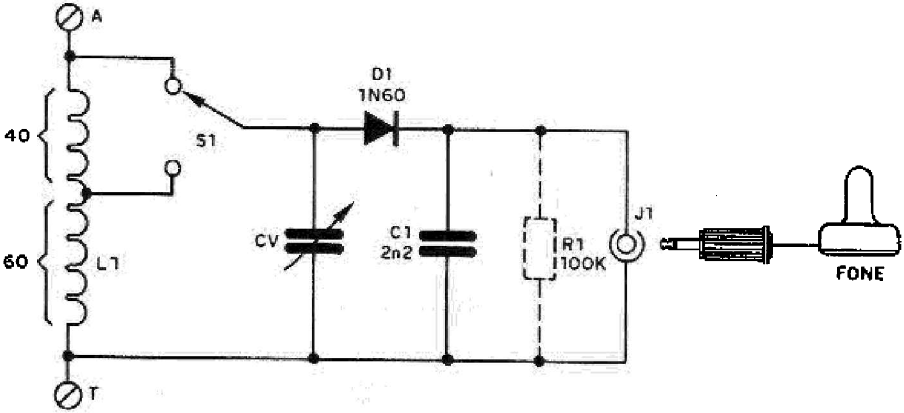


Figura 6 – O diodo de germânio e um rádio de galena
(veja mais em ART031 no site www.newtoncbraga.com.br)

A bobina é enrolada num cabo de vassoura ou tubo de PVC de aproximadamente 2,5 cm de diâmetro. Ela consta de 100 voltas de fio esmaltado 28 ou 26 (40 + 60). O capacitor variável CV é aproveitado de qualquer rádio antigo fora de uso e o fone deve ser de cristal ou magnético de alta impedância.

Sugerimos o uso de uma cápsula piezoelétrica. Não devem ser usados fones de walkman ou radinhos modernos que são de baixa impedância.

A antena deve ter pelo menos 10 metros de comprimento, consistindo num fio comum encapado. A ligação à terra pode ser feita num cano de água ou qualquer objeto de metal acessível de grande tamanho como a esquadria de uma janela.

A Válvula, o Transistor e a Amplificação Direta

Thomas Alva Edison havia descoberto um importante efeito em suas lâmpadas: quando uma placa adicional era colocada no interior da lâmpada, uma corrente podia ser detectada nesse elemento. Essa corrente, conforme se verificou posteriormente, era formada por elétrons que deixavam o filamento aquecido, conforme mostra a figura 7.

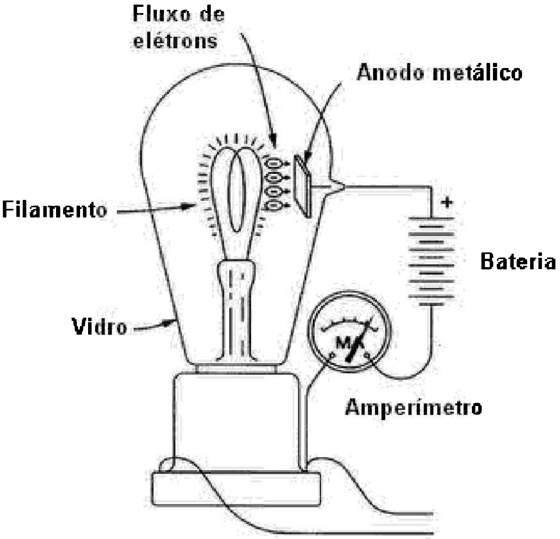

Figura 7 – A válvula diodo

J. A. Fleming, um inglês que visitava Edison justamente quando ele fez essa descoberta, observou que o dispositivo em questão funcionava como um diodo, deixando a corrente circular apenas num sentido.

Posteriormente, trabalhando nessa mesma válvula, o americano Lee de Forest, em 1906, colocou uma espécie de grade entre o filamento aquecido e a placa. Aplicando tensões nesta grade ele podia controlar a corrente que circulava entre o filamento e a placa, conforme mostra a figura 8.

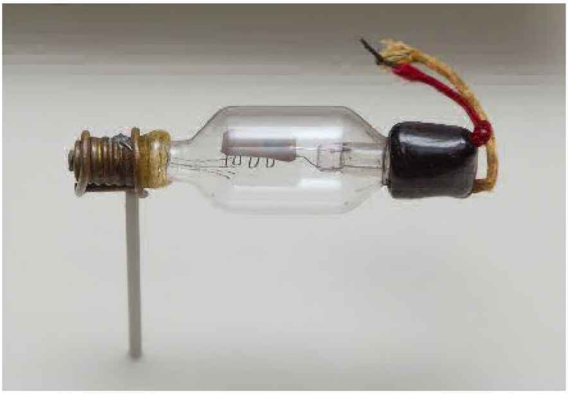

Figura 8 – Uma válvula triodo de 1906

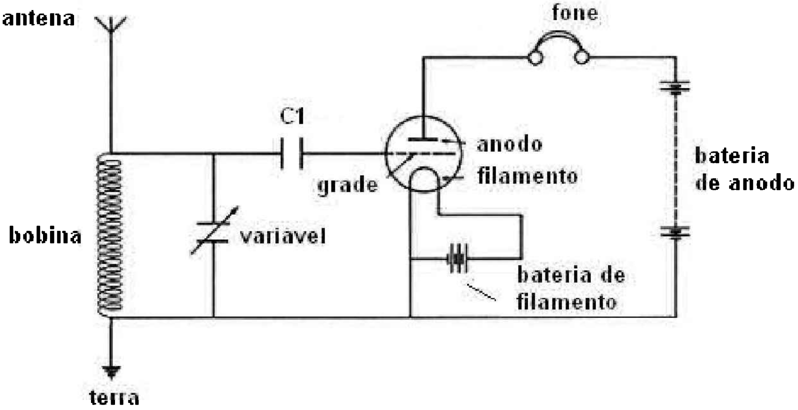
Essa configuração, denominada válvula triodo, poderia ser usada num circuito conforme mostra a figura 9, para amplificar um sinal de rádio detectado e dessa forma obter muito maior volume num fone de ouvido. Um rádio de maior sensibilidade poderia ser obtido com essa configuração.



antena
fone
C1

variavel
bateria de
filamento
terra

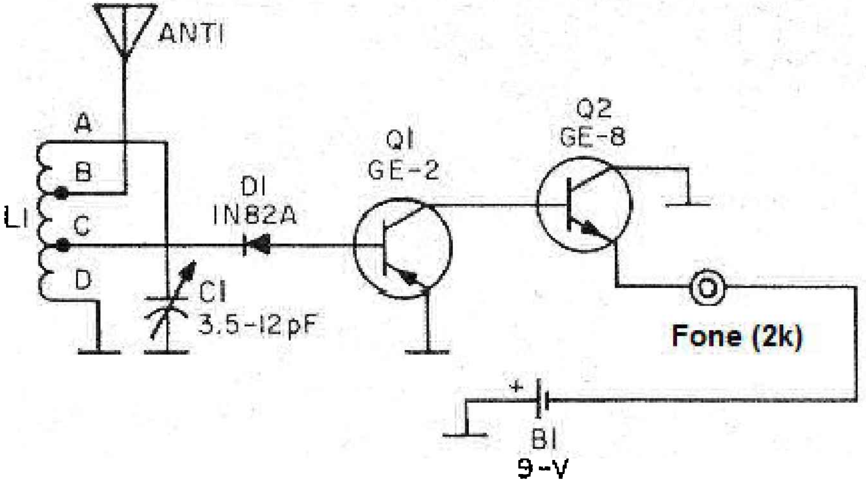
Figura 9 – Rádio com válvula triodo (audion)

Esse tipo de rádio, em que o sinal detectado (retirado do diodo) era aplicado diretamente a uma válvula amplificadora, recebeu o nome de receptor de "amplificação direta".

O transistor, que foi inventado somente em 1948, na verdade funciona como um amplificador de sinais semelhante a válvula triodo, com a vantagem de que não usa um filamento.

Pelo fato das correntes circularem num transistor através de um meio sólido (o material semicondutor), dizemos que se trata de um dispositivo de estado sólido, que substituem as válvulas com vantagens, quer seja pelo seu tamanho diminuto, quer seja pela pouca energia que precisam para funcionar.

Na figura 10 temos um receptor de amplificação direta, equivalente à configuração valvulada que mostramos na figura 9, mas que usa um transistor.



Se o leitor quiser montá-lo, a bobina é formada por 80 espiras de fio esmaltado 28 ou mais fino, com tomada na 30ª e 50ª espira, e o capacitor variável pode ser aproveitado de qualquer rádio antigo.

O diodo é de germânio e o fone deve ser de alta impedância ou de cristal com um resistor em paralelo. A antena deve ter pelo menos 5 metros de comprimento.

Entretanto, já nos tempos das válvulas verificou-se que a recepção dos sinais poderia ser melhorada através do uso de diversos artifícios, que também podem ser usados em circuitos transistorizados (com finalidades experimentais).

No caso dos transistores, o que ocorre é que quando eles surgiram, as técnicas de recepção já estavam suficientemente desenvolvidas para se adotar a melhor. Assim, as outras ficaram apenas como curiosidades históricas.

Receptores Reflex

Verifica-se que uma válvula triodo tanto podem amplificar os sinais detectados como os próprios sinais de alta frequência captados pela antena. Num receptor reflex utiliza-se a mesma válvula para amplificar duas vezes o sinal: na primeira vez o sinal amplificado é o de alta frequência, vindo do circuito de sintonia.

Logo depois da amplificação, este sinal é detectado, voltando então a componente de baixa frequência à mesma válvula, onde recebe nova amplificação. Daí ele pode então ser aplicado ao fone de ouvido. Na figura 11 temos um circuito de um receptor desse tipo.

Receptores Regenerativos

Outra técnica interessante usada na recepção de sinais de rádio consiste na regeneração. O que se faz é amplificar o sinal uma vez e depois "jogá-lo" de volta à entrada do mesmo amplificador, para que ele receba nova amplificação. Uma mesma válvula (ou transistor) tem então sua capacidade de amplificação multiplicada, com resultados bastante interessantes. Na figura 13 temos um rádio desse tipo usando uma válvula.

Figura 13 – Um receptor regenerativo valvulado (V008 no site do autor www.newtoncbraga.com.br)

A bobina L3 sintoniza o sinal, enquanto que L1 é usada para "jogar" de volta o sinal amplificado. Este tipo de circuito tem uma característica interessante: se a regeneração for muito forte, ou seja, muito do sinal "for jogado de volta" na entrada, ele entra em oscilação, ou seja, o sinal começa a "rodar" pelo circuito num processo que impede a audição de qualquer estação, aparecendo apenas um forte apito no fone.

Existe então um controle que "dosa" a regeneração de modo que ela seja máxima, mas não o suficiente para ocorrer a oscilação. Isso o operador pode perceber facilmente, pois no momento em que o ponto crítico é ultrapassado, o fone "apita".

Na figura 14 temos um circuito de um receptor transistorizado regenerativo.

A bobina L2 consiste em 20 + 80 espiras de fio 28 num bastão de ferrite e L120 espiras sobre L2. Os transistores podem ser os BC548

Diversas Etapas

É claro que, em lugar de se usar apenas uma válvula ou transistor para amplificar o sinal, é possível usar diversos. O sinal passa de um para o outro sendo amplificado, até atingir a intensidade desejada.

Com um número suficiente de válvulas ou transistores pode-se chegar a intensidade suficiente para excitar um alto-falante. Na figura 15 temos circuitos de rádios com diversas etapas, usando transistores (mais podem ser encontrados na parte prática deste livro). Evidentemente são circuitos que têm apenas finalidade didática.

Figura 15 – Rádios de mais de uma etapa

Tente montar o segundo circuito transistorizado. A bobina L1 tem 80 voltas de fio esmaltado 28 e L2 é formada por 20 espiras, tudo num bastão de ferrite de 210 a 15 cm. O capacitor variável é do tipo usado em rádios AM. O fone deve ser piezoelétrico de alta impedância e B1 é formada por 4 pilhas pequenas.

A antena pode ser um pedaço de fio estendido de 3 a 5 metros de comprimento, já que temos muito maior sensibilidade do que nos receptores dados anteriormente. Essa antena pode ser ligada à base do primeiro transistor.

Mas, mesmo com diversas etapas, os rádios ainda não podem ser considerados ideais, pois apresentam problemas como:

Instabilidade: muitas etapas tendem a gerar oscilações por sinais que voltam às etapas de entrada. Apitos e ruídos podem ocorrer.

Falta de seletividade: o rádio não consegue separar estações que transmitem em freqüências próximas.

Para solucionar estes problemas existem outras técnicas que apareceram com o tempo, algumas das quais muito engenhosas.

Neutrodinos, Sincrodinos e Outros

Nesta fase da história do rádio, passou-se a ter uma preocupação maior com a estabilidade dos circuitos. Assim, um primeiro passo foi o que levou aos receptores denominados neutrodinos. Um processo de neutralização evitava que ocorressem oscilações por realimentação entre as diversas etapas do circuito.

No receptor sincrodino, o circuito gerava um sinal sincronizado com o da estação, dando assim maior estabilidade ao circuito. No entanto, esse rádios logo foram superados por uma categoria de circuito que existe até hoje: o superheteródino.

O Superheteródino

Como conseguir aliar alta sensibilidade a uma ótima seletividade e tudo isso num circuito de grande estabilidade? A resposta para este problema está no circuito superheteródino.

Rádios de todos os tipos e até mesmo receptores de TV e telecomunicações modernos se baseiam nesta configuração que se revela satisfatória para a maioria dos casos em que a recepção dos sinais deva ser feita de forma estável e sensível.

Na figura 16 temos a estrutura em blocos de um receptor superheteródino, a partir da qual procuraremos explicar o funcionamento da maneira mais simples possível.

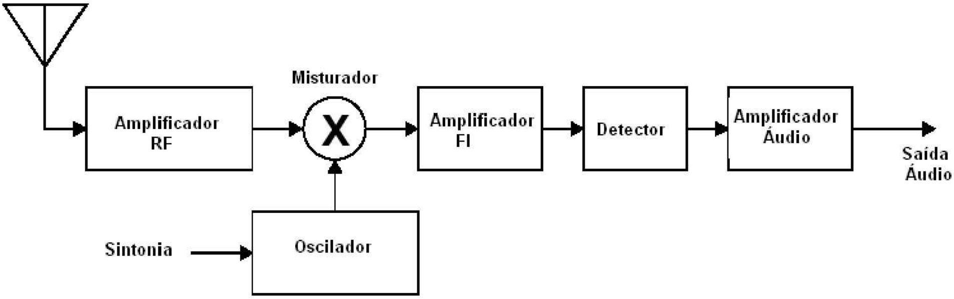

Figura 16 – Receptor superheteródino em blocos

Os sinais são captados pela antena e levado a um circuito de sintonia, onde o sinal da estação que se deseja ouvir é separado. O primeiro passo desse sinal é ser processado por uma etapa chamada misturadora.

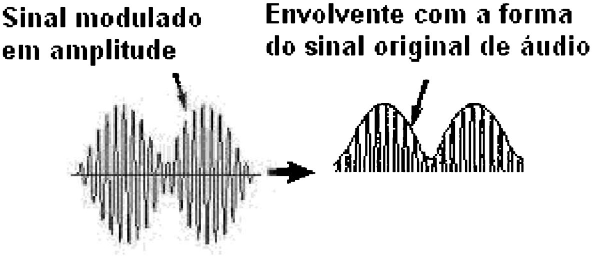
A função da etapa misturadora ou misturador é simplesmente combinar o sinal da estação selecionada com um sinal que é gerado no próprio receptor. Este sinal deve ter uma frequência, que no caso do AM, deve ser 455 kHz maior que o sinal captado e no caso do FM, 10,7 MHz maior.

A mistura dos dois sinais provoca um fenômeno denominado batimento ou heterodinagem: obtemos na saída da etapa dois sinais que correspondem à soma e diferença de suas frequências. Como a diferença é fixa, 455 kHz ou 10,7 MHz, as etapas seguintes podem perfeitamente trabalhar com frequências fixas, não se necessitando mais de circuitos de sintonia variável.

Nos receptores de AM temos então etapas amplificadoras seguintes operando em 455 kHz e nos de FM, operando em 10,7 MHz. Estas etapas são denominadas "de FI" ou "Frequência Intermediária".

O sinal de FI que leva então a informação do sinal original captado, tendo apenas uma frequência, pode ser amplificado por uma ou duas etapas adicionais até ficar suficientemente intenso para poder ser detectado.

A detecção é feita então da maneira convencional: nos rádios AM usamos um diodo que detecta a envolvente, ou seja, separa a modulação do sinal original de sua portadora, conforme mostra a figura 17.



Sinal modulado em amplitude
Envolvente com a forma do sinal original de áudio

Figura 17 – Detecção do sinal modulado em amplitude

Nos rádios de FM utiliza-se um circuito denominado discriminador, pois a modulação é feita de modo diferente. De qualquer forma, a partir dessa etapa temos no circuito apenas sinais de baixas frequências ou áudio que correspondem aos sons originais emitidos.

Podemos então amplificá-los ainda mais, mas agora usando um amplificador comum de áudio. O volume ou potência do som que obteremos na saída vai depender das características deste amplificador.

Nos rádios de FM estéreo, existe ainda um circuito adicional que é o decodificador (multiplex) que faz a separação dos sons dos dois canais que são enviados a dois amplificadores diferentes.

Assim, para rádios portáteis ou do tipo walkman, temos pequenos amplificadores com potências da ordem de milésimos de watt (mW), para os rádios maiores e de carro, as potências aumentam para vários watts e finalmente nos grandes sons, essa potência podem superar os 100 W. Na figura 18 temos um circuito típico de receptor superheteródino.

O leitor não deve tentar montar esse rádio. O que ocorre é que as técnicas industriais que levam à produção em massa fazem uso de circuito integrados que unem todas as funções em chips (circuitos integrados) e eles são fabricados por máquinas automáticas que barateiam sua produção.

Conclusão

Circuitos integrados podem reunir milhares ou milhões de componentes possibilitando a elaboração de receptores extremamente complexos e eficientes. As novas técnicas que vão possibilitar a transmissão da informação na forma digital para o rádio comum já estão a caminho.

Assim, tudo o que vimos passará definitivamente para a história, uma história muito interessante que alguns de nós viveram uma boa parte, testemunhando até a época em que o rádio era considerado uma das maravilhas da tecnologia e a TV ainda era uma simples curiosidade acessível a poucos.

Apresentação

Durante nossa longa carreira como escritor de artigos técnicos, incluindo também informações, abordamos o termo Coletânea de Circuitos. Assim, há diversos anos passados, abordando este tema, publicamos as séries “Circuitos e Informações” (7 volumes) e “Circuitos e Soluções” (5 volumes) contendo centenas de circuitos úteis e informações técnicas de todos os tipos. As séries se esgotaram, o tempo passou, mas os leitores ainda nos cobram algo semelhante atualizado e que possa ser usado ainda em projetos de todos os tipos. De fato, circuitos básicos usando componentes discretos comuns, de transistores a circuitos integrados, são ainda amplamente usados como solução simples para problemas imediatos, parte de projetos mais avançados e até com finalidade didática atendendo à solicitação de um professor que necessita de uma aplicação para uma teoria,ou de um aluno que precisa fazer um trabalho. Assim, voltamos com esta série, mas com uma estrutura diferenciada, novos projetos e nova abordagem. O diferencial na abordagem será dividir os diversos volumes da série por temas. Assim, no nosso primeiro volume tivemos circuitos de áudio, depois circuitos de fontes, no terceiro, circuitos osciladores, e assim por diante. Chegamos ao trigésimo primeiro volume com uma seleção de circuitos de Rádios e Transmissores, a segunda da série, pois na primeira não conseguimos colocar todos os circuitos que temos. Na verdade como temos uma enorme quantidade de circuitos em nosso estoque, mais de 9000 deles e a cada dia este estoque aumenta, já fizemos 1 volume anterior com circuitos de transmissores e receptores, mas temos muito mais. Muitos dos circuitos apresentados podem ser acessados de forma dispersa no site do autor e também em outros livros. A vantagem de se ter estes circuitos organizados em volumes, além do acesso em qualquer parte, está na fácil localização de um circuito de determinado tipo. Teremos ainda artigos complementares de utilidade, relacionados com os temas abordados. A maioria destes circuitos, colhidos em publicações que, em alguns casos, podem não ser muito atuais, recebe um tratamento especial com comentários, sugestões e atualizações que viabilizam sua execução mesmo em nossos dias. Enfim, com esta série, damos aos leitores a oportunidade de ter em seus tablets, iPhones, iPads, PCs, notebooks e outras mídias uma fonte de consulta de grande importância tanto para seu trabalho, como para seus estudos ou simples como hobby.

Newton C. Braga

Introdução

Depois do sucesso da seção Banco de Circuitos no meu site e das coleções esgotadas de Circuitos e Informações e Circuitos e Soluções, levo aos meus leitores uma coletânea de circuitos selecionados de minha enorme coleção de documentos técnicos e livros. Durante minha vida toda colecionei praticamente todas as revistas técnicas de eletrônica estrangeiras, dos Estados Unidos, França, Espanha, Itália, Alemanha, Argentina e até mesmo do Japão, possuindo assim um enorme acervo técnico. Não posso reproduzir os artigos completos que descrevem os projetos que saem nessas revistas, por motivos ditados pela lei dos direitos autorais, mas a mesma lei permite que eu utilize uma figura do texto, com citação, comentando seu conteúdo para efeito de informação ou complementação de um conteúdo maior. É exatamente isso que faço na minha seção no site e também disponibilizo neste livro. Estou selecionando os principais circuitos destas publicações, verificando quais ainda podem ser montados em nossos dias, com a eventual indicação de componentes equivalentes, fazendo alterações que julgo necessárias e disponibilizando-os aos nossos leitores. Para o site já existem mais de 9000 circuitos, no momento que escrevo este livro, mas a quantidade aumenta dia a dia. Acesse o site, que ele poderá lhe ajudar a encontrar aquela configuração que você precisa para seu projeto. Os 100 circuitos selecionados para esta edição da série são apenas uma pequena amostra do que você vai encontrar no site. Para esta edição escolhemos mais uma remessa com 100 circuitos de receptores e transmissores, tais como rádios AM, transmissores de AM, FM e CW e muito mais. Estes circuitos, na maioria dos casos, podem ser montados com facilidade, já que na maioria usam componentes comuns. Fica por conta do leitor a obtenção das partes necessárias, caso deseje ter uma montagem prática.

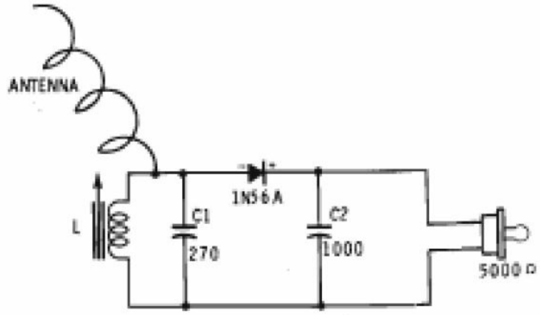
Conserte Tudo

1 - Rádio de Cristal

Este circuito tradicional de rádio de cristal, mas que tem a versão moderna com diodo foi encontrado numa revista italiana Sperimentare de 1977. O fone também pode ser de cristal e a bobina consta de 100 espiras de fio 28 num tubo que pode deslizar sobre um bastão de ferrite para fazer a sintonia. A antena deve ser bem longa. O diodo pode ser o 1N34 ou 1N60 também.



2 - Rádio de Cristal (2)

Este circuito é de um manual de transistores da Raytheon de 1957. O diodo pode ser de germânio de uso geral como o 1N34 e a bobina enrolada com 30 + 70 espiras de fio 28 num bastão de ferrite. A antena deve ser longa e o fone deve ser magnético de alta impedância. O variável pode ser obtido num rádio AM comum.

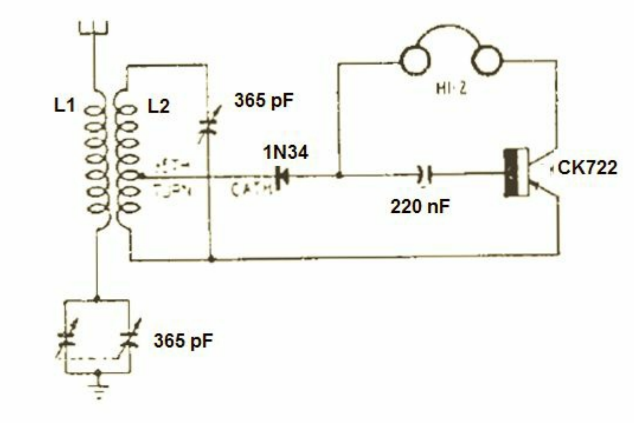
Diode – 1 Raytheon 1N295.

3 - Rádio sem Fonte de Energia

Este receptor usa a própria tensão induzida pelo sinal da estação para alimentar o amplificador com 1 transistor. O transistor é o CK722, o primeiro transistor comercial do mundo, lançado pela Raytheon na década de 50. O fone deve ser de alta impedância e as bobinas têm as seguintes características: L1: 30 espiras de fio 28, L2 60 + 40 espiras de fio 28, as duas no mesmo bastão de ferrite. Qualquer transistor PNP de germânio pode ser usado.



4 - Galena Tradicional

Este circuito é de uma publicação do início do século XX. O detector é um cristal de galena e a bobina formada por 100 espiras de fio 28 com a parte em que desliza o cursor raspada. A forma é de 3 a 5 cm. A antena deve ser longa e o fone magnético de alta impedância

5 - Galena Completo de 1922

Os planos de construção deste receptor de galena de 1922 foram encontrados numa publicação de Hugo Gernsback. Na figura temos todos os detalhes construtivos do rádio de ondas médias da época. O fone deve ser de alta impedância (acima de 2k) e a antena muito longa. O cristal de galena pode ser substituído por um diodo 1N34 ou equivalente.

6 - Galena com Capacitor Variável

Este rádio de galena usa um capacitor variável de construção caseira. O circuito é do início do século XX. A bobina é formada por 100 espiras de fio 28 ou próximo num tubo de PVC ou papelão de 2,5 cm de diâmetro. Pode ser usado um capacitor variável de rádio AM comum a e antena deve ser bem longa. A ligação à terra é importante.

7 - Receptor a Cristal Potente

O circuito mostrado na figura foi encontrado numa publicação de 1964. Os diodos podem ser de germânio e L2 têm 100 4espiras de fio 28 num bastão de ferrite. L1 é enrolada sobre L2 com 30 espiras. L3 é formada por 22 voltas de fio 22 no mesmo bastão de ferrite em que é enrolada L3. Os diodos podem ser 1N34 e o fone é cerâmico ou magnético de alta impedância. A antena deve ser longa.

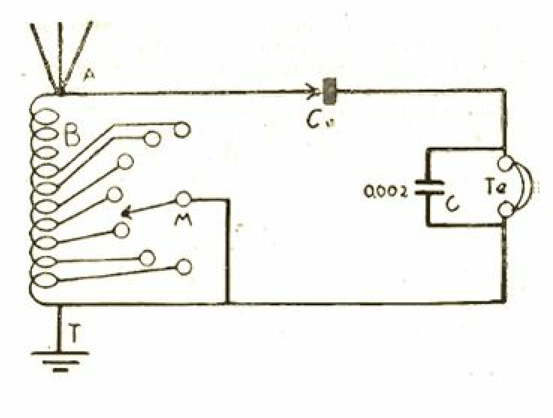
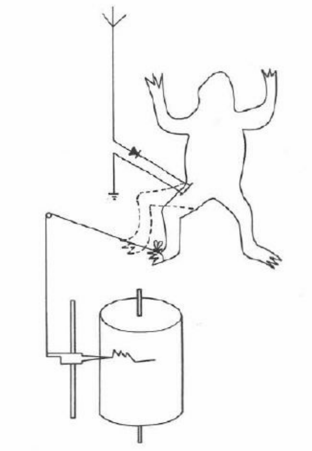
8 - Galena de 1926

Encontramos este circuito na revista La Radio per Tutti da Itália de 1926. A bobina pode ser elaborada com 100 espiras fio 28 num tubo de papelão ou PVC de 2 a 2,5 cm e com tomadas de 10 em 10 ou de 15 em 15 espiras. A antena deve ser longa e o cristal de galena pode ser substituído por um diodo de germânio. O fone deve ser de alta impedância. O capacitor C pode ser de 2n2 cerâmico.



9 - Rádio com Detector de Perna de Rã

Sim, é isso mesmo: perna de rã. Naquela época os experimentos de Galvani com "eletricidade animal" faziam crer que a eletricidade que se manifestava nos seres vivos era diferente da eletricidade natural e muitos experimentos foram feitos com a excitabilidade das pernas de rã. O circuito mostrado é de uma publicação de 1921 e mostra um detector de sinais de rádio usando uma perna de rã.



10 - Rádio de 1 Transistor de 1957

Encontramos este rádio AM num manual de aplicações de transistores de 1957, publicado pela Raytheon. O transistor pode ser um equivalente moderno como o BC558 e a bobina tem 20 + 80 espiras de fio 28 num bastão de ferrite. O fone deve ser de alta impedância.

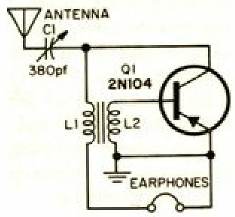
12 - Receptor Sem Alimentação

No receptor apresentado, de uma documentação de 1964, um transistor é usado como detector, funcionando sem alimentação. A antena deve ser muito longa e L1 formada por 100 espiras de fio 28 num bastão de ferrite. L2 é formada por 30 espiras do mesmo fio sobre L1. O fone é de alta impedância. Qualquer transistor pode ser usado, mas melhores resultados são obtidos com tipos antigos de germânio.



13 - Micro Receptor de AM

Este circuito experimental que preferivelmente deve usar transistor de germânio foi encontrado numa publicação de 1964. A bobina é formada por 30 + 70 espiras de fio 28 num bastão de ferrite. A antena deve ser longa e o circuito funciona com células fotoelétricas comuns, como as obtidas em velhas calculadoras. O fone deve ser magnético de alta impedância.

43 - Receptor Para 11 Metros

Este receptor recebe os sinais da faixa de PX ou Rádio Cidadão em 27 MHz. O circuito é de uma publicação americana dos anos 60 e o componente crítico é a bobina. A bobina é formada por 8 + 8 espiras de fio 22 em forma de 1,5 cm sem núcleo. O transformador T1 é de rádios transistorizados (driver) e a saída é em fone de alta impedância.

45 - Transmissor OM Experimental

Este circuito foi obtido numa revista Italiana Sperimentare de 1975. A bobina consta de 100 espiras de fio 28 num bastão de ferrite e os transistores podem ser equivalentes mais modernos como os BC548. A sintonia pode ser feita em C5, trocando por um capacitor variável de um velho rádio de ondas médias. A antena telescópica pode ser ligada ao coletor de TR3.

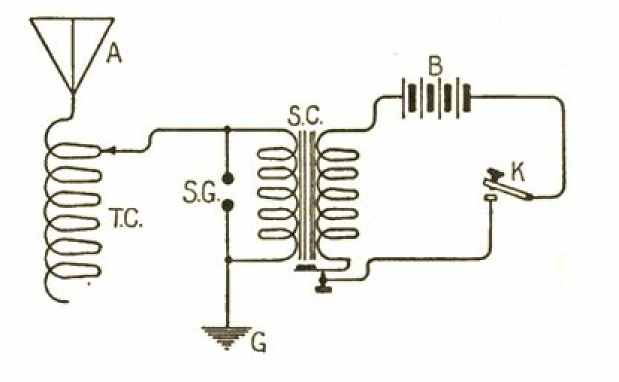
46 - Transmissor de Centelha

Este circuito é de uma publicação de Hugo Gernsback de 1922. O circuito gera centelhas que produzem ondas determinadas pela bobina TC. SC é um transformador de alta tensão podendo ser usada uma bobina de ignição. A alimentação pode ser feita com tensões de 6 a 12 V.



47 - Microfone sem Fio AM

Encontramos este circuito de pequeno alcance para a faixa de ondas médias numa publicação de 1964. L1 consta de 80 espiras de fio 28 num bastão de ferrite e sobre ela é enrolada L2 com 20 espiras do mesmo fio. O transistor pode ser o BC558 e a antena é telescópica de 30 a 90 cm de comprimento. O microfone deve ser de carvão. Se for usado cerâmico, ligue em paralelo um resistor de 10 k.

68 - Transmissor de FM Experimental

Encontramos este circuito numa publicação francesa dos anos 80. A bobina L1 e L2 são formadas por 4 espiras de fio 26 em forma de 1 cm de diâmetro com tomada central. T2 pode ser um 2N2222 e T3 um 2N2218 ou outro de maior potência. O circuito deve ser alimentado por fonte, dado seu consumo, ou ainda por pilhas grandes.

90 - Grid Dip Meter

Este circuito é de uma publicação americana de 1973. Podemos implementá-lo com o NF494 para o transistor de RF e BC548 para os demais. A lâmpada pode ser trocada por um LED em série com um resistor de 220 ohms. A bobina depende da frequência que se deseja detectar. O diodo é de germânio como o 1N34. O circuito opera até uma frequência de algumas dezenas de megahertz.

100 - Transmissor Integrado Sem Bobinas

O TAA131 usado neste circuito não é muito fácil de encontrar atualmente, mas pode ser usado um amplificador de áudio de baixa potência equivalente em seu lugar. O transmissor não utiliza bobinas, tem curto alcance e sua faixa de sintonia, bastante precária é muito ampla com a emissão de muitas harmônicas. Trata-se de circuito experimental.

A Qualidade dos Rádios AM

Com o final das transmissões da faixa de ondas médias terminando, com a migração das emissoras para a faixa de FM, devemos fazer algumas considerações sobre a tecnologia antiga do AM que dominou por muitos anos a radiodifusão e as novas tecnologias que estão chegando como, por exemplo, o rádio digital.

Sempre gostei de ouvir rádios AM, pois é ainda nesta modalidade de transmissão que temos a maioria das transmissões de jogos de futebol e também noticiários.

Se bem que as notícias possam ser vistas no computador, ainda é agradável para muitos não precisar ficar olhando para a tela, pois desejam descansar, numa rede, por exemplo, ou simplesmente sem se preocupar com nada.

No interior, as emissoras de AM ainda têm bastante força, pois em alguns casos, elas chegam nos sítios e fazendas onda a internet ainda não chegou, consistindo sua audição num hábito das pessoas mais velhas.

No entanto, mesmo podendo encontrar rádios AM à venda, tem nos preocupado a perda de qualidade desses aparelhos.

Antigamente, era possível comprar um bom rádio AM com excelente sensibilidade e seletividade capaz de sintonizar emissoras distantes ou fracas sem problemas.

Tais rádios utilizavam a tecnologia do super-heteródino com diversos circuitos sintonizados (FIs) capazes de aumentar a seletividade e com muitas etapas de amplificação, tinham excelente sensibilidade.

Rádios como o Transglobe, Moto-Rádio eram comuns e os preferidos por quem desejava uma boa recepção.

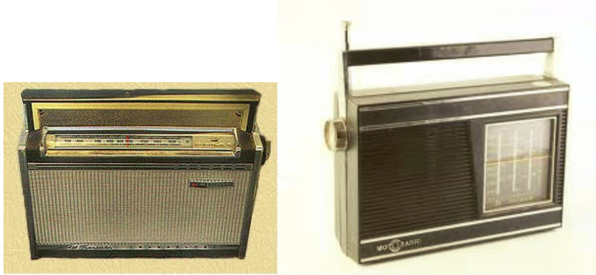

FIGURA 1 – RÁDIOS TRANSGLOBE DA PHILCO E MOTO-RADIO AM

Hoje, o que temos são rádios AM de procedência chinesa que, para maior economia, usam chips únicos com amplificadores de RF e Áudio simples, para reduzir custos e etapas de amplificação direta.

FIGURA 2- RADIO AM DE BAIXA SELETIVIDADE E SENSIBILIDADE

Essas etapas simplesmente detectam o sinal de áudio captado pela antena de ferrite sem que eles passem por outros circuitos sintonizados.

O resultado disso é uma perda de seletividade e de sensibilidade que afetam em muito a qualidade de recepção.

A faixa de ondas curtas de tais rádios é péssima, e a de ondas médias muito ruins quando se deseja sintonizar uma estação mais fraca ou mesmo separar estações próximas.

A não disponibilidade de bons receptores é talvez uma das causas da alegação de que o AM "está sujeito a muitas interferências e ruídos", que está levando justamente a migração para o FM.

Sim, está sujeito a mais interferências e ruídos, mas isso foi minimizado durante muito tempo com bons receptores.

Fiz uma experiência muito simples, para mostrar isso.

Liguei meu Moto-Rádio antigo perto de meu computador e mesmo assim, pude ouvir com clareza a maioria das estações de AM que costumo sintonizar, facilmente "driblando" as interferências que estavam presentes.

No entanto, meu rádio chinês de baixo custo não conseguiu sintonizar sequer a mais forte das estações que costumo ouvir.

Sim, vamos mudar para o FM e depois para o digital, mas não há necessidade de desativar o AM que ainda pode ser recebido em muitos locais, sem problemas, desde que estejam disponíveis bons receptores...

AJUSTE DE RÁDIOS AM

Muitos ainda possuem rádios e FM com circuitos tradicionais (super-heteródinos) com boninas de FI, osciladora e antena que precisam estar corretamente ajustadas para se obter um bom funcionamento. Os técnicos que recebem estes receptores eventualmente, dependendo do componente trocado, precisam refazer o ajuste. Damos a seguir os procedimentos possíveis:

Procedimento 1:
O primeiro procedimento de ajuste que vamos dar é “de ouvido”, sendo indicado para o caso do leitor não possuir um gerador de sinais.

a) Sintonize uma estação fraca no meio da escala (em torno de 900 a 1000 kHz).

b) ajuste os núcleos dos transformadores de FI, começando pelo terceiro (que está ligado ao detector) de modo a obter o melhor nível de sinal.

c) Os ajustes devem ser feitos com ferramentas não magnéticas (plástico ou madeira) conforme mostra a figura 1.

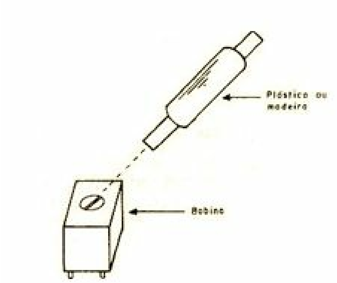

FIGURA 1 – USANDO FERRAMENTAS NÃO METÁLICAS PARA O AJUSTE.

Use o diagrama do receptor para identificar os transformadores de FI do receptor, lembrando que o vermelho não deve ser tocado, pois é a bobina osciladora.

d) Procure agora sintonizar uma estação no extremo superior da faixa de ondas médias (entre 1300 e 1600 kHz). Procure uma estação de frequência conhecida, de preferência.

e) Mova o trimmer do oscilador junto ao variável até que, retocando a sintonia você consiga levar a estação sintonizada para a frequência correta, se ela estiver incorreta.

Na figura 2 mostramos a localização deste trimmer (veja que o trimmer do oscilador “muda” a frequência do sinal sintonizado, enquanto que o outro trimmer do variável, que é de sintonia, atua sobre a intensidade do sinal).

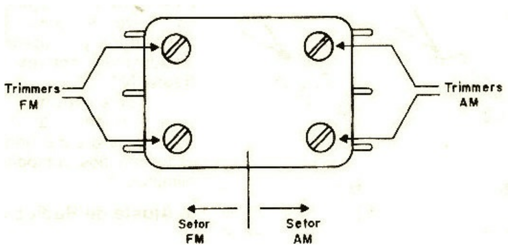

FIGURA 2 – LOCALIZAÇÃO DO TRIMMER DE AJUSTE DO OSCILADOR.

f) Sintonize agora uma estação de frequência conhecida no extremo inferior da faixa de ondas médias, entre 520 e 700 kHz.

g) Ajuste o núcleo da bobina osciladora (vermelha) para que o sinal seja captado no ponto correto da escala, se estiver fora dela (indicação errada). Isso será necessário, por exemplo, se a estação transmitir em 550 kHz e você a captar em 600 kHz.

h) Sintonize agora novamente uma estação no extremo superior da faixa e ajuste o trimmer do capacitor variável para que seu sinal seja captado com máxima intensidade.

i) Volte a sintonia para a estação do extremo inferior e mova o núcleo da bobina de antena (de núcleo de ferrite) até obter o melhor sinal. Este ajuste é feito deslocando-se levemente a bobina sobre o bastão de ferrite conforme mostra a figura 3.

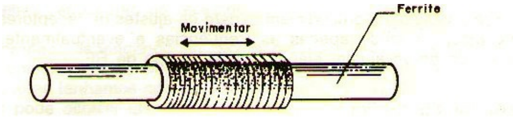

FIGURA 3 – AJUSTANDO A BOBINA DE ANTENA PELA POSIÇÃO DO NÚCLEO DE FERRITE.

j) refaça todos os ajustes algumas vezes até obter o melhor rendimento.

k) Fixe a posição da bobina de antena no núcleo de ferrite pingando algumas gotas de cera de vela.

Procedimento 2:

O procedimento que vamos ver agora faz uso de instrumentos, no caso o gerador de sinais ou RF que produza sinais na faixa de 100 kHz a 10 MHz pelo menos. Ajustes das FIs:

a) Coloque o gerador de sinais em 455 kHz e aplique seu sinal ao receptor de uma das formas indicadas no procedimento anterior.

b) Ajuste os núcleos das bobinas com uma ferramenta não magnética até obter o máximo de sinal no alto-falante (maior nível de apito).

c) Refaça os ajustes várias vezes, pois eles são interdependentes.

Ajustes de RF:

a) Certifique-se que o receptor a ser calibrado está com a chave seletora na posição de ondas médias (OM) de 520 ou 550 a 1600 ou 1630 kHz.

b) Conecte o gerador ao receptor usando para isso a antena ou ainda um elo de acoplamento, conforme mostra a figura 4.

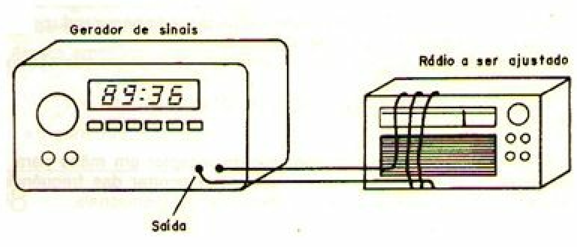

FIGURA 4 – ACOPLANDO O GERADOR DE SINAIS OU FUNÇÕES AO RECEPTOR QUE DEVE SER AJUSTADO.

c) Coloque a sintonia no extremo superior da faixa (1600 kHz).

d) Ajuste o gerador para fornecer um sinal modulado na frequência máxima sintonizada pelo receptor.

e) Ligue o receptor e retoque o trimmer do oscilador (junto ao variável) até ouvir o sinal do gerador. Ajuste sua intensidade para que o sinal não sature o receptor, mas seja apenas audível, pois devemos nos orientar pelo aumento de sua intensidade na reprodução.

f) Coloque gora a sintonia do receptor no extremo inferior da faixa de ondas médias, em torno de 540 kHz.

g) Coloque o gerador de sinais para produzir um sinal na mesma frequência em que o receptor está sintonizado.

h) Ajuste o núcleo da bobina osciladora até que o sinal seja captado.
Reduza a intensidade do sinal do gerador se ele estiver se tornando muito forte.

i) Reajuste o núcleo da bobina osciladora até obter a máxima intensidade, agora com um nível de sinal menor do gerador.

j) Ajuste a sintonia do receptor para o extremo superior da faixa, em torno de 1450 kHz.

k) Coloque o gerador na mesma frequência. Ajuste levemente a sintonia do receptor até que o sinal seja localizado. Se estiver muito longe da frequência desejada refaça os ajustes iniciais até conseguir isso.

l) Ajuste o trimmer de antena para que haja maior intensidade de sinal.

m) Coloque o gerador de sinais para produzir um sinal em 700 kHz.

n) Ajuste a sintonia do receptor para a mesma frequência do sinal. Se esse sinal não for captado, desloque a bobina de antena sobre o núcleo de ferrite até que ele seja sintonizado.

o) Obtida a sintonia fixe a bobina com um pouco de cera de vela.

p) Refaça os ajustes pelo menos duas vezes, pois eles são interdependentes.

AJUSTANDO TRANSMISSORES

O máximo rendimento de um transmissor, e também a menor possibilidade de se irradiar sinais indesejáveis, só se consegue com um ajuste perfeito de todos os seus circuitos. No entanto, não basta ter um transmissor e se fazer sua conexão a uma boa antena para se garantir que o bom funcionamento esteja garantido. Como ajustar um transmissor e como obter o máximo de seu rendimento é o que veremos agora.

Um transmissor ideal, corretamente ajustado, deve emitir sinais numa única frequência e com a máxima intensidade possível. Porém, na prática, não é isso o que ocorre.

Os circuitos não são perfeitos, gerando sinais espúrios e harmônicas; o acoplamento a antena e o próprio cabo não são perfeitos, gerando reflexões responsáveis por ondas estacionárias e a própria antena não é perfeita, não irradiando 100% da energia que recebe de um transmissor.

Tudo isso faz com que o sinal que realmente sai de uma estação fique reduzido em diversas proporções, levando transmissores de igual potência, com o mesmo circuito, quando instalados a apresentarem desempenhos completamente diferentes.

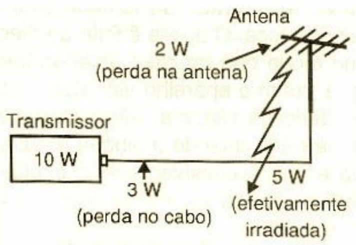

Fig. 1 - Perdas podem afetar o rendimento de uma estação transmissora.

Até a própria topografia do local em que o transmissor é instalado pode influir no seu desempenho, dependendo de sua faixa de frequências, com a dificuldade que os sinais podem encontrar para passar por determinados obstáculos ou se propagar em função de um terreno de baixa condutividade elétrica.

Colocar um transmissor em condições de funcionar com o máximo rendimento não é simples, exigindo-se um profundo conhecimento técnico de quem vai fazer isso.

Para cada modalidade de operação, para cada tipo de instalação, para cada tipo de antena existem procedimentos típicos que vão desde o ajustes dos circuitos, até a instalação dos cabos e posicionamento da antena.

Neste artigo falaremos especificamente dos ajustes dos circuitos, mostrando como devem ser feitos.

MODULAÇÃO

Os transmissores mais comuns usados por radioamadores, em transmissores de radiodifusão e em alguns serviços públicos operam com modulação em amplitude ou modulação em frequência (AM ou FM).

Na modulação em amplitude, a intensidade do sinal varia com o sinal de áudio que deve ser transmitido, ou ainda o sinal de vídeo se for uma emissão de TV analógica, conforme mostra a figura 2.

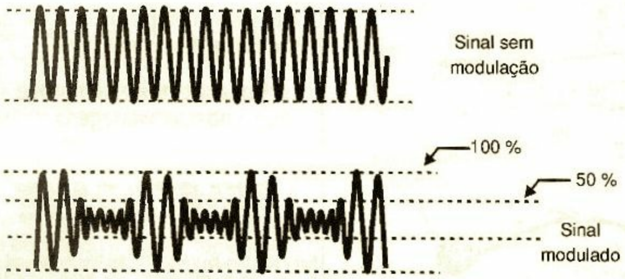

Fig. 2 - Sinal modulado em amplitude.

Nesta figura mostramos um sinal sem modulação, ou seja, um sinal portador de alta frequência puro ou sem modulação e um sinal modulado.
Veja que o sinal de áudio que vai modular a portadora e que portanto corresponde à informação transmitida faz com que a amplitude do sinal de alta frequência varie de 50% sua intensidade.
Nos pontos de menor amplitude temos 50% da intensidade dos pontos de maior amplitude. Dizemos, neste caso, que este sinal tem uma modulação de 50%.
Para que uma transmissão tenha o máximo rendimento, o ideal é que ela tenha uma porcentagem de modulação maior, ou seja, 100%.
Isso significa que, nos pontos de menor intensidade o sinal praticamente deve ser cortado quando nos pontos de maior intensidade temos a amplitude máxima do sinal que o transmissor pode gerar, conforme mostra a figura 3.

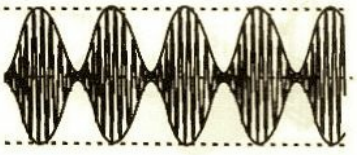

Fig. 3 - Sinal com 100% de modulação.

Tudo seria simples no ajuste se aplicando uma boa potência a um transmissor conseguíssemos chegar aos 100% de modulação com facilidade. Mas, não é isso o que ocorre.
Se a potência do sinal modulador for muito pequena teremos uma modulação de menos de 100% e o rendimento do transmissor não será dos melhores.
No entanto, se excedermos a potência que o circuito precisa para modulação, ocorre uma sobremodulação, ou seja, mais de 100% de modulação, conforme mostra a figura 4.

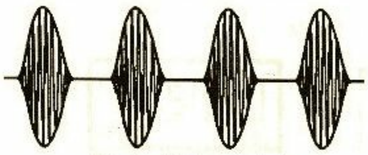

Fig. 4 - Sinal com mais
de 100% de modulação sobremodulação.

O problema da sobremodulação não é apenas a distorção que ocorre com a informação que o sinal carrega, mas também a produção de sinais espúrios que causam fortes interferências.
Parte da potência do transmissor é então desviada para estes sinais e com isso o rendimento do equipamento na frequência que se deseja transmitir cai.
Como medir a porcentagem de modulação?

OSCILOSCÓPIO

O osciloscópio é um instrumento de grande utilidade também no ajuste de transmissores.

Com ele podemos ver a porcentagem de modulação de um sinal modulado em amplitude com facilidade, conforme mostra a figura 5.

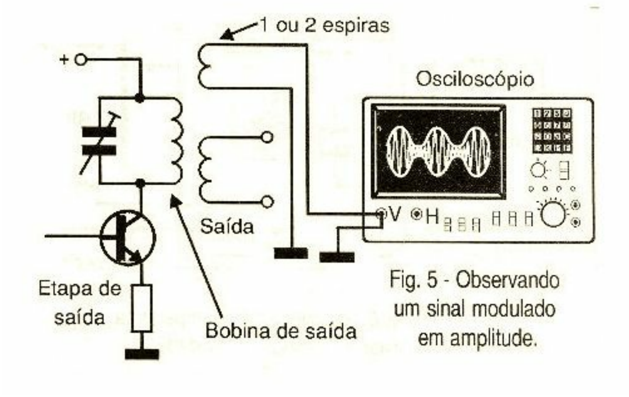

Fig. 5 - Observando um sinal modulado em amplitude.

Basta fazer um elo de captação de sinal e colocá-lo junto à bobina do tanque de saída do transmissor, conforme mostra a figura, e aplicar um sinal de áudio senoidal na entrada do transmissor, por exemplo 1 kHz.

Podemos visualizar na tela do osciloscópio o sinal modulado e fazer os ajustes no sentido de obter 100% de modulação.

Uma outra maneira de se medir a porcentagem de modulação de um transmissor é com o arranjo mostrado na figura 6.

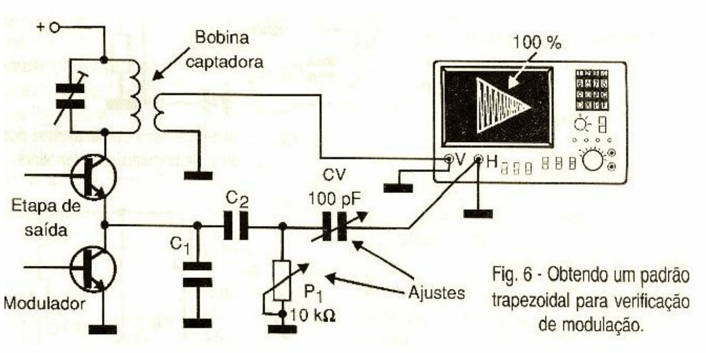

Fig. 6 - Obtendo um padrão trapezoidal para verificação de modulação.

Neste arranjo, a varredura horizontal é desativada, ou seja, colocada na posição de "varredura externa" ou EXT,.

O sinal de varredura vai então ser fornecido pelo transformador de modulação do próprio transmissor conforme indicado no mesmo diagrama.

O sinal do transmissor será então aplicado à entrada vertical do osciloscópio sendo retirado da saída do transmissor com a ajuda de um elo de captação.

Este elo pode ser formado por algumas espiras de fio comum colocado próximo da bobina tanque de saída do transmissor.

Veja que o transmissor deve estar conectado a uma carga fantasma nestes testes já que sem antena corre-se o perigo de provocar a queima dos transistores de saída.

As formas de imagem obtidas com este arranjo são mostradas na figura 7, indicando as porcentagens de modulação.

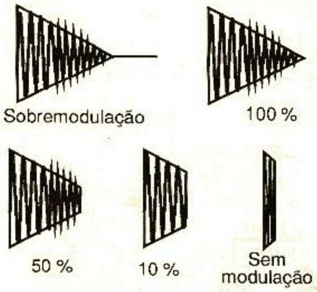

Fig. 7 - Formas de visualização para diferentes porcentagens de modulação.

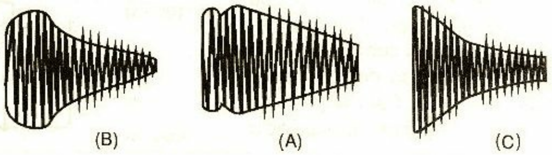
A porcentagem de modulação será obtida dividindo-se o comprimento relativo da base menor do trapézio pelo comprimento da base maior.
Se o padrão trapezoidal tiver deformações como as mostradas na figura 8, isso indica que os circuitos de RF podem ter problemas de linearidade.

Fig. 8 - Deformações que indicam problemas de circuito e não de ajuste.



A presença de barras verticais no padrão mostrado, por exemplo indica que a etapa de potência do circuito não está devidamente neutralizada com tendência à oscilação.

AJUSTE DE TRANSMISSORES DE FM

A verificação do funcionamento dos transmissores de FM é um pouco mais complexa, exigindo métodos diferentes.
Duas quantidades devem ser analisadas quando examinamos o funcionamento de um transmissor de FM: desvio de frequência e linearidade.

a) verificando a frequência

A frequência de um transmissor de FM, sem modulação, deve ser estável e mantida num valor determinado, mesmo quando as condições ambientes variam (temperatura, umidade, etc.).
Os transmissores comerciais, para que isso realmente ocorra, são controlados por cristais, os quais são mantidos em câmaras térmicas, conforme mostra a figura 9.

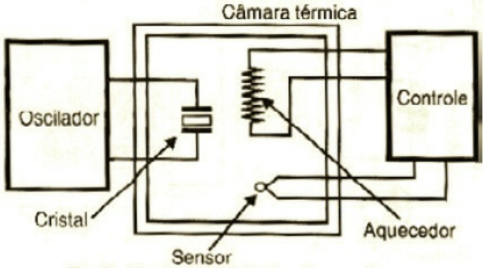


Fig. 9 - Mantendo constante a temperatura do cristal para maior estabilidade.

Nestas câmaras a temperatura é mantida constante graças a um sensor e a um elemento de aquecimento.

O ajuste da frequência é simples, já que hoje pode-se contar com frequencímetros de precisão que medem as frequências produzidas pelos circuitos com facilidade.

Mesmo os frequencímetros mais baratos podem ser usados com a ajuda de um prescaler.

Este dispositivo, conforme mostra a figura 10, divide a frequência de um sinal por um valor inteiro (10 por exemplo) possibilitando assim o uso de frequencímetros de menor alcance na medida de frequências mais altas.

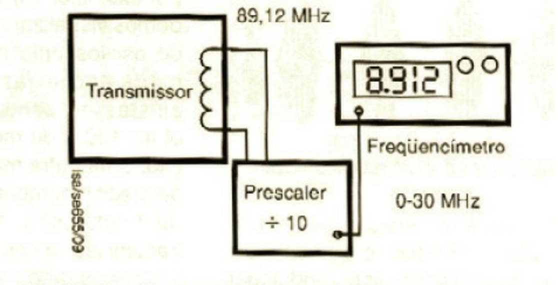

Fig. 10 - Estendendo o alcance de um fenômeno com um *prescale*

b) Desvio

Um sinal modulado em frequência tem sua frequência variando com a informação (áudio, por exemplo), conforme mostra a figura 11.

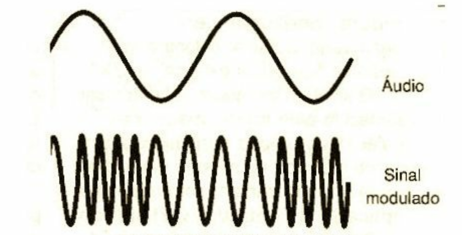

Fig. 11 - Sinal modulado frequência.

Isso significa que, com a máxima intensidade de modulação, este sinal deve ter sua frequência variando em torno do valor central entre dois valores muito bem determinados.

Veja que não é a frequência do sinal que determina a frequência que o sinal de alta frequência se desloca mas sim sua amplitude.

Esta largura de faixa é que vai determinar a eficiência na recuperação da informação nos circuitos discriminadores do receptor.

Se o transmissor estiver mal calibrado, com um desvio muito pequeno do sinal, a tensão na saída do discriminador será pequena e o sinal de áudio recuperado fraco.

Do mesmo modo, se o desvio for muito grande, o sinal "satura" o discriminador e a informação não é recuperada da forma desejada, conforme mostra a figura 12.

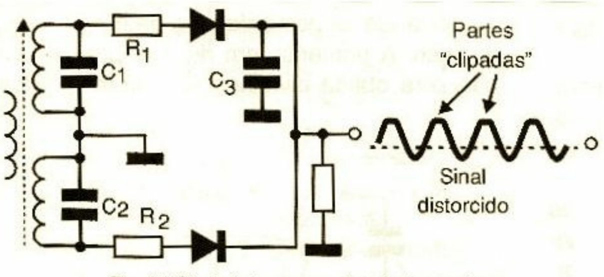

Fig. 12 Sinais intensos ou desajustes podem afetar a demodulação de um sinal.

Na figura 13 temos um circuito simples que permite a medida do desvio de frequência de um sinal modulado em frequência.

Figura 13

Este circuito foi originalmente sugerido no Radio Amateur Handbook (edição de 1987) e os transistores usados podem ser substituídos por equivalentes como os BC548 ou equivalentes/

O circuito é ligado na etapa discriminadora de qualquer receptor de FM antes do circuito de ênfase.

O transformador usado pode ser qualquer um do tipo encontrado em velhos rádios transistorizados com impedâncias de 100 a 1000 ohms de primário e 8 ohms de secundário.

O que se faz então é sintonizar o sinal de um transmissor de FM e ligar este circuito observando a indicação do instrumento.

O instrumento deve ser ajustado com base num sinal que tenha uma modulação-padrão.

Normalmente esta modulação é feita com um sinal que provoque um desvio de 15 kHz de frequência na frequência do sinal central.

Para esta edição escolhemos mais uma remessa com 100 circuitos que podem ser usados para interfacear com microcontroladores tendo como ponto de partida o Arduino. No entanto, eles também são compatíveis com outros microcontroladores como PICs, MSP430. E muitos outros, em alguns casos exigindo apenas modificações ou alterações de valores de componentes. Estes circuitos, denominados Shields, podem ser tanto usados para transferir os sinais de um microcontrolador a um circuito externo, como podem ser os próprios circuitos externos usados pelo microcontroladores. Eles também podem ser usados para transferir sinais de sensores e outras fontes para os microcontroladores. Todos eles usam componentes comuns.

We can say that in this serie we will give to the readers the opportunity to have in their tablets, iPhones, iPads and PCs a powerful source of ideas for projects and informartions. Microcrocontrollers such as Arduino, MSP430, PICs and others can´t source a large amount of current to loads like motors, relays and lamps. They also can´t work with signals sourced by some types of sensors plugged to their inputs. In these cases they need special ads, circuits to allow the use of power loads and sensor. These circuits are called shields. This book is a collection of 100 circuits of shields including drive to high current loads, motors, sensor, to produce audio signals and much more.

Em 1976 publicávamos nosso primeiro livro, uma coletânea de projetos simples para amadores, iniciantes e estudantes, que chamamos de Experiências e Brincadeiras com Eletrônica. O livro fez um sucesso incrível com a venda de dezenas de milhares de exemplares. O grande sucesso da época pode ser constatado ainda hoje quando encontramos professores universitários, engenheiros em cargos de chefia de grandes empresas, profissionais donos de grandes empresas que nos falam, com satisfação, que graças a este livro e a esta série eles se interessaram por eletrônica, seguindo então suas carreiras de sucesso. Ainda hoje, encontramos profissionais que guardam suas edições como verdadeiras relíquias, ou tesouros de valor incalculável, pois elas representam muito em sua vida, na verdade, o ponto de partida de sua vida profissional. Muitos, ao nos encontrar, já não tendo suas edições nos perguntam se não temos "guardada no fundo do baú" uma edição antiga para lhes ceder. Infelizmente, as que temos também são guardadas a sete-chaves, pelo seu valor e justamente pegando uma delas, a primeira, resolvemos atender, não só os que desejam ter em mãos esta relíquia, tanto na versão impressa como virtual, para recordação dos "bons tempos" de inicio de carreira, como desejam algo mais: iniciar seus filhos e netos nesta maravilhosa ciência que é a eletrônica. Assim fizemos um novo livro baseados naquele, uma edição inicial (e depois virão as outras) em que usamos os projetos originais, inserimos notas ou comentários que visam facilitar quem deseja repetir aquelas montagens em nossas dias ou iniciar seus filhos, netos ou jovens de uma sala de aula num curso de iniciação ou num clube de eletrônica. Enfim, uma nova edição baseada num livro histórico com a abordagem que tanto sucesso fez na época.

Con esta serie, damos a los lectores la oportunidad de tomar sus tablets, iPhones, iPads, PCs, notebooks y otros medios de comunicación una fuente de consulta de gran importancia tanto por su trabajo y para sus estudios o para un simple hobby. Los 100 circuitos seleccionados para esta edición de la serie son sólo una pequeña muestra de lo que encontrará en el sitio. Para esta edición hemos elegido otro envío con 100 circuitos que pueden utilizarse para el Arduino y otros microcontroladores como punto de partida. Sin embargo, también son compatibles con otros microcontroladores tales como fotos, MSP430, PIC y muchos otros, en algunos casos requiriendo sólo modificaciones o actualizaciones a los valores de los componentes. Estos circuitos, llamados shields, pueden ser utilizados para transferir señales de un microcontrolador a un circuito externo, como sus propios circuitos externos utilizados para microcontroladores. También puede utilizarse para transferir señales de sensores y otras fuentes para los microcontroladores. Todos utilizan componentes comunes y en muchos casos aprovechados de aparatos fuera de uso.

During more than 30 years, as a collaborator with American, European and Latin American electronics magazines (*), has published a large assortment of practical circuits using common parts. In 1999 he included the first selection in a volume published by Prompt Publications in USA. The idea was to proceed with the series, publishing many volumes more. But, Prompt closed his activities and the idea was forgotten although the first volume became a best seller. Now with his own publishing house (NCB Publications) the author returned with the idea of make many volumes more of the series. So, the second volume is here proceeding with the same idea: give simple projects to the experimenters who want learn electronics using common parts and with no need of special knowledge about electronics. So, as in the first volume, many of the projects collected by the author are included in this volume, most of which you can build in one evening. The projects range from fun types through practical types to amusement types. Of course, there are other devices that can be used to teach you something about circuits and components. An important feature of theses projects are the ideas to Explore, intended for students looking for projects in science or to use in practical research. This ideal can be complemented by our book Science Fair and Technology Education Projects, also published in English by the author. We can consider this book as a source book of the easiest and fun-to-make of hundreds of projects created and published by the author during his life. (see more about Newton C. Braga in "about the author" in his site).

Prólogo **al contenido**

La electrónica comenzó con el diodo de vacío, cuando John Ambrose Fleming colocó una lámina dentro de una bombilla para evitar el ennegrecimiento en la ampolla de vidrio. Pasó más de un siglo de esta invención y la electrónica evolucionó a pasos agigantados, hasta llegar a la actual era digital.

Ingresar en el universo de la Electrónica Digital es descubrir cómo se componen y funcionan muchos de los dispositivos tecnológicos que se utilizan en la actualidad, tanto en el ámbito hogareño como en el industrial y en el de entretenimiento. El bajo costo de aplicación, la versatilidad y la eficiencia de los sistemas digitales permiten su aplicación en las computadoras, en los equipos de telefonía, en los de comunicaciones y en una larga lista de dispositivos de alta complejidad. Estos aspectos son solo algunos de los motivos por los cuales invitamos a los lectores a recorrer este apasionante mundo.

Tanto el aficionado a la Electrónica como el hobbista –aquél que tiene algunas nociones teóricas y prácticas en sistemas digitales– encontrarán, en este libro, las herramientas para realizar sus primeros proyectos.

El material teórico y práctico que abarca esta obra se alinea en un solo sentido: explicar todos los fundamentos de la Electrónica Digital y su aplicación real y práctica. Por medio de un despliegue editorial de alto impacto visual y de ágil lectura, el lector encontrará una respuesta para cada una de las preguntas que se plantee.

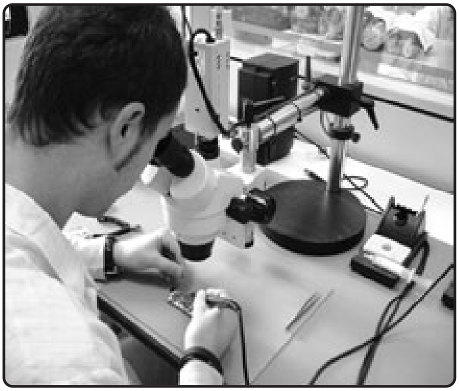
www.FreeLibros.me

El libro **de un vistazo**

Este libro está enfocado a aficionados de la electrónica, hobbistas y a todo aquel que tiene algunas nociones teóricas y prácticas en sistemas digitales. A lo largo de la obra, veremos cómo aplicar los conocimientos adquiridos mediante proyectos prácticos..

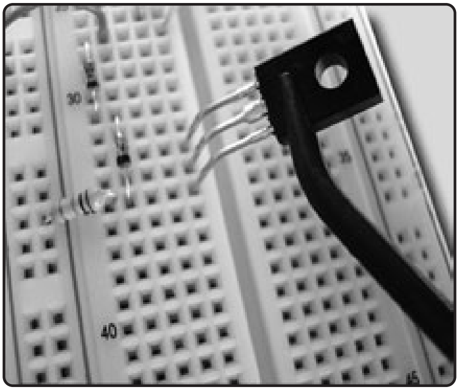
CAPÍTULO 1
ELECTRÓNICA DIGITAL

Conoceremos las primeras nociones de electrónica digital, cuáles son sus alcances y los límites que debemos respetar. Veremos las herramientas más importantes y qué instrumentos no nos pueden faltar.



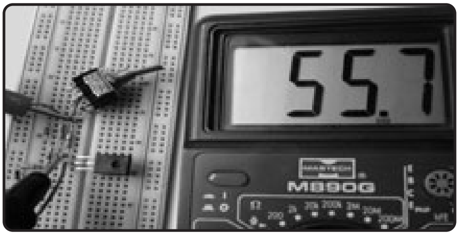
CAPÍTULO 2
CONSTRUCCIÓN DE CIRCUITOS

Comprender las bases de la composición de los circuitos digitales resulta de suma importancia para poder abordar, más adelante, los procesos complejos.



CAPÍTULO 3
INSTRUMENTOS DE MEDICIÓN

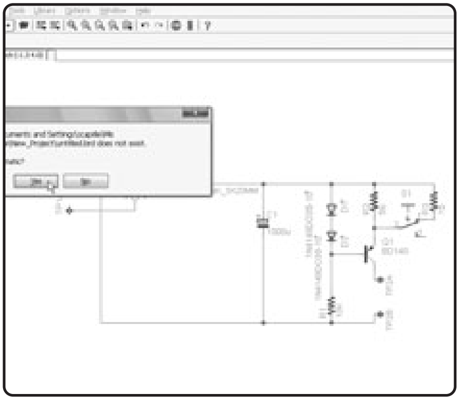
En este capítulo, explicaremos cuáles son las medidas que podemos realizar sobre un circuito, cuál es la manera apropiada de hacerlo y qué instrumentos necesitamos.



www.FreeLibros.me

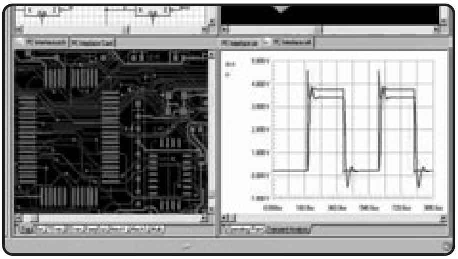
CAPÍTULO 4
DISEÑO DE CIRCUITOS IMPRESOS

Conoceremos las características, funciones y limitaciones de algunos paquetes de diseño para la creación, edición y gestión de proyectos electrónicos.



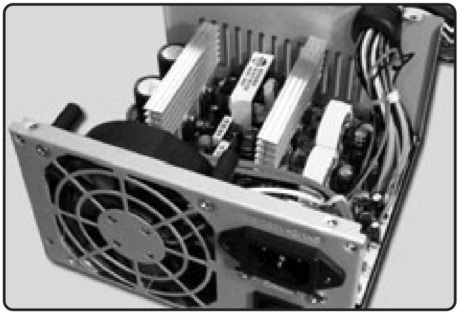
CAPÍTULO 5
SIMULACIÓN DE CIRCUITOS EN LA PC

En esta clase explicaremos qué es la simulación de circuitos, su utilidad en el proceso de diseño y cómo simular un circuito, utilizando el software ISIS.



CAPÍTULO 6
FUENTES DE ALIMENTACIÓN

La fuente de alimentación es la encargada de proveer la tensión adecuada para el correcto funcionamiento de un circuito. Conoceremos sus características y funciones.



APÉNDICE
EL MERCADO LABORAL

En este apéndice, describiremos el amplio abanico laboral sobre el cual se desarrollaran las personas con conocimientos en electrónica.

SERVICIOS
AL LECTOR

En este último apartado, encontraremos un índice temática que nos ayudará a encontrar de forma más rápida y precisa los principales conceptos de la obra.

Introducción a Electrónica Práctica

Este libro, realizado por expertos, ofrece un extenso y muy completo recorrido por el maravilloso mundo de los sistemas digitales, donde tanto el ensayo como el error son claves fundamentales para perfeccionarse.

A lo largo de los primeros capítulos, conoceremos cuál es el alcance de la Electrónica y sus aspectos prácticos. Veremos en detalle las herramientas e instrumentos infaltables para un taller que se especialice en este área. Además, nos familiarizaremos con la construcción de circuitos electrónicos mediante la utilización de un protoboard.

Una vez que conozcamos las primeras nociones sobre el tema, nos iniciaremos en el mundo de la instrumentación electrónica: aprenderemos a usar el voltímetro, el amperímetro y los multímetros digitales, para medir los parámetros más importantes de un circuito. Siguiendo el orden de aprendizaje, conoceremos el proceso de simulación de circuitos en la PC con ISIS y su utilidad en proyectos electrónicos.

Además, desarrollaremos cuáles son los programas y las funciones para simular el comportamiento real de un circuito electrónico. Por otro lado, conoceremos las funciones y las características de las fuentes de alimentación, su utilidad y los diferentes tipos existentes. Aprenderemos cada una de las etapas de su circuito y los parámetros para diseñar.

Encontrarán, en esta obra, las herramientas para realizar sus primeros proyectos. Es una excelente oportunidad para que transitemos juntos este sorprendente recorrido donde se combinan aspectos vinculados con la programación, el hardware y la Robótica, entre muchos otros. A lo largo de todo el libro, encontrará un completo desarrollo teórico y podrá llevar a cabo proyectos de aplicación real.

www.FreeLibros.me

Capítulo 1

Electrónica Digital

En este primer capítulo, haremos una introducción a los principales conceptos de Electrónica Digital.

RedUSERS.com

www.FreeLibros.me

Electrónica **Digital**

En la actualidad, y desde hace muchos años, la **Electrónica Digital** ha estado presente en infinidad de aparatos domésticos, industriales y militares (**Figura 1**). Nació al mismo tiempo que la **Electrónica Analógica**, pero tomó especial significación desde el momento en que se empleó para el diseño y la construcción de **sistemas básicos de cómputo**, el **control industrial**, los **autómatas programables**, los **microcontroladores**, los **microprocesadores** y los **computadores personales**. Gracias a que la Electrónica Digital considera solo dos valores –concepto que veremos más adelante–, es mucho más simple procesar y manipular las señales de forma digital que hacerlo de manera analógica. Esta ventaja se produce a partir de que esta última resulta inexacta y costosa, considerando la gran cantidad de componentes que necesita para su fabricación: **transistores** y **resistores electrónicos**.

> La Electrónica Digital ha estado presente en infinidad de aparatos domésticos, industriales y militares

FIGURA 1. **Actualmente, la electrónica brinda un abanico de posibilidades laborales muy diversas.**

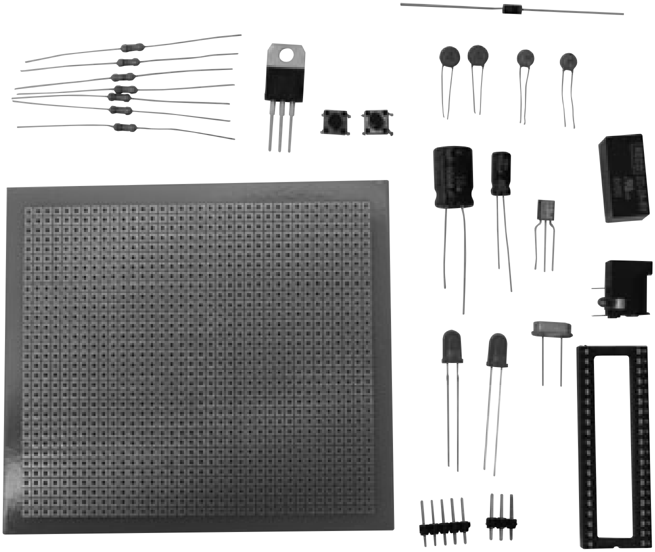
SEÑALES DIGITALES

Si bien podemos manejar señales digitales con un transistor que trabaja de forma lineal o analógica, lo cierto es que no tiene ningún sentido hacerlo, ya que no nos interesan los valores intermedios, sino solo los extremos mínimos y máximos de una señal.

www.FreeLibros.me

EL CONCEPTO

La Electrónica Analógica trata con variables (**tensión**, **corriente** y **potencia**, entre otras) que varían de forma continua con el tiempo. Como ejemplo podemos citar una señal de audio o la tensión que proporciona un sensor de temperatura. Todas estas señales están compuestas por múltiples valores de tensión y la Electrónica Analógica considera todos estos valores. Como contrapartida, en la Electrónica Digital, las variables pueden tomar solo **dos valores** o **estados** posibles y bien definidos. Dado que estamos tratando el aspecto eléctrico del concepto, esos dos valores pueden ser **0 V** y **5 V** o, de forma binaria, **0** y **1**. La elección del valor de **5 V** no es caprichosa o antojadiza. Es debido a que la mayoría de los sistemas digitales trabajan con una tensión de **5 V**. Sin embargo, en la actualidad, podemos encontrar a menudo sistemas que operan con tensiones de **3,3 V** y aún menores, dependiendo del circuito.



ANALÓGICA Y DIGITAL

Un circuito analógico es mucho más costoso de diseñar y construir. Es por este motivo que el concepto de Electrónica Digital cobra sentido y evoluciona constantemente. En este libro, analizaremos todas sus ventajas y desventajas.

www.FreeLibros.me

Términos fundamentales

ELECTRÓNICA ANALÓGICA
Trata con variables, como la tensión, la corriente y la potencia, que varían de forma continua con el tiempo.

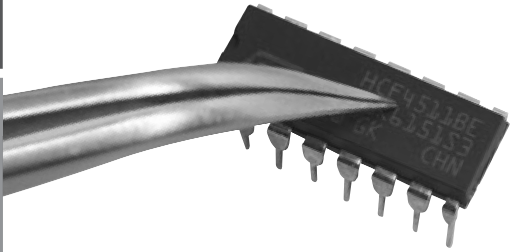
ELECTRÓNICA DIGITAL
Las variables pueden tomar solo dos valores o estados posibles y definidos.

DAC
Es un circuito cuya función es convertir un valor digital en uno analógico.

ADC
Es un circuito cuya función consiste en convertir un valor analógico en digital.

DISCRETOS
Son componentes primitivos, como las resistencias, diodos, capacitores y transistores, entre otros.

TRANSISTOR
Dispositivo electrónico semiconductor que cumple funciones de amplificador, oscilador, conmutador o rectificador.



LOS COMPONENTES

En Electrónica –tanto Analógica como Digital– se utilizan exactamente los mismos **componentes discretos**. Cuando decimos discretos, queremos significar que se trata de **componentes primitivos**, como las resistencias, los diodos (**Figura 2**), los capacitores y los transistores, entre otros. Por ejemplo, un circuito integrado no es un componente discreto, ya que contiene un circuito en su interior que hace un trabajo determinado por el fabricante. Sin embargo, el circuito integrado está construido en base a varios componentes discretos interconectados entre sí.

Es entonces que nos preguntamos cuál es la diferencia, ya que se utilizan los mismos componentes, tanto para Electrónica Analógica como para Digital. La diferencia se halla en la manera de hacer funcionar estos componentes. Observemos lo siguiente:

Los componentes discretos son: resistores, diodos, capacitores y transistores

www.FreeLibros.me

ELECTR_Cap1_xxx_xxx_ajustado.qxp 04/07/2011 16:30 PÆgina 15

un transistor puede funcionar como una resistencia variable que opera como un interruptor eléctrico que anula el paso por completo de la corriente o la deja pasar. Estos dos estados del transistor se los conoce como estado de **bloqueo** (cuando está abierto) y estado de **saturación** (cuando se encuentra cerrado).

Cuando un transistor funciona solo con los estados de bloqueo y saturación (como si fuese un interruptor) podremos decir que está operando de **manera digital**, ya que no considera los valores intermedios. Un ejemplo de ello puede ser un **interruptor**, que conecta o desconecta una bombilla de luz. Si, en cambio, hacemos funcionar un transistor de manera tal que tenga en cuenta los estados o valores intermedios, el transistor estará operando de **manera lineal** o analógica. Como ejemplo, podemos citar el **regulador de luminosidad** o **dimmer** con que cuentan algunos hogares, que permite graduar la intensidad de luz deseada emitida por la bombilla.

A lo largo de todo el libro, se estudiarán las **compuertas digitales**. Si bien comercialmente se adquieren bajo la denominación de **Circuito Integrado** (**CI**), interiormente son transistores que operan de forma digital, que es lo mismo que decir en estado de bloqueo y saturación.

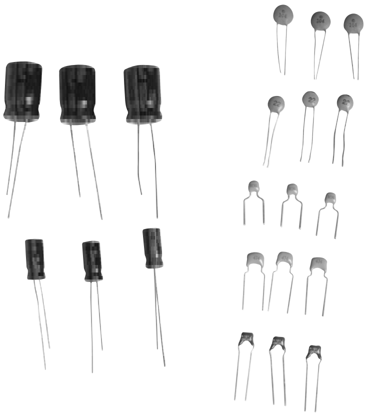


FIGURA 2.
El diodo permite la circulación de corriente eléctrica en un sentido. El más común es el diodo semiconductor.

DESCARGA A TIERRA

Es fundamental conectar a tierra todas las clavijas centrales de los tomacorrientes y de la pulsera de descarga estática. Si no disponemos de una conexión a tierra en la red domiciliaria, podemos utilizar una jabalina enterrada, siguiendo las especificaciones del fabricante.

www.FreeLibros.me

El **taller**

El taller es el espacio en el cual efectuaremos todas las pruebas y tareas de Electrónica (**Figura 3**). Por este motivo, es necesario equiparlo adecuadamente. Veamos qué necesitamos. Debe proveer una adecuada ventilación **para evacuar los gases emitidos** por desengrasantes, tóxicos, productos químicos empleados en la fabricación de circuitos impresos y los compuestos de soldadura. Para lograr una buena ventilación, es necesario tener extractores de aire para asegurarnos la renovación constante de oxígeno.

EL BANCO DE TRABAJO

El banco o **mesa de trabajo** debe tener una altura adecuada, el estándar es de **80 centímetros**. Si bien el uso de **cajones** no es aconsejable ya que entorpecen nuestro movimiento, pueden aceptarse si los tiene solo a los costados. Como manipularemos artefactos eléctricos, el banco debe ser de **madera** o un **compuesto aislante de fibra**. Siempre es recomendable adherir, en toda su superficie, una lámina de goma lisa de un espesor de **2 milímetros**.

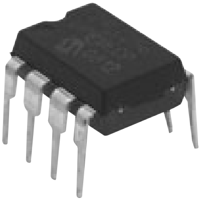
El banco debe ser muy robusto, ya que permanentemente soportará el peso de los equipos de medición, herramientas y, ocasionalmente, aparatos muy pesados, que contengan transformadores o baterías. Sobre su **fondo** podremos agregar una alzada o estante para colocar equipos y componentes sin ocupar espacio de trabajo en su superficie.

Es importante incorporarle una **lámpara con lupa** (lente de aumento) de brazo flexible, para poder ajustar con la mano la posición exacta del circuito que necesitemos. Debemos proveerlo de cuatro o más **tomacorrientes** de **tres clavijas**

FIGURA 3. El ambiente donde desarrollemos nuestra tarea debe ser un espacio bien iluminado en general, independientemente de la iluminación puntual sobre el banco de trabajo.

www.FreeLibros.me

El banco o mesa de trabajo debe tener una altura adecuada, el estándar es de 80 centímetros



con conexión a tierra a cada lado (izquierdo y derecho). Es sumamente relevante contar con un **interruptor térmico bipolar** para desconectar eléctricamente el banco en caso de ser necesario.

SOBRE LA SEGURIDAD

El primero de los equipos de seguridad que debemos instalar en el taller es el interruptor diferencial o disyuntor. A pesar de tomar todos los recaudos posibles para mantenernos aislados de tierra, existe una situación de extrema peligrosidad y es nuestra conexión a la **pulsera antiestática**. No olvidemos que esta pulsera nos conecta a tierra, todo lo contrario a lo que evitamos con el piso aislante de goma y los recaudos de aislamiento del banco de trabajo.

En caso de que, accidentalmente, toquemos con nuestra mano el terminal positivo o "vivo" de la red de canalización, quedaremos con nuestro cuerpo conectado directamente a la red eléctrica. Si bien el interruptor diferencial actuaría en consecuencia, es preferible no llegar a esta situación. Para ello, evitemos colocarnos la pulsera antiestática, a menos que sea indispensable.

Una solución definitiva a este problema es aislar eléctricamente el taller por completo o, en su defecto, el banco de trabajo de la red eléctrica externa. Para hacerlo, podemos colocar un **transformador** con relación **1:1** y de la potencia adecuada.

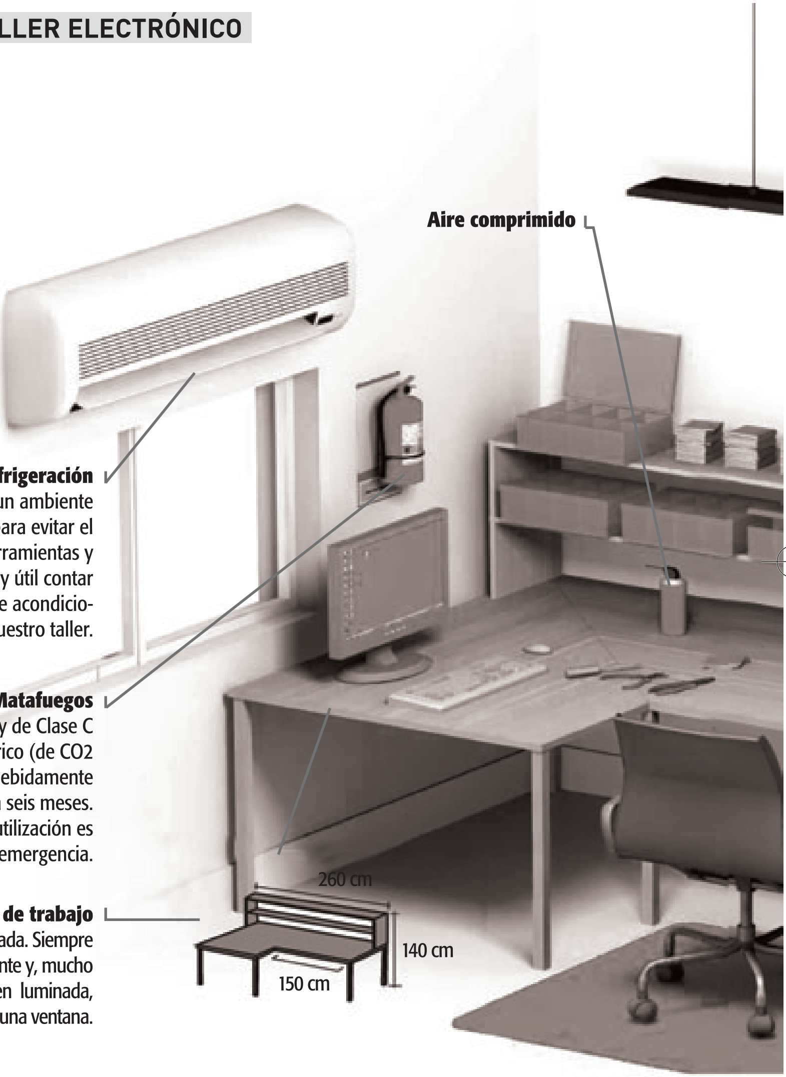
Por ejemplo, si la **tensión nominal es de 110 V** (depende del país), el transformador deberá ser de **110 V** de entrada y **110 V** de salida, conectando esta última al banco de trabajo. Si tenemos previsto conectar aparatos de gran consumo, debemos emplear un transformador con una potencia mínima de **1 KVA** (**VA: VoltAmper - K: Kilo**) o superior.

PULSERA ANTIESTÁTICA

Consiste en una cinta, con un abrojo para ajustarla a la muñeca, conectada a un cable de toma de tierra que permite descargar cualquier acumulación de electricidad estática en nuestro cuerpo. Lleva una resistencia de **1 MOhm**.

www.FreeLibros.me

INFOGRAFÍA 1: EL TALLER ELECTRÓNICO

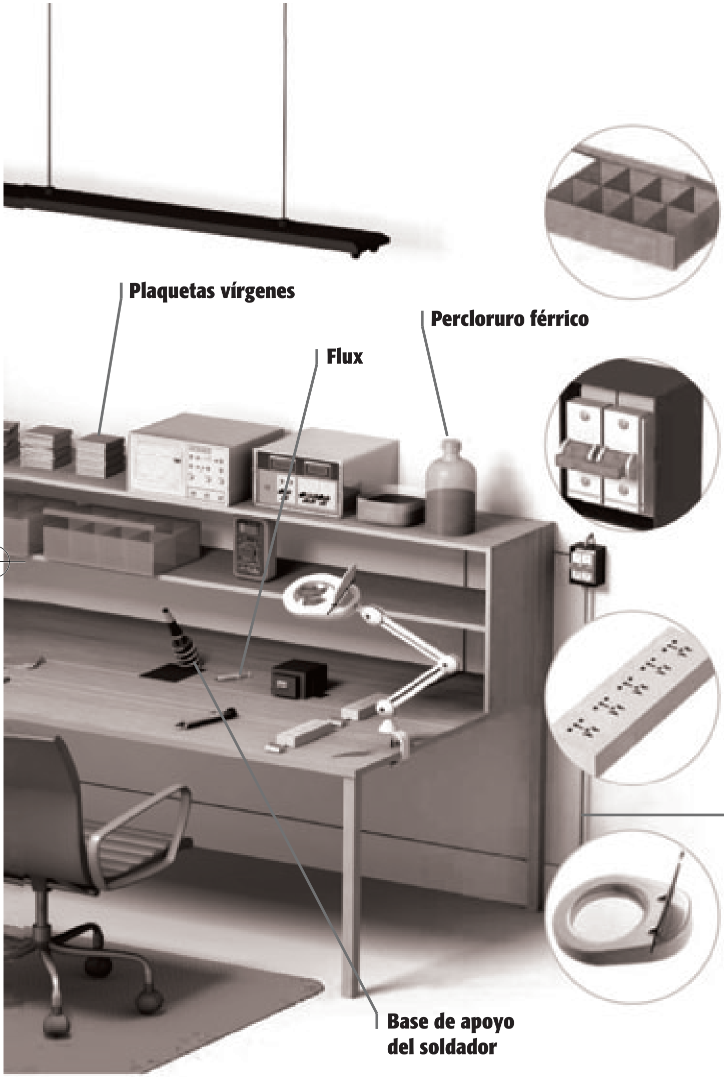


Refrigeración
Conviene trabajar en un ambiente cómodo y seco para evitar el deterioro de herramientas y componentes. Es muy útil contar con un equipo de aire acondicionado en nuestro taller.

Matafuegos
Matafuegos siempre a mano y de Clase C para incendios de origen eléctrico (de CO2 o de tipo Polvo ABC), debidamente cargados y controlados cada seis meses. Darle una correcta utilización es fundamental en situaciones de emergencia.

Mesa de trabajo
Cómoda, amplia, limpia y ordenada. Siempre de madera o de material aislante y, mucho mejor, con estantes. Debe estar bien luminada, en lo posible, cerca de una ventana.

www.FreeLibros.me



Gaveteros
Estos cómodos clasificadores de elementos nos permitirán mantener ordenado el taller, teniendo siempre a disposición los componentes en forma ágil y rápida.

Disyuntor
Es imprescindible contar con un disyuntor en la entrada de la casa y, al menos, un interruptor termomagnético individual, en la sección del taller, para trabajar con riesgo mínimo. El dimensionado debe realizarlo personal matriculado.

Tomacorrientes
Se necesitan una puesta a tierra general en buen estado y tomacorrientes de 3 bocas en la instalación. Las zapatillas se ubicarán de manera que permitan fácil acceso, evitando cruces de cables.

Jabalina a tierra

Lupa articulada
Muy útil para tareas de soldado through-hole y superficial. Se utiliza para observar el estado final de Zlas soldaduras y para facilitar las maniobras sobre los diferentes circuitos electrónicos.

www.FreeLibros.me

Claves de seguridad

RED ELÉCTRICA

Debemos asegurarnos de que la red domiciliaria se encuentre en perfectas condiciones de funcionamiento. De ello dependerá nuestra seguridad.

TOMACORRIENTES

Es preciso tener una buena cantidad de tomacorrientes en cada uno de los rincones del taller. De este modo, podremos conectar varios dispositivos sin necesidad de alargues.

DESCARGA A TIERRA

En la actualidad, un taller de Electrónica que no posea un sistema de descarga a tierra es impensable; de él dependerá nuestra seguridad personal.

MATAFUEGO

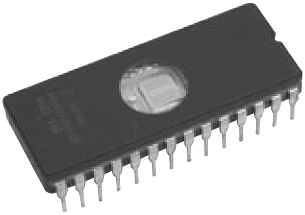
Es natural que en un taller de Electrónica se genere algún cortocircuito y, para evitar incendios, es recomendable tener a mano un matafuego para fuegos clases A B C.

El taller es el espacio de trabajo en el que pasaremos gran parte del tiempo. Es por eso que debemos mantenerlo en óptimas condiciones operativas y de seguridad. Un espacio incómodo impide el desarrollo de tareas prolongadas (**Figura 4**).

Las herramientas

El taller puede convertirse en un verdadero laboratorio electrónico, siempre que tengamos los instrumentos y las herramientas adecuadas. Veamos cada herramienta en detalle (**Figura 5**).

- **Alicate**: el alicate común produce un corte en forma de "**V**" y está indicado para cortar cables o terminales gruesos. Tiene que ser de mango aislado pero no necesariamente grueso, ya que no lo usaremos en líneas energizadas, sino en alambres de conexión sin energía domiciliaria.
- **Pinza de fuerza**: es una pinza convencional con mango aislado, utilizada para sujetar tuercas cuando montamos disipadores de calor y, también, otros elementos.
- **Pinza de punta**: puede ser de punta recta u oblicua y se emplea para sujetar componentes o doblar terminales, según sea necesario.



www.FreeLibros.me

FIGURA 4. **Un taller inseguro pone en riesgo nuestra salud y los componentes que debemos reparar.**

- **Pinzas Bruselas**: son pequeñas pinzas de punta que se usan para manipular pequeños componentes, por ejemplo, para introducir los alambres en un protoboard o tablero de experimentación.
- **Destornilladores**: aunque resulte obvio, los destornilladores en Electrónica cumplen un papel fundamental para ajustar controles electrónicos y sujetar o retirar tornillos. Recomendamos adquirir un kit para Electrónica de destornilladores pequeños, con punta plana y en cruz.

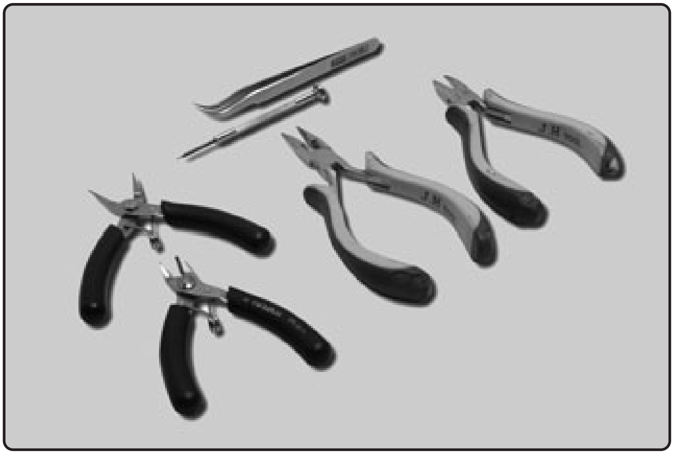


FIGURA 5. **El taller ideal se construye progresivamente. Primero, se adquieren las herramientas más elementales; luego, las más complejas y, finalmente, los instrumentos.**

www.FreeLibros.me

- **Fuente de alimentación**: si bien no es un instrumento de medición, la mencionamos aquí porque es indispensable para efectuar todos los experimentos o prácticas en nuestro taller. Una pequeña fuente que suministre dos tensiones fijas y reguladas será más que suficiente (**Figura 6**).

SOLDADOR Y ACCESORIOS

Además de las herramientas mencionadas, necesitamos varios accesorios para reparaciones electrónicas:

- **El soldador** es fundamental para los trabajos electrónicos, ya que todas las conexiones son unidas por una aleación de estaño y plomo o soldadura libre de plomo (**Figura 7**). Es importante el uso de un soporte para poder depositarlo sobre el banco caliente sin riesgos. Algunos soportes, además, cuentan con una espuma renovable de limpieza para la punta del soldador, algo muy útil debido a los residuos que se acumulan en ese sector, que pueden entorpecer la correcta soldadura.

- **Estaño o soldante**: es un alambre de un diámetro de entre **0,5 mm** y **1 mm**, compuesto de una aleación de **60%** de **plomo** y **40%** de **estaño**. Además, en su núcleo cuenta con una pasta a base de resina natural que ayuda a la soldadura. Requiere almacenamiento refrigerado.

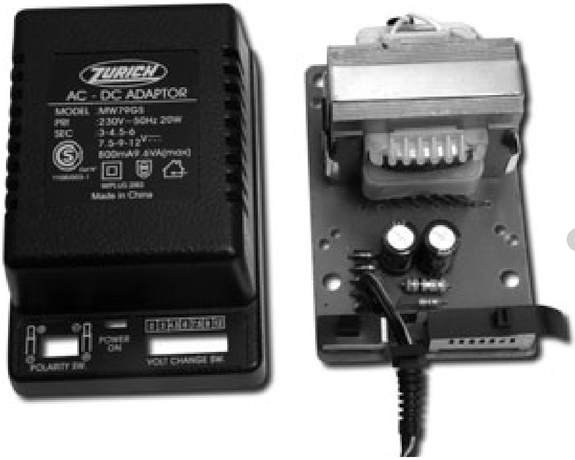
Necesitamos también ciertos accesorios en el taller de reparaciones electrónicas

- **Pasta para soldar o "flux"**: es un compuesto en forma de pasta o líquido, que ayuda a soldar/desoldar debido a sus propiedades limpiadoras, ya que baja el punto de fusión del estaño. Es ampliamente utilizado en la soldadura de componentes **SMD**.
- **Bomba succionadora de estaño**: es una pequeña bomba de vacío accionada a mano que, al momento de dispararla sobre la soldadura caliente, la aspira y la remueve. Es indispensable para desoldar circuitos integrados.
- **Cinta desoldante**: es una malla o entretejido de hilos de cobre muy delgados, que están tratados con un producto similar a la pasta para soldar. Para desoldar, apoyamos la punta de la cinta sobre la soldadura que deseamos eliminar, ubicamos el soldador encima de la cinta y dejamos que el calor la traspase hasta fundir la soldadura. Esta se licuará y será absorbida por la malla de cobre. También es fundamental para desoldar circuitos integrados o efectuar una limpieza de los puntos de soldadura de los circuitos impresos y demás componentes.

ALICATE DE CORTE AL RAS

Se utiliza para cortar los terminales sobrantes en una tarjeta de circuito impreso, ya que sus hojas de corte tienen un lado en ángulo y otro totalmente plano, que puede lograr un corte realmente al ras de la tarjeta. No debemos emplearlo para cables o terminales gruesos.

www.FreeLibros.me



ZURICH
AC - DC ADAPTOR
MODEL MW79GS
PRI 230V~50Hz 20W
SEC 3-4.5-6
7.5-9-12V
800mA
Made in China
POLARITY SW
POWER ON
VOLT CHANGE SW

FIGURA 6.
Las tensiones recomendadas son de 5 V **y** 12 V **de** 1 Amper **o superior.**

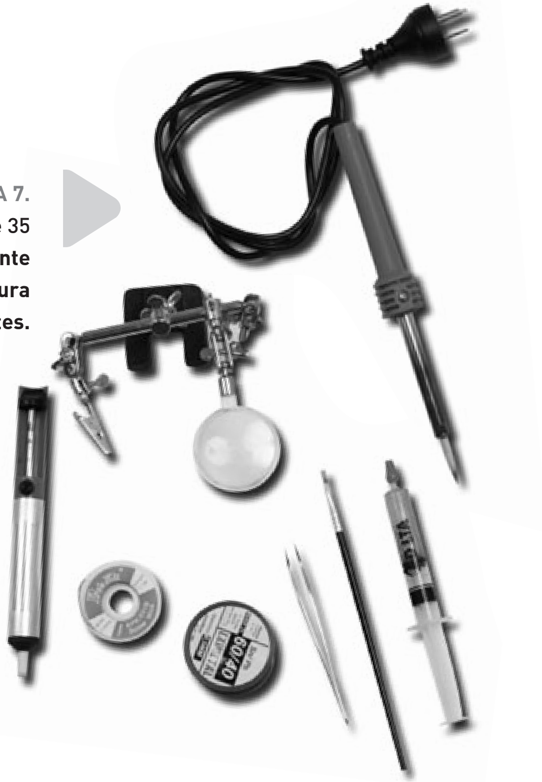


FIGURA 7.
Recomendamos un soldador del tipo lápiz de 35 **o** 40 **Watts de potencia porque resulta suficiente para la mayoría de los trabajos de soldadura de componentes y partes.**

LOS INSTRUMENTOS

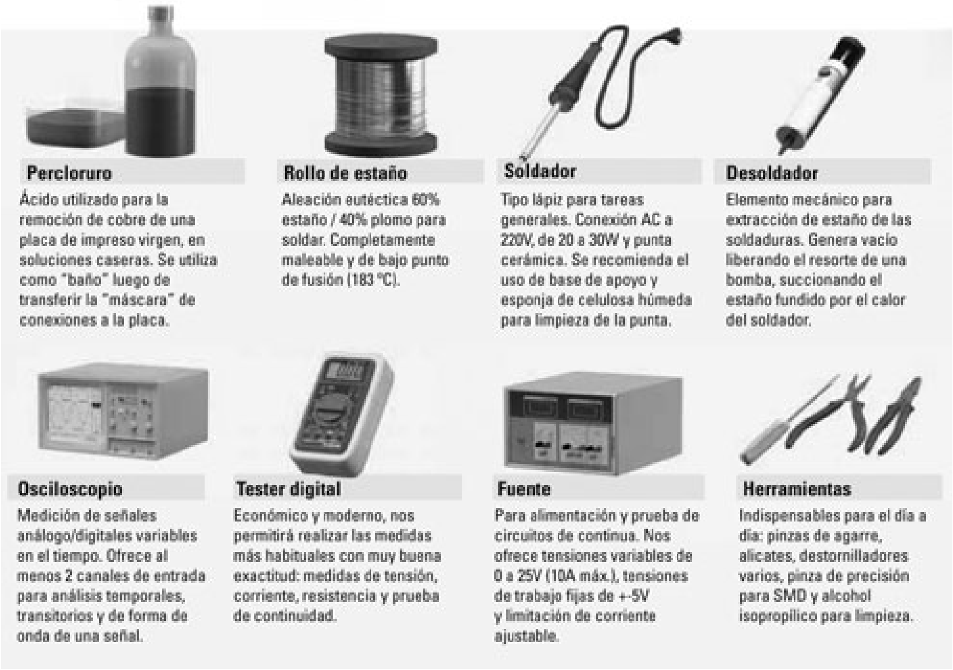
Además de las herramientas y los accesorios mencionados anteriormente, el taller debe contar con los instrumentos imprescindibles (**Figura 8**), que detallaremos a continuación:

- **Multímetro Digital**: también conocido como **DMM** (*Digital MultiMeter*), es el principal instrumento de medición de todo taller electrónico. Por medio del DMM, podremos medir tensiones, corrientes y resistencias, además de cortocircuitos.

www.FreeLibros.me

Algunos modelos tienen un zumbador que emite un sonido cuando se tocan sus puntas, y es muy útil para seguir trazas en un **PCB** (*Printed Circuit Board*) o cortocircuitos. Los modelos más sofisticados disponen de una sonda para medir temperatura en determinadas partes de un circuito. Otros de los agregados son medidores de capacidad en condensadores o capacitores, medidores de transistores bipolares y **FET** (*Field Effect Transistor* - Transistor de Efecto de Campo). En el **Capítulo 2** estudiaremos el uso del DMM.

- **Sonda o punta lógica**: una punta lógica permite visualizar, por medio de **LEDs** (**Diodo Emisor de Luz**), los estados lógicos en un punto del circuito. Por ejemplo, si en el punto de medición hay **0 V**, se iluminará el led que indica un **cero lógico** (**0**). En cambio, si hay **5 V**, se iluminará solo el led que indica el estado que denominaremos binario uno (**1**).
- **Osciloscopio**: el osciloscopio es un instrumento de medición y visualización de señales en el transcurso del tiempo.



Percloruro
Ácido utilizado para la remoción de cobre de una placa de impreso virgen, en soluciones caseras. Se utiliza como "baño" luego de transferir la "máscara" de conexiones a la placa.

Rollo de estaño
Aleación eutéctica 60% estaño / 40% plomo para soldar. Completamente maleable y de bajo punto de fusión (183 °C).

Soldador
Tipo lápiz para tareas generales. Conexión AC a 220V, de 20 a 30W y punta cerámica. Se recomienda el uso de base de apoyo y esponja de celulosa húmeda para limpieza de la punta.

Desoldador
Elemento mecánico para extracción de estaño de las soldaduras. Genera vacío liberando el resorte de una bomba, succionando el estaño fundido por el calor del soldador.

Osciloscopio
Medición de señales análogo/digitales variables en el tiempo. Ofrece al menos 2 canales de entrada para análisis temporales, transitorios y de forma de onda de una señal.

Tester digital
Económico y moderno, nos permitirá realizar las medidas más habituales con muy buena exactitud: medidas de tensión, corriente, resistencia y prueba de continuidad.

Fuente
Para alimentación y prueba de circuitos de continua. Nos ofrece tensiones variables de 0 a 25V (10A máx.), tensiones de trabajo fijas de +-5V y limitación de corriente ajustable.

Herramientas
Indispensables para el día a día: pinzas de agarre, alicates, destornilladores varios, pinza de precisión para SMD y alcohol isopropílico para limpieza.

FIGURA 8. **El taller puede convertirse en un verdadero laboratorio electrónico, siempre que tengamos los instrumentos y las herramientas adecuados.**

www.FreeLibros.me

ACCESORIOS Y COMPLEMENTOS

Además de las herramientas, instrumentos y productos mencionados hasta el momento, un taller se completa con los siguientes accesorios:

- **Protoboard**: es una tarjeta con perforaciones a lo largo de toda la superficie, que permite construir un circuito electrónico sin soldadura. Las conexiones entre los componentes se realizan con alambre del tipo convencional.
- **Circuito impreso**: es una placa de PCB perforada en toda su superficie, que posibilita introducir los componentes y soldarlos. Las conexiones se efectúan manualmente.
- **Resistores**: recomendamos tener todas de 1/4 de Watt y una cantidad de **10** por cada valor: **100 ohms** – **330 Ohms** - **470Ω** - **1 KÙ** - **2,2 KΩ** - **3,3 KΩ** - **4,7 KΩ** - **10 KΩ** - **22 KΩ** - **47 KΩ** - **100 KΩ**.
- **Capacitores cerámicos**: Todos con aislamiento para **25 V** o más y una cantidad de **10** por cada valor: **.01 µF - 1 µf.** (**µ** significa micro y la letra **F** es la unidad de medida, el **Faradio**). Por lo tanto, **µF** significa **microfaradio**. Cuando se indica un punto delante de la capacidad, como **.01**, en realidad es para resumir, queriendo significar **0,01**.
- **Capacitores electrolíticos**: todos con un aislamiento de **25 V** o más y un cantidad de **10** por cada valor: **1 µF** – **10 µF** - **100 µF** - **470 µF** - **1000 µF**.

> El analizador es una sonda que permite ver, en pantalla, varias señales al mismo tiempo

- **Transistores**: el transistor BC548 es de uso muy frecuente en Electrónica Digital. Recomendamos tener una cantidad de 10 unidades disponibles.
- **Diodos**: el diodo de conmutación por excelencia es el 1N4148. Con una decena de ellos, será suficiente.
- **Reguladores**: en este caso, solo será necesario contar con **5** unidades de cada tipo: **7805** - **7812**.
- **Zócalos Dip**: los zócalos permiten insertar, sin soldadura, integrados, memorias o microcontroladores. Cantidad: **5** de cada tipo: **4x2** - **7x2** - **8x2** - **9x2**.
- **Micro Switch**: pequeños interruptores que tienen el mismo tamaño y distribución de contactos que un circuito integrado ordinario y convencional.
- **Led**: indispensable como indicador lumínico. Cantidad: varios colores, de varios diámetros.
- **Indispensables**: Fusibles de **1 Ampe**r y **20 mm** de longitud - forro o **spaghetti termo contraible** - cables de varios colores - alambres para insertar en protoboard.

MÁS SOBRE SOLDADORES

Algunos soldadores tienen un regulador de temperatura, aunque no es indispensable para los trabajos comunes del taller. No aconsejamos el uso de los llamados soldadores instantáneos, ya que la punta no es lo suficientemente fina y precisa para trabajar en electrónica.

Multiple **choice**

1 ¿Cuál de las siguientes herramientas es un alambre compuesto por una aleación 60% plomo y 40% estaño?

a- Pasta de soldar o "flux".
b- Cinta desoldante.
c- Estaño o soldante.
d- Multímetro.

2 ¿Cuál de las siguientes herramientas es una malla o entretejido de hilos de cobre muy delgados?

a- Pasta de soldar o "flux".
b- Cinta desoldante.
c- Estaño o soldante.
d- Multímetro.

3 ¿Cuál de las siguientes herramientas es un compuesto en forma de pasta o líquido, que ayuda a soldar/desoldar?

a- Pasta de soldar o "flux".
b- Multímetro.
c- Bomba succionadora de estaño.
d- Osciloscopio.

4 ¿Cuál de las siguientes herramientas es una pequeña bomba de vacío accionada a mano?

a- Estaño o soldante.
b- Multímetro.
c- Bomba succionadora de estaño.
d- Osciloscopio.

5 ¿Cuál de los siguientes es el principal instrumento de medición de todo taller electrónico?

a- Estaño o soldante.
b- Multímetro.
c- Bomba succionadora de estaño.
d- Osciloscopio.

6 ¿Cuál de los siguientes es un instrumento de medición y visualización de señales en el transcurso del tiempo?

a- Estaño o soldante.
b- Multímetro.
c- Bomba succionadora de estaño.
d- Osciloscopio.

Respuestas: 1 c, 2 b, 3 a, 4 c, 5 b, 6 d.

Capítulo 2

Construcción de circuitos

En este segundo capítulo, analizaremos las bases de la composición de los circuitos digitales.

RedUSERS.com

www.FreeLibros.me

Primeros **pasos**

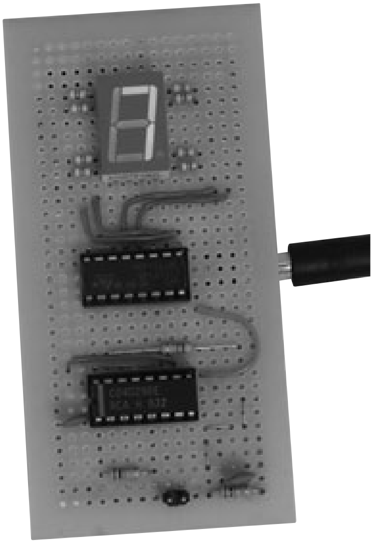
Para iniciarnos en el universo de la **Electrónica Digital** es necesario conocer los principios elementales del funcionamiento de los circuitos. Es por este motivo que comenzaremos a dar los primeros pasos en la construcción de un circuito sobre la base de un **protoboard**, plantilla que ofrece la ventaja de trabajar sin soldaduras.

Con el transcurso de las páginas avanzaremos sobre las características de los **circuitos universales**, conoceremos sus ventajas, limitaciones y utilización práctica. Además, en este segundo capítulo, subiremos la apuesta para detallar de forma teórica y práctica el proceso de **construcción** de un **circuito impreso casero**. Sobre el final de este capítulo, conoceremos todos los secretos sobre la **soldadura** para electrónica y cuáles son los **elementos** necesarios para realizarla correctamente.

Circuitos **electrónicos**

Un circuito electrónico es un conjunto de componentes eléctricos o electrónicos, interconectados por medio de hilos conductores, con el objetivo de generar, transportar o procesar una señal eléctrica.

Existen diferentes métodos de construcción de circuitos electrónicos, dependiendo de su complejidad, el volumen de producción y el tipo de componentes utilizados.



LOS COMPONENTES

Dentro de un circuito podemos encontrar una gran variedad de componentes, como **fuentes de señal** (sensores y micrófonos), **fuentes de alimentación** (baterías o la red domiciliaria), **dispositivos eléctricos** (bobinas, lámparas, resistencias y capacitores), **componentes electrónicos** (diodos, transistores, circuitos integrados) y **dispositivos mecánicos** (llaves y conmutadores), (**Figura 1**).

> El "esquemático" es la representación gráfica de un circuito electrónico

www.FreeLibros.me

Según el modo en que se monta un circuito, un componente puede ser de tecnología **through hole** (a través de orificio) o de **montaje superficial**.

EL ESQUEMÁTICO

Antes de comenzar con la construcción de cualquier circuito, debemos contar con un **esquema circuital**. El esquemático es una representación gráfica de un circuito electrónico. Muestra los diferentes componentes con su simbología asociada y las conexiones entre los mismos. Podemos dibujarlo a mano alzada o utilizar un **software** de captura de esquemático, como **Eagle** u **Orcad**. En este libro, utilizaremos el software Eagle.

La creación de un esquema circuital es clave, ya que cualquier error en la construcción derivará en el mal funcionamiento del circuito. Por esta razón recomendamos dibujar el esquemático con un software para tal fin, lo que nos permitirá también, en la mayoría de los programas disponibles, realizar una simulación del comportamiento real del circuito, predecir sus características antes de construirlo y generar el circuito impreso.

EL PCB

Una vez que tenemos el esquemático debemos construir físicamente el circuito. Generalmente, los circuitos se montan mediante un **circuito impreso** o **PCB** (*Printed Circuit Board*). Es una tarjeta plástica que conecta eléctricamente los componentes del circuito a través de pistas de cobre laminadas sobre un **sustrato no conductor** (fenólico o epoxi). Actúa también como soporte de todo el circuito.

A partir de un esquemático, el diseño del circuito impreso puede hacerse con un software como los mencionados anteriormente; estos poseen muchísimas librerías con las formas físicas de los componentes (**footprints**) para facilitar el diseño. El trazado de las pistas (**ruteo**) puede realizarse de forma manual o automática.

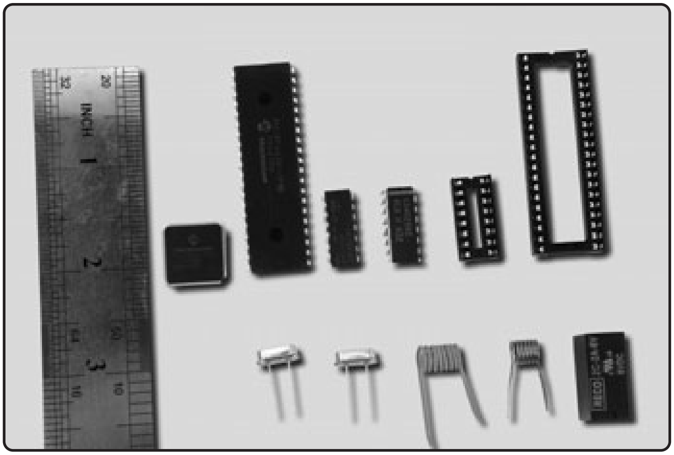


FIGURA 1.
Es importante que sepamos reconocer los componentes más utilizados y sus características para poder construir nuestros propios circuitos. Por ejemplo, un diodo emisor de luz posee polaridad, y no es lo mismo conectarlo hacia un lado o hacia otro.

www.FreeLibros.me

LA TRANSFERENCIA DEL TRAZADO A LA PLACA

Cuando el diseño está terminado, necesitamos pasarlo a la placa. Para ello existen diversos métodos, pero casi todos se hacen a partir de una lámina de cobre que cubre completamente el sustrato (placa virgen), donde luego se quita el cobre indeseado para dejar los trazados diseñados (**Figura 2**). Este proceso se logra utilizando primero una máscara de trazado, que se obtiene al aplicar tintas (serigrafía) o mediante un proceso de fotograbado.

También existen métodos donde se utiliza una fresa mecánica o hasta un láser para eliminar el cobre residual. Sin embargo, el método más accesible es el de la transferencia del diseño a la placa a través de calor. Para ello, se imprime el trazado en un **material termosensible** como el papel de ilustración.

LA PERFORACIÓN Y EL ESTAÑADO

Los orificios para colocar los componentes se realizan, a nivel industrial, con un taladro controlado por computadora. Nosotros podremos utilizar una

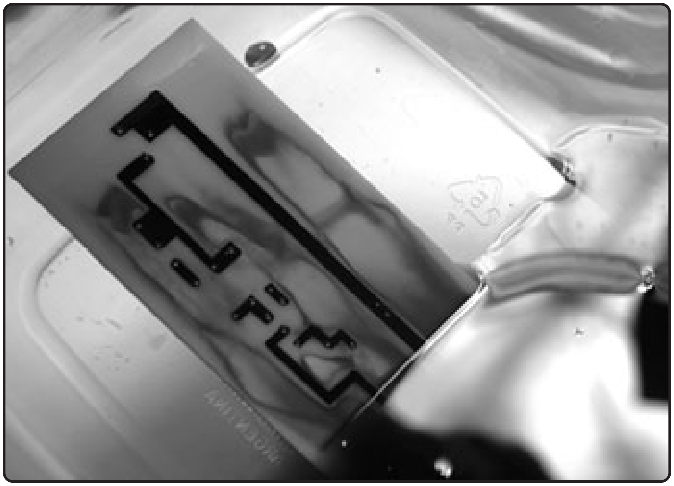

FIGURA 2. **Una** máscara temporal de tinta **aplicada a la placa virgen. De esta forma, queda preparada para el ataque químico. El** percloruro férrico **es el elegido para realizar esta acción, al eliminar el** cobre indeseado**.**

MÚLTIPLES CAPAS

Un **PCB** puede estar formado por múltiples capas conductoras (hasta **dieciséis**). La mayoría de sus componentes son de montaje superficial y son colocados por un robot denominado **pick and place**. Para nosotros, un PCB de una o dos capas será más que suficiente.

www.FreeLibros.me

agujereadora de banco o un **mini torno**. Para finalizar con la construcción del circuito, los componentes se insertan en los orificios (si son de montaje through hole) o apoyan sobre las pistas de la tarjeta, si son de montaje superficial. Luego se sueldan con estaño, ya sea con un soldador manual o mediante una máquina de soldadura por ola (en caso de grandes volúmenes de producción). Con el circuito armado, ya estamos en condiciones de comprobar su funcionamiento.

Los orificios para colocar los componentes se realizan, a nivel industrial, con un taladro controlado por computadora

El **protoboard**

El protoboard o tarjeta de proyecto es una placa plástica con orificios metalizados y conexiones eléctricas preestablecidas que se utiliza como banco de pruebas para la realización de circuitos electrónicos sencillos. Es económico y su mayor ventaja es que no requiere de soldaduras para interconectar los componentes, los cuales son simplemente insertados en los orificios para tal fin. La disposición de sus conexiones internas hace posible el montaje temporal de cualquier circuito (**Figura 3**).

TOPOLOGÍA

El espaciado de los orificios de la tarjeta es generalmente de **2,54** mm, una medida estándar en el

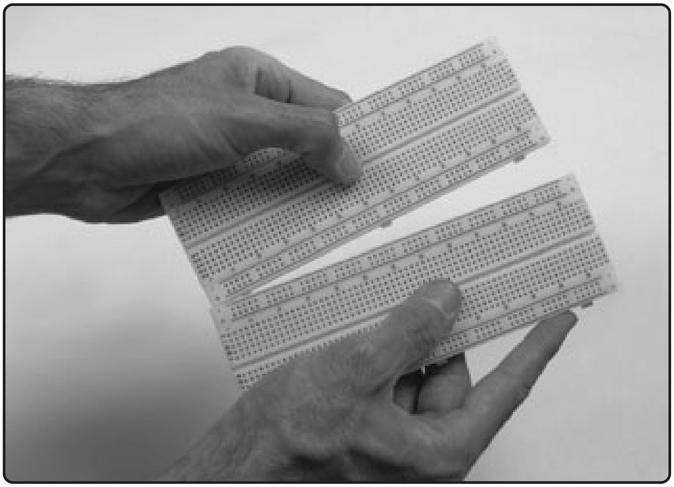

FIGURA 3. Protoboard **de tamaño estándar; son** 62 **columnas, donde cada una tiene** dos secciones **de orificios (de** A a E **y de** F a G**). Es posible unir dos o más protoboards mediante los enganches ubicados sobre uno de los bordes.**

www.FreeLibros.me

mundo de la electrónica. Podemos distinguir en el protoboard, seis secciones de orificios separadas entre sí por un material aislante. Las secciones **1** y **5**, marcadas en **rojo**, tienen continuidad horizontal y se utilizan como una de las **líneas de alimentación del circuito** (**Vcc**). En general se conectan entre sí externamente para disponer de ellas a ambos lados de la tarjeta, al igual que las secciones **2** y **6**, marcadas en azul, que constituyen la otra línea de alimentación, es decir, la **masa circuital** o **retorno de corriente** (**Gnd**).

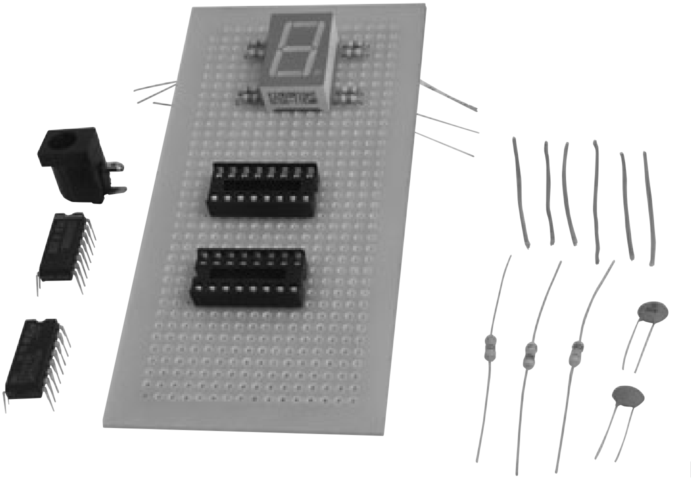
Las secciones **3** y **4** están compuestas por columnas de cinco orificios cada una y poseen continuidad vertical, haciendo posible la formación de nodos en el circuito. Cada columna se encuentra eléctricamente aislada de las columnas adyacentes.

El **canal o surco central** del protoboard se utiliza para insertar los circuitos integrados con encapsulado tipo **DIP** (*Dual In-line Package*), cuya separación de pines es justamente la misma que la del protoboard. Este hecho los convierte en los circuitos integrados más prácticos a la hora de construir prototipos.

Es importante aclarar que para colocar el protoboard en un lugar fijo, como por ejemplo un tablero, la placa trae un **adhesivo doble faz**. Si no deseamos pegarlo en ningún lugar, le pegamos una plancha de aluminio que también viene incluida, para que no moleste la cinta doble faz.

ACCESORIOS ÚTILES

Para el armado de los circuitos en el protoboard, recomendamos algunos accesorios que nos facilitarán la tarea. Podemos realizar las conexiones entre puntos del circuito mediante un cable **unifilar**, es decir, un alambre constituido por una sola pieza, como lo son el **cable UTP** y el **multipar calibre 20** o **22**. Estos poseen el diámetro adecuado para su inserción en el protoboard. Podemos utilizar el alambre sobrante de las patas



www.FreeLibros.me

de resistencias y capacitores solo para conexiones cortas, ya que no es un conductor aislado.

Debemos saber que existen componentes electrónicos que no pueden ser colocados directamente sobre el protoboard, como los potenciómetros e interruptores. En estos casos soldaremos el cable unifilar a los pines de los componentes para poder colocarlos en nuestro prototipo.

LIMITACIONES

Si bien el protoboard es una herramienta útil a la hora de construir prototipos, tiene ciertas limitaciones. En cuanto a especificaciones de potencia, el límite máximo es de **5 Watts**, lo que equivale a manejar **1 A** (Amper) en **5 V** (Volts) o **0,4 A** en **12 V**. Si sobrepasamos este límite. las conexiones internas de la tarjeta podrían dañarse y el plástico se derretirá.

El protoboard tiene una pobre funcionalidad para circuitos donde intervienen señales de radiofrecuencia debido a sus características de capacitancia: **2** a **30 pF** (pico Faradios) por punto de contacto. Por esta razón, recomendamos usarlo en aplicaciones que trabajen a frecuencias menores a **20 MHz** (Mega Hertz). El valor de capacitancia expresa la habilidad de un capacitor para almacenar carga eléctrica. La unidad de capacitancia es el Faradio.

El valor de capacitancia expresa la habilidad de un capacitor para almacenar carga eléctrica; su unidad de medida es el Faradio

Otra de sus limitaciones es que no nos permite insertar componentes de montaje superficial directamente. Para poder hacerlo, debemos comprar adaptadores, muchas veces costosos y difíciles de conseguir, o lanzarnos a la compleja tarea de construirlos nosotros mismos.

Uso **del protoboard**

Si queremos armar un circuito electrónico en el protoboard, debemos proceder ordenadamente para obtener los resultados esperados. Para ello, necesitamos contar con ciertos materiales. Primero, tenemos que disponer de un diagrama esquemático donde se encuentra el diseño del circuito. Debemos tener a mano todos los componentes electrónicos que

FALSOS CONTACTOS

Es alta la probabilidad de encontrarnos durante el armado del prototipo con falsos contactos o cables sueltos, que no se observan a simple vista. Debemos tener paciencia y ser organizados al montar un circuito en el protoboard para evitarnos posibles dolores de cabeza.

www.FreeLibros.me

forman el diseño. Necesitamos cables unifilares calibre 20 o 22 para realizar las conexiones. Además, precisamos algunas herramientas, como por ejemplo una pinza, un alicate y un cúter, que nos servirán para trabajar los puentes de cable y colocar los componentes. Por último, nos será útil el uso de un multímetro para evaluar el funcionamiento del circuito.

ALIMENTACIÓN DEL CIRCUITO

En los dos bordes de mayor longitud del protoboard se hallan las líneas o buses de alimentación. En color **rojo** tenemos la línea de tensión de alimentación (Vcc), y en **azul**, la de masa de circuito (Gnd). Es útil muchas veces hacer un puente entre ambos Vcc y otro puente entre ambos Gnd. En algunos protoboards, estas líneas están divididas a la mitad en un mismo extremo y es conveniente conectarlas también. De esta manera tendremos energía a ambos lados y a lo largo de la tarjeta cuando conectemos los bornes de la fuente de alimentación a estas líneas.

COLOCACIÓN DE COMPONENTES

Los primeros componentes que tenemos que colocar son los circuitos integrados o chips. Recordemos que el protoboard dispone de un surco o canal central para tal fin. El chip debe quedar sobre el canal central y paralelo al mismo, con sus pines insertados en los orificios que bordean el surco. Así nos aseguramos de que no exista un cortocircuito entre los pines del circuito integrado.

Observando el chip desde arriba, vemos que tiene una pequeña muesca. A la izquierda de ella, se encuentra el pin número 1. Debemos consultar la hoja de datos del componente (buscando por Internet) para conocer la función de cada uno de sus pines y no correr el riesgo de dañar el circuito integrado por una conexión incorrecta. Además, tenemos que colocar todos los chips en la misma dirección para simplificar el montaje del circuito (**Figuras 4** y **5**).

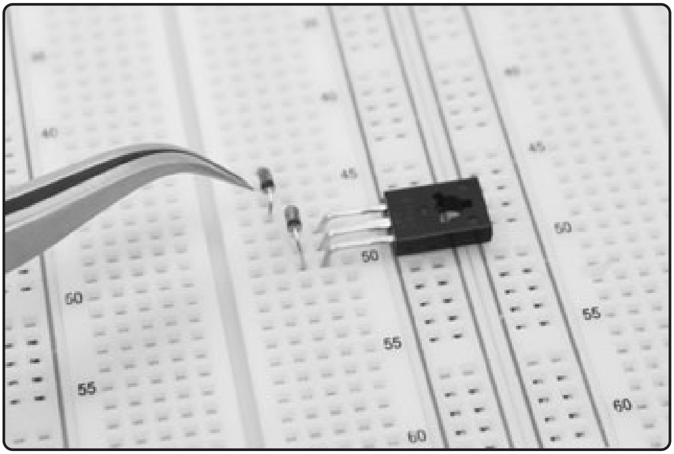


FIGURA 4. **Una de las ventajas que ofrece el protoboard es la posibilidad de insertar los cables sin necesidad de utilizar soldaduras.**

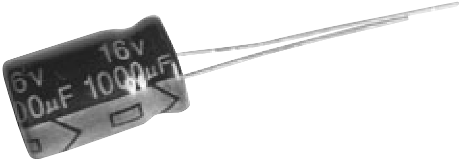
www.FreeLibros.me

En los dos bordes de mayor longitud del protoboard se hallan las líneas o buses de alimentación



Para colocar resistencias, capacitores, diodos y transistores fácilmente, podemos usar una pinza con la que doblar sus patas. También podemos acortárselas utilizando un cúter y evitaremos así que queden demasiado elevados por encima del protoboard.

Debemos tener en cuenta que hay componentes que poseen polaridad. Esto quiere decir que tienen una pata etiquetada como [+] (positiva) y otra como [–] (negativa). Las resistencias no tienen esta característica y las podemos conectar de cualquier manera. No olvidemos considerar los rangos de operación de cada componente, es decir, las especificaciones de potencia, tensión y corriente máxima.

CONSEJOS FINALES

Daremos algunos consejos para montar un circuito electrónico en el protoboard y no fracasar en el intento. Debemos planear la distribución de los componentes en la tarjeta para que no se produzcan concentraciones de los mismos en una zona. Es preciso asegurarnos de interconectar los componentes correctamente.

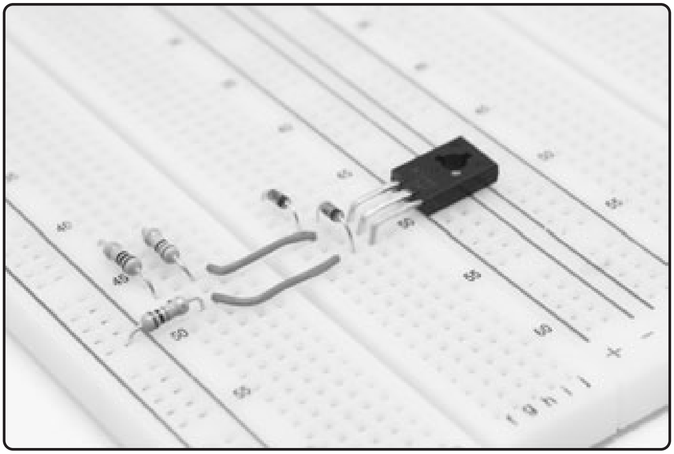


FIGURA 5.
Aquí podemos observar que tenemos energía a ambos lados de la tarjeta gracias a los puentes de cable que conectan estas líneas.

www.FreeLibros.me

Un consejo que puede parecer obvio, pero en el que queremos hacer hincapié, es que siempre tenemos que guiarnos por el esquemático para realizar el montaje. Es importante ir tachando las conexiones en el diagrama a medida que vamos realizándolas. También es conveniente que utilicemos cables de la menor longitud posible para disminuir los problemas de ruido.

En lo posible, los cabes deben estar aislados para evitar cortocircuitos con las patas de los componentes y con otros cables. Tratemos de utilizar cables de diferentes colores en zonas donde se concentran muchas conexiones. En caso de mal funcionamiento del circuito, revisemos primero las conexiones de alimentación y, luego, los falsos contactos en el resto del circuito. Si no podemos solucionar el problema, montemos el circuito en otra zona del protoboard.

En caso de mal funcionamiento del circuito, revisemos primero las conexiones de alimentación y, luego, los falsos contactos

Cómo trabajar con el protoboard

Realizaremos el montaje de un sencillo **cargador de baterías de níquel-cadmio** basado en un **transistor modelo BD140**. Este actúa como una fuente de corriente constante para entregar la carga necesaria a la batería. Para que el transistor funcione de esta manera, utilizaremos diodos de tipo **1N4148** y, con el fin de fijar las corrientes del circuito, emplearemos resistencias de **10k**, **56**, y **15 Ohms**. También incluiremos una **llave** que nos dará la posibilidad de alternar entre una carga rápida o lenta. Debemos disponer del esquemático del diseño y comprender cómo se interconectan los componentes electrónicos (**Figura 6**).

Vemos en la parte izquierda del diagrama un transformador conectado a la línea domiciliaria, un puente rectificador de diodos (**4x1N4001**), un fusible de **0,5 A** y un capacitor electrolítico de **1000 uF**. Estos componentes constituyen la fuente de alimentación del circuito (**Figura 7**). Debemos identificar cada uno de ellos. En la imagen vemos las **resistencias** de diferentes valores con su **código de colores**, el transistor, los **diodos 1N4148** y el **interruptor**. Para facilitar el montaje del circuito, utilizaremos una fuente de alimentación de banco de pruebas, como podemos ver en el **Paso a paso 1**.

www.FreeLibros.me

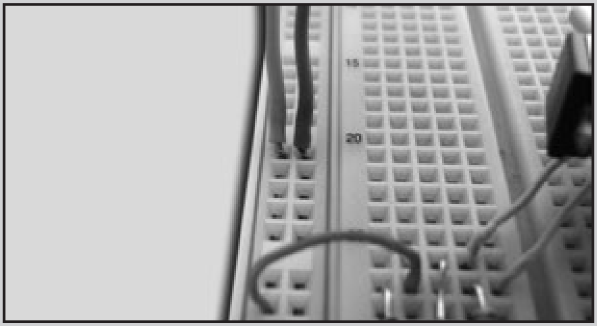
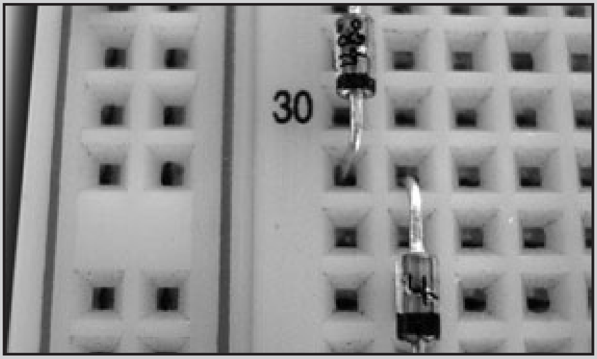
PASO A PASO /1
Montaje del circuito

1



Conecte cada línea de alimentación con su opuesta mediante puentes de cable, respetando los colores: **rojo** para la **alimentación positiva** (**Vcc**) y **azul** para la **negativa** (**Gnd**). Tiene que conectar otro cable para cada línea con uno de sus extremos al aire para engancharlo con las pinzas cocodrilo de la fuente de alimentación. Para evitar cortocircuitos, **Vcc** debe quedar del lado izquierdo y **Gnd** del lado derecho, o viceversa.

2

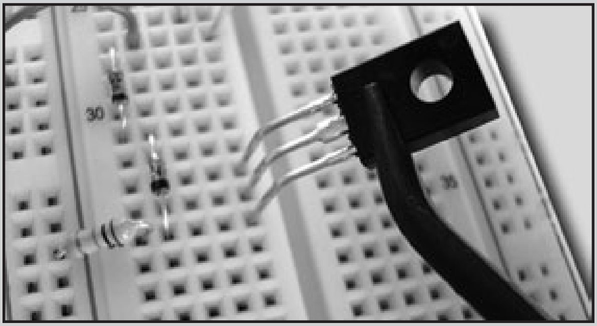


Ahora coloque los dos **diodos 1N4148**, cuyas caídas de tensión hacen que el transistor funcione como fuente de corriente constante. Estos van conectados en serie como se ve en la imagen. El **ánodo** del primer diodo va conectado a la línea de alimentación positiva. El **cátodo** se conecta a la misma columna que el ánodo del segundo diodo.

www.FreeLibros.me

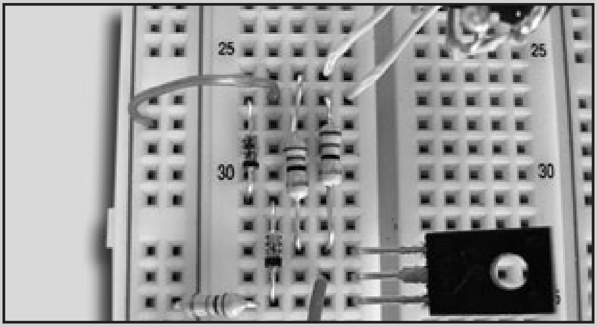
PASO A PASO /1 (cont.)

3



El **transistor BD140** es de tipo **PNP**, lo que significa que la corriente de emisor tiene sentido entrante, mientras que las de colector y base, sentido saliente. Observando el transistor del lado del orificio con unas **pequeñas marcas**, de izquierda a derecha, se observa: **emisor**, **colector** (**centro**) y **base**. Debe entonces conectar la base del transistor al cátodo del segundo diodo, y el emisor y el colector, a distintas columnas del protoboard.

4

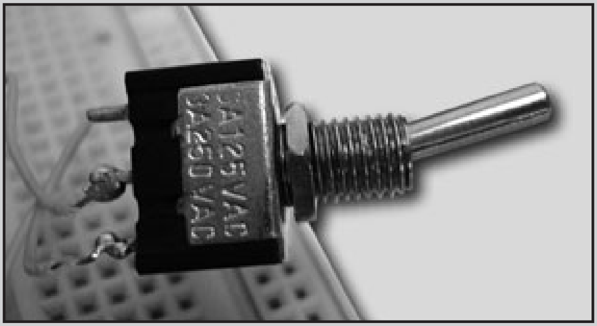


Tome la resistencia de valor **10k Ohms** (marrón, negro, naranja) y coloque una de sus patas en la misma columna que la base del transistor del paso anterior. Conecte la otra al **bus de alimentación** marcado con azul (Gnd). Inserte la resistencia de valor **56 Ohms** (verde, azul, negro) de manera que uno de sus extremos quede conectado al bus de alimentación positivo (Vcc) y, el otro, a la columna donde se encuentra el emisor del transistor.

www.FreeLibros.me

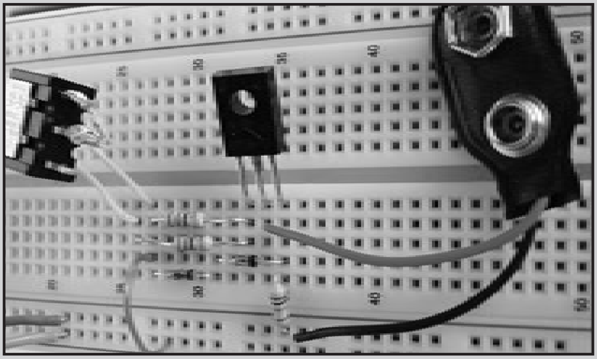
PASO A PASO /1 (cont.)

5



Para colocar la llave de selección debe soldarle un cable en cada uno de los extremos. Uno de los cables debe ir conectado a Vcc, y el otro, a una columna libre del protoboard. Coloque entonces la última resistencia, la de **15 Ohms**. Inserte una de sus patas en la columna donde conectó el extremo de la llave que no está unido a Vcc, y la otra, en la columna donde se encuentra el emisor del transistor.

6



Ahora tiene que conectar el porta batería de manera que el extremo positivo quede unido al **colector del transistor** (pata central), y el extremo negativo, a la **masa circuital Gnd** (la línea de alimentación azul). Luego coloque la batería en el porta batería. Una vez que realice esta acción, el circuito está listo para ser alimentado.

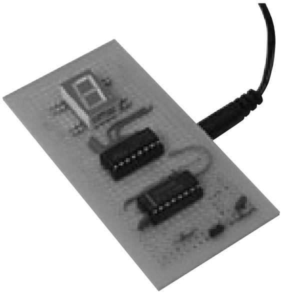
www.FreeLibros.me

ELECTR_Cap2_xxx_xxx_ajustado.qxp 04/07/2011 16:32 PÆgina 41

Circuito impreso **universal**

El circuito impreso universal o **UPCB** (*Universal Printed Circuit Board*) es una tarjeta de uso general para construir prototipos electrónicos permanentes utilizando soldadura (**Figura 8**, **9**, **10 y 11**).

Entonces, no necesitaremos recurrir al diseño y fabricación de un circuito impreso específico, con lo cual nos ahorraremos un tiempo considerable. Al igual que en el protoboard, el espaciado de los orificios es de **2,54 mm** (0,1 pulgadas). Su precio es accesible, y viene en diferentes tamaños, configuraciones y calidades.

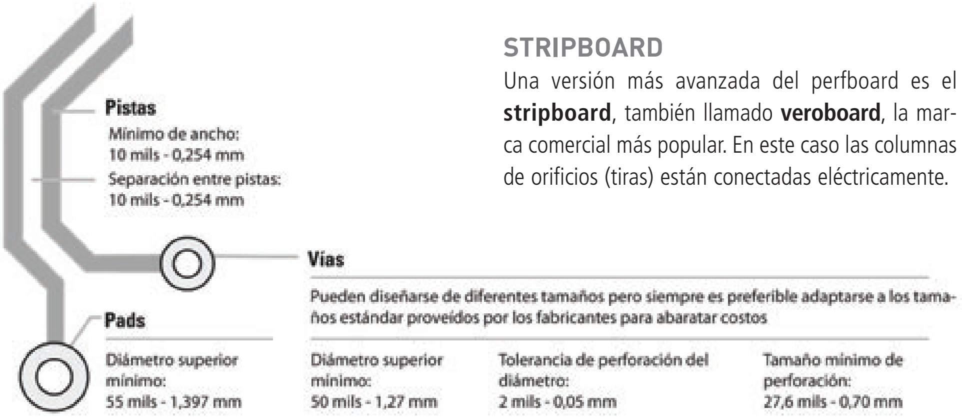


PERFBOARD

El circuito impreso universal más básico es el **perfboard,** una placa compuesta de **fenólico** o **epoxi**. Consta de varias columnas de orificios metalizados aislados eléctricamente. Los componentes se insertan en estos agujeros, pero para hacer las conexiones debemos utilizar puentes de cable o estaño. Este tipo de placa se utiliza para la realización de proyectos no profesionales y los diseños resultantes no son muy prolijos. No es recomendable si queremos hacer el mismo circuito más de una vez.

STRIPBOARD

Una versión más avanzada del perfboard es el **stripboard**, también llamado **veroboard**, la marca comercial más popular. En este caso las columnas de orificios (tiras) están conectadas eléctricamente.



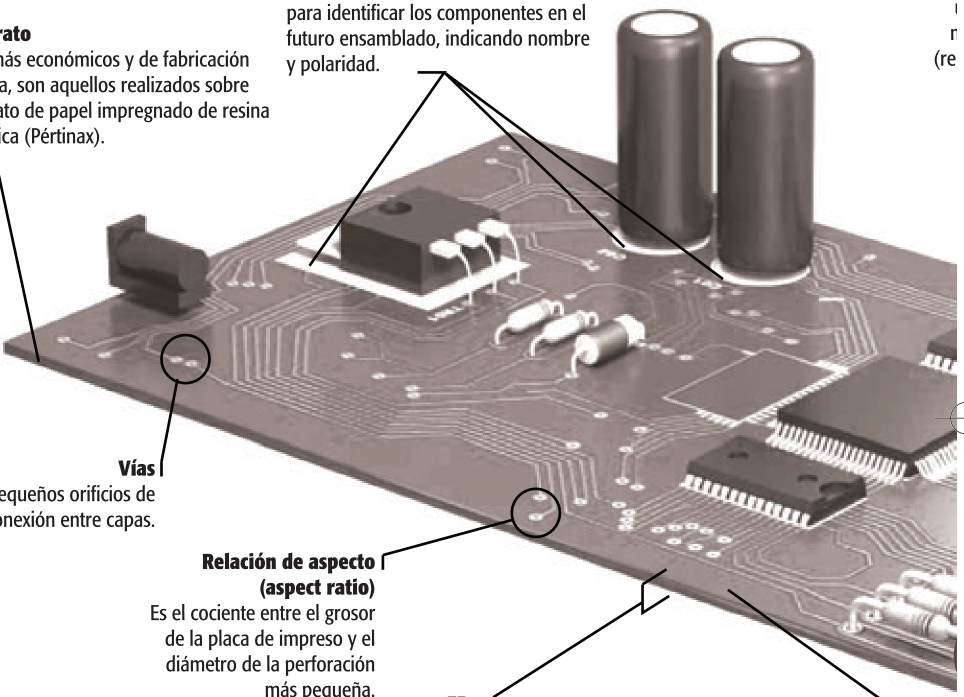
Pistas
Mínimo de ancho:
10 mils - 0,254 mm
Separación entre pistas:
10 mils - 0,254 mm
Vías
Pueden diseñarse de diferentes tamaños pero siempre es preferible adaptarse a los tamaños estándar proveídos por los fabricantes para abaratar costos
Pads
Diámetro superior mínimo:
55 mils - 1,397 mm
Diámetro superior mínimo:
50 mils - 1,27 mm
Tolerancia de perforación del diámetro:
2 mils - 0,05 mm
Tamaño mínimo de perforación:
27,6 mils - 0,70 mm

FIGURA 8. **Vemos el ejemplo de especificaciones de un fabricante. Existe la posibilidad de trabajar con pistas más finas y vías más pequeñas.**

www.FreeLibros.me

ELECTR_Cap2_xxx_xxx_ajustado.qxp 04/07/2011 16:32 PÆgina 42

INFOGRAFÍA 2: EL CIRCUITO IMPRESO (PCB)



Silkscreen
Grabado de colores (generalmente blanco) sobre la superficie de un impreso, utilizado para identificar los componentes en el futuro ensamblado, indicando nombre y polaridad.

tes.
(re

Sustrato
Los más económicos y de fabricación casera, son aquellos realizados sobre sustrato de papel impregnado de resina fenólica (Pértinax).

Vías
Son pequeños orificios de conexión entre capas.

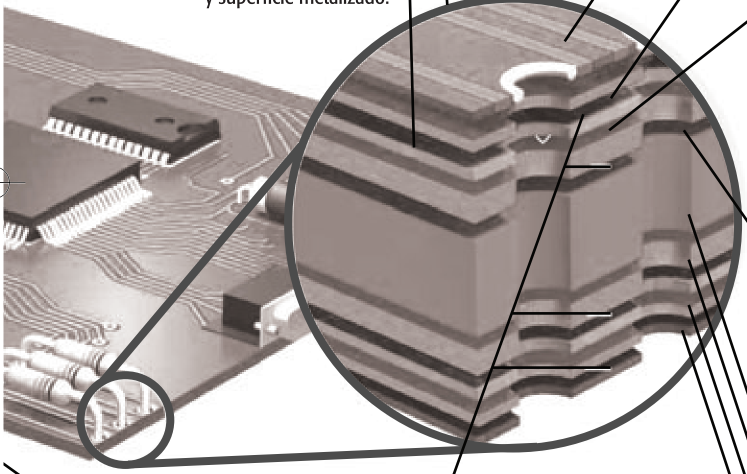
Relación de aspecto (aspect ratio)
Es el cociente entre el grosor de la placa de impreso y el diámetro de la perforación más pequeña.

FR-4
Existen también los llamados impresos "doble capa" –double layer-. Son generalmente de sustrato de fibra de vidrio del tipo FR-4 ("Flame retardant" : retardante de llama de factor 4) .

www.FreeLibros.me

Pad
Área de material conductor en un PCB designado para el montaje de componentes. Puede ser una patita de un footprint de un componente SMD o una perforación metalizada para montar un componente (resistencia, capacitor, etc.) ó un integrado through-hole.

Corona (annular ring)
Es el anillo circular remanente luego de la perforación de un pad. Es de sustrato conductivo y superficie metalizado.



Foots prints
Huellas de montaje para componentes de montaje superficial (SMT)

Signal layer
Generalmente esta capa externa se usa para ruteado general.

Prepreg
Es una delgada capa de fibra de vidrio impregnada de resina epoxi, aplicada entre 2 capas internas o “cores” de un PCB multilayer. Funciona como pegamento en el proceso de “laminación” del fabricante.

Internal layer
Capa interna de un PCB multicapa. En impresos de 4 capas se las destina a planos de tierra o alimentación, aunque puede ser usada para ruteado general.

Core

Internal layer

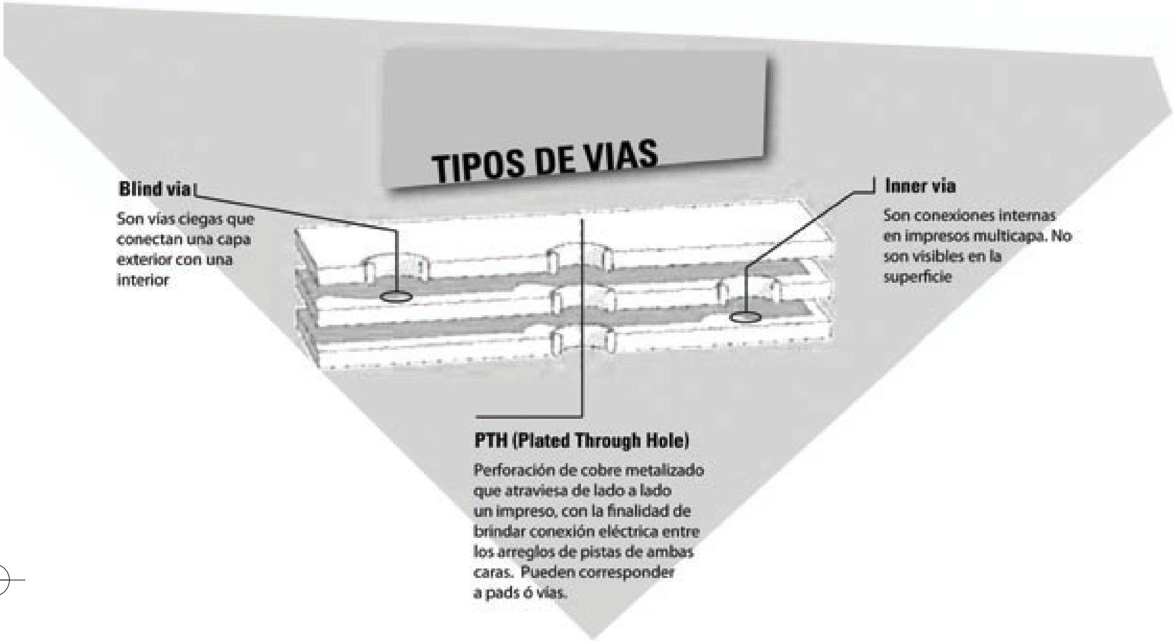
Prepreg

Signal layer

Lado de componente (component side)
El lado o cara de un circuito en donde se montarán la mayoría de los componentes.

Four-Layer PCB (PCB 4 capas):
Es un impreso que cuenta con 4 capas de interconexión. Generalmente se utilizan 2 para ruteado general (las 2 externas) y 2 para planos de tierra y alimentación respectivamente (las internas).

www.FreeLibros.me



Blind via

Son vías ciegas que conectan una capa exterior con una interior

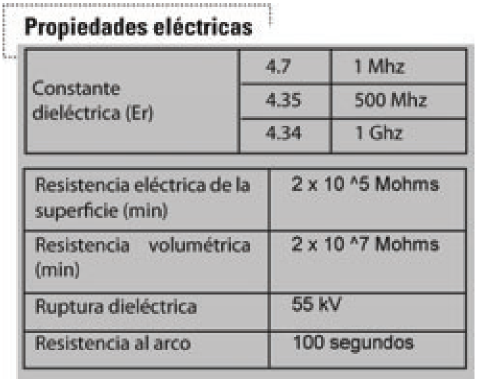
Inner via

Son conexiones internas en impresos multicapa. No son visibles en la superficie

PTH (Plated Through Hole)

Perforación de cobre metalizado que atraviesa de lado a lado un impreso, con la finalidad de brindar conexión eléctrica entre los arreglos de pistas de ambas caras. Pueden corresponder a pads ó vías.

FIGURA 9. El PCB está formado por una capa de cobre montada sobre un sustrato aislante.



Propiedades eléctricas

Constante dieléctrica (Er)	4.7	1 Mhz
	4.35	500 Mhz
	4.34	1 Ghz

Resistencia eléctrica de la superficie (min)	2 x 10 ^5 Mohms
Resistencia volumétrica (min)	2 x 10 ^7 Mohms
Ruptura dieléctrica	55 kV
Resistencia al arco	100 segundos

FIGURA 10. En esta tabla podemos analizar sus propiedades eléctricas.

Es importante que diseñemos la distribución y el trazado antes de montar el circuito. Una vez hecho esto, debemos montar los circuitos integrados para que queden perpendiculares a las columnas de conducción. Luego, cortamos la conducción de las tiras de orificios de manera que los pines enfrentados del integrado no se encuentren unidos. Habiendo tomado esta precaución, aprovechamos las tiras de orificios para conectar el resto de los componentes. Al igual que en el protoboard, los puentes de cable también serán útiles.

Es mucho más fácil hacer una réplica del circuito en el stripboard que en el perfboard. La única

FIGURA 11.
El circuito impreso es una placa especialmente diseñada para el montaje de los componentes.

desventaja es que es menos modificable, ya que cortamos algunas columnas de orificios para adecuarlas a nuestro diseño.

UPCB

Es el circuito impreso universal propiamente dicho, lo más parecido a un PCB. Cuenta con el surco central necesario para montar circuitos integrados de encapsulado DIP (*Dual In Package*). También incluye las líneas o buses en los bordes para alimentar el circuito electrónico. Permite una gran variedad de conexiones, ya que también podemos utilizar puentes de cables en él. Es la opción de mejor calidad, pero también la más costosa. Posee una máscara que recubre las áreas que no necesitan de soldadura y que protege contra la oxidación de la placa y los posibles cortocircuitos. Si operamos con cuidado, lograremos una muy prolija presentación del circuito utilizando el UPCB.

MONTAJE DEL CIRCUITO

La construcción del diseño en el circuito impreso universal depende en gran medida del formato elegido. Debemos familiarizarnos profundamente con la forma y la estructura de la configuración de la placa que vamos a utilizar. Necesitamos disponer de las mismas herramientas que en el caso del protoboard, y sumar el soldador para electrónica (o cautín) y el estaño.

Partiendo de un esquema circuital, será conveniente dibujar primero la distribución de los componentes y su conexión en un papel, para después lanzarnos a la tarea de colocarlos y soldarlos a la placa. Recordemos que al no tratarse de un protoboard, cada vez que decidamos quitar un componente soldado, el cobre de las pistas se verá debilitado, y podrá despegarse de la tarjeta si es que realizamos el desmontaje sucesivas veces. Si al finalizar la construcción del circuito dejamos una parte de la tarjeta sin utilizar, podemos cortarla con un cúter o sierra. De esta forma minimizaremos el tamaño del prototipo y aprovecharemos la placa sobrante para armar otro circuito. Si deseamos producir en serie el diseño probado en el circuito impreso universal, deberemos realizar un PCB específico.

El UPCB posee una máscara que protege a la placa de la oxidación y de los cortocircuitos

www.FreeLibros.me

Circuito impreso **en detalle**

Una vez hecho el diseño del circuito impreso, es necesaria la construcción del mismo. Esta es una tarea que requiere ciertos cuidados, ya que una plaqueta mal fabricada puede poner en peligro el funcionamiento de nuestro proyecto.

MÉTODO DE FABRICACIÓN CASERA

Para impresos que no tengan un alto grado de complejidad, podemos optar por la construcción casera. Se parte de una plaqueta virgen, la cual consta de una base aislante llamada sustrato, sobre la cual se encuentra adherida una fina placa de cobre. El objetivo es obtener nuestro circuito sobre dicha placa, eliminando el cobre sobrante. Para lograr esto tenemos que dibujar a mano sobre la capa de cobre el circuito a obtener, utilizando un marcador indeleble. Luego, para eliminar el cobre sobrante se sumerge la plaqueta en una solución de percloruro férrico.

FABRICACIÓN PROFESIONAL

Para plaquetas con alto grado de dificultad o para producción a gran escala, la construcción de circuitos impresos en forma profesional es la más indicada. De esta manera podemos obtener en forma automatizada circuitos multicapas, los cuales poseen varias capas conductoras. El proceso de fabricación de estos impresos comienza por las capas internas, las cuales poseen láminas de cobre en ambos lados.
Se aplica en estas un film fotosensible para que, mediante fotoexposición y posterior revelado, el diseño del circuito impreso quede grabado sobre las láminas de cobre. Posteriormente se elimina el cobre sobrante, es decir, el que no se encuentra grabado, y los restos de film.

Luego, se realiza una inspección óptica automática, en la cual se compara el impreso obtenido con el diseño original para detectar diferencias. Las placas que no pasan el test son descartadas. Pasado el test, se agregan las capas siguientes mediante prensado y se vuelve a repetir el proceso. La interconexión entre los circuitos correspondientes a cada capa del impreso se realiza mediante orificios llamados vías.

La construcción casera solo es viable para impresos simples, sin demasiada complejidad

OTRO MÉTODO DE FABRICACIÓN

Otro método de fabricación es realizar el diseño en una PC e imprimirlo en un papel vegetal con una impresora láser. Ese dibujo se pasará a la plaqueta virgen por medio del planchado del papel impreso sobre la capa de cobre.

www.FreeLibros.me

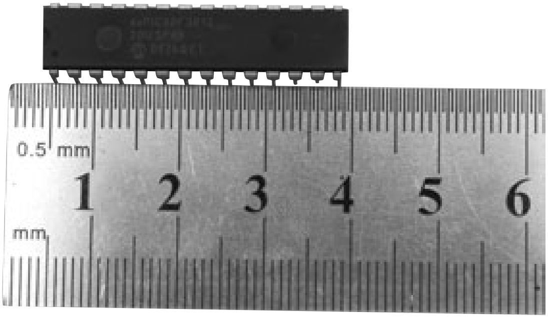
CONSTRUCCIÓN DE UN CIRCUITO IMPRESO

En este apartado aprenderemos paso a paso cómo realizar la construcción de un circuito impreso correspondiente a un **cargador de baterías de Ni-Cd**. Los materiales que necesitamos son: **plaqueta virgen de pertinax** o **epoxi** (de **10 cm** x **10 cm**), **percloruro férrico**, **lana de acero**, **guantes de látex, alcohol fino**, **marcador indeleble**, **multímetro**, **alicate**, **agujereadora** y **mecha de acero rápido** de **1 mm**. Con respecto a los componentes electrónicos, necesitamos: **2** diodos **1N4148**, una resistencia de **10 KΩ**, una resistencia de **56Ω**, una resistencia de **15Ω**, un transistor **BD140** y una llave simple. Para soldar los componentes a la plaqueta, necesitaremos un soldador de **30 W** y **estaño** (**Paso a paso 2**).

Soldadura
para electrónica

El soldador es una de las herramientas básicas de todo electrónico profesional o hobbista. Con él podremos realizar las uniones entre los componentes electrónicos y las pistas de cobre de los circuitos impresos. Para estos casos, los soldadores empleados son de baja potencia, alrededor de **30 W**, para evitar el deterioro de los componentes electrónicos en el proceso de soldado.

El soldador está formado por una resistencia eléctrica en su interior, una **punta de cobre** y un **mango aislante**. Al conectar el cable de alimentación, la resistencia eléctrica se calienta, transmitiendo ese calor a la punta de cobre. Dado que se trata de una herramienta que alcanza temperaturas elevadas, es conveniente el empleo de un soporte adecuado para el mismo. Existen diferentes tipos de soldadores, pero los que se utilizan en electrónica son los llamados “lápiz”, nombre que se les da debido a su forma. La potencia estos instrumentos es de alrededor de 30 W.



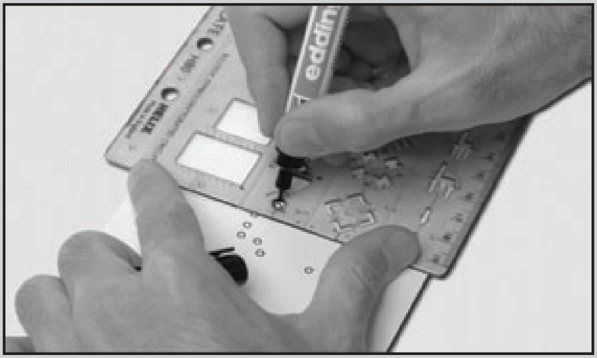
TIPOS DE SOLDADORES

Existen diferentes clases de soldadores. Los más comunes son los de tipo lápiz y pistola. El segundo se calienta por medio de una corriente que pasa por él. Es útil para trabajos esporádicos porque se calienta instántaneamente.

www.FreeLibros.me

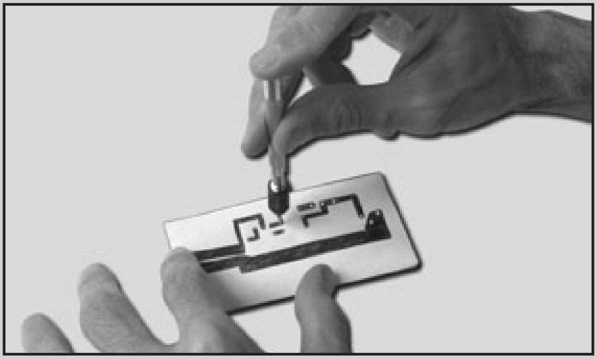
PASO A PASO /2
Construcción de circuito impreso

1



Lo primero que debe hacer es diseñar el circuito que quiere desarrollar. Para ello tiene que utilizar un marcador indeleble y una plantilla para diseño electrónico (*electronic template*). Simplemente, debe trazar las líneas que corresponden a las pistas y los orificios, que es donde colocará los componentes.

2

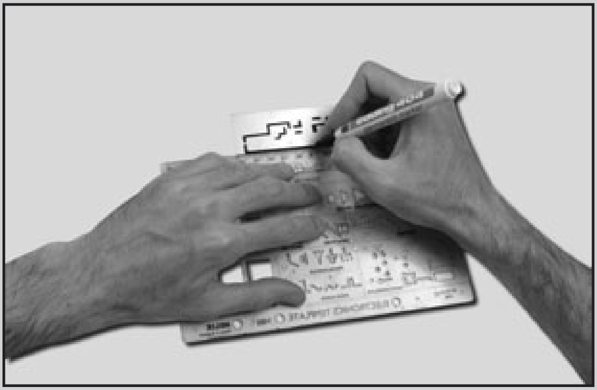


Superponga el diagrama del circuito sobre la plaqueta para realizar las perforaciones donde posteriormente se soldarán los componentes electrónicos. Utilice una perforadora con mecha de **1 mm**. Es una tarea delicada, ya que corre el riesgo de que se levante alguna isla de la plaqueta. Las islas son las áreas de cobre donde van soldados los componentes y donde se debe perforar.

www.FreeLibros.me

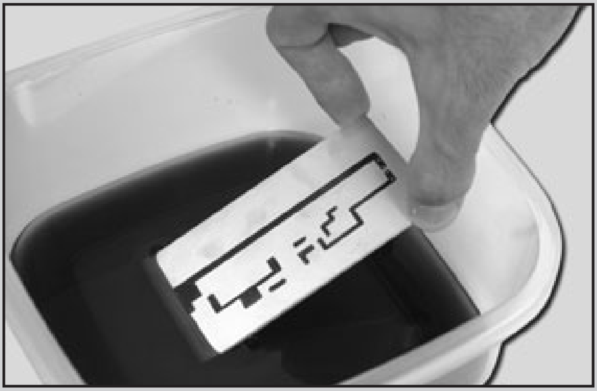
PASO A PASO /2 (cont.)

3



Una vez que tiene los orificios creados, copie el diseño del circuito (**PCB**) de la figura sobre la capa de cobre. Esto se hace con el marcador indeleble. Recuerde que todo lo que esté cubierto con la tinta del marcador indeleble no será atacado por la solución de percloruro férrico.

4

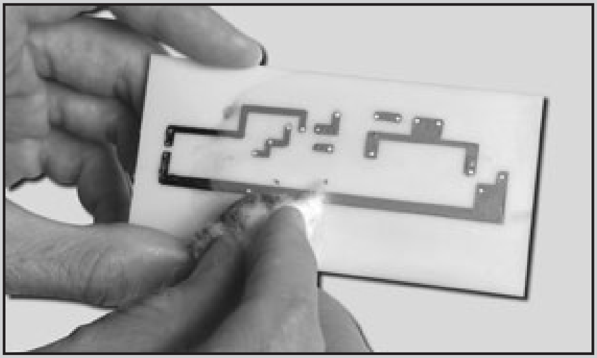


Vierta **percloruro férrico** en un recipiente plástico o de vidrio y sumerja la plaqueta en él durante **15 minutos** aproximadamente. Pasado el tiempo, retire la plaqueta y verifique que no queden sectores de cobre más que los correspondientes al circuito.

www.FreeLibros.me

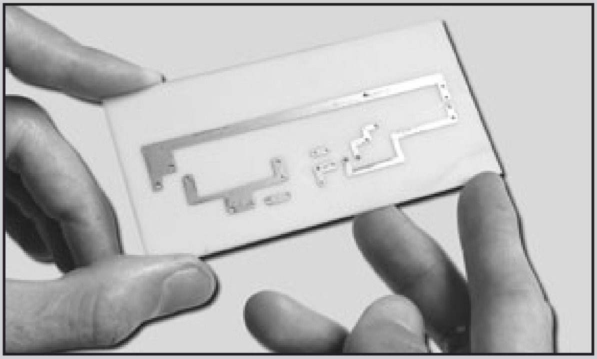
PASO A PASO /2 (cont.)

5



Retire la plaqueta del recipiente y lávela varios minutos con agua. Recuerde que el **percloruro férrico** es un ácido, con lo cual deberá tener mucho cuidado al manipularlo. Seque la plaqueta y retire la tinta del marcador indeleble con una lana de acero. Luego, limpie la superficie con papel tissue humedecido en alcohol fino.

6

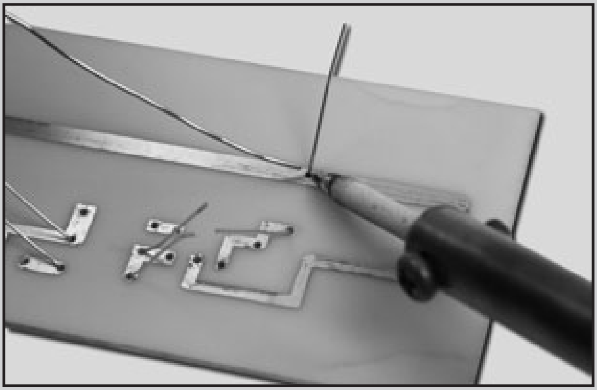


Una vez que tiene la plaqueta lista, debe verificar que las pistas hayan quedado correctamente formadas, del mismo modo que las islas. Para una revisión más exhaustiva utilice un multímetro en la función de continuidad o midiendo resistencia. En el caso de que exista un corto entre dos pistas, será necesario eliminar el cobre excedente con un cúter o herramienta similar.

www.FreeLibros.me

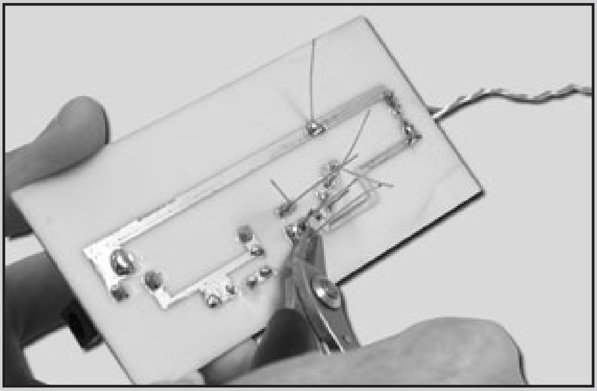
PASO A PASO /2 (cont.)

7



Con la plaqueta en condiciones, coloque los componentes más pequeños, como las resistencias y los diodos. Luego dé vuelta la plaqueta y aplique la soldadura. Siempre es recomendable que el soldador tenga una buena temperatura para trabajar mejor con la aleación de estaño.

8



Luego, siga con los componentes más grandes, como los capacitores, transistores, integrados y llaves. Esta práctica facilitará el proceso de soldado. Finalmente, debe cortar con el alicate el alambre excedente de los terminales de los componentes.

www.FreeLibros.me

MATERIAL PARA SOLDAR

El estaño es el elemento que se utiliza para realizar la soldadura. En realidad, no se trata de estaño solamente, sino de una aleación de **60% de estaño** y **40% de plomo**. Además de estos dos materiales, posee una resina, la cual permite realizar una buena soldadura, protegiendo a las superficies de la temperatura del soldador. Físicamente es un alambre de contextura blanda. Se vende en carretes y existen distintos espesores, como de **0,5 mm**, **1 mm**, etc., dependiendo del tamaño del área a soldar.

PROCESO DE SOLDADO

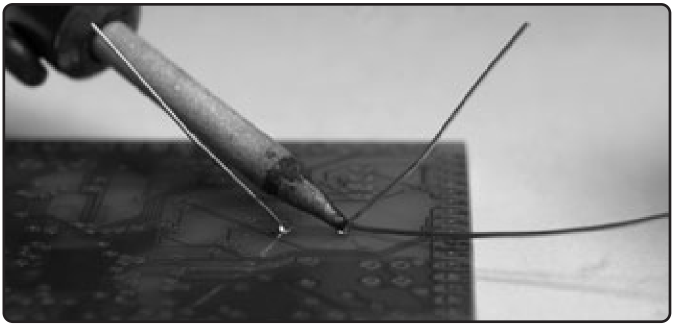
El proceso de soldado consiste en unir, tanto mecánica como electrónicamente, un componente electrónico con la correspondiente pista de cobre, empleando un soldador y estaño.
Una vez que el soldador alcanzó la temperatura de operación, se deberá tener la precaución de que la punta del instrumento esté limpia. Para ello, se puede emplear un cepillo o un trozo de tela de jean. Nunca se deben usar materiales que rayen la punta. Las partes que se vayan a soldar deben estar limpias y libres de impurezas. Una buena práctica es estañar previamente las partes a soldar.

Los soldadores empleados son de baja potencia y manejan cerca de 30 Watts

Ahora sí estamos listos para soldar. Para hacerlo, tomamos con una mano el soldador y, con otra, un trozo de estaño. Calentamos entre 2 y 3 segundos el área a soldar y sin quitar el soldador aplicamos el alambre de estaño en la zona. Rápidamente quitamos el estaño y por último el soldador, con el fin de permitir que se enfríe la soldadura. No debemos forzar el enfriamiento, ya que esto puede derivar en una mala soldadura.

Dependiendo del tamaño del área a soldar, variará la cantidad de estaño a utilizar. Si aplicamos poca cantidad, si bien conducirá la electricidad, la soldadura no va a tener una adecuada resistencia mecánica, con lo cual, puede desoldarse fácilmente. Si aplicamos estaño en exceso, corremos el riesgo de poner en corto las pistas del circuito impreso al desbordarse el estaño. En general, con unos pocos milímetros es suficiente (**Figura 12, 13, 14 y 15**).

FIGURA 12.
Soldar es sencillo, pero requiere de experiencia. Es importante cumplir con las buenas prácticas, como mantener limpia la punta del soldador, aplicar el calor adecuado y usar la correcta cantidad de estaño.



www.FreeLibros.me

Se debe aplicar el calor justo y necesario, ya que si nos excedemos, es probable que se dañen los componentes o que se levanten las pistas del circuito impreso. Por otro lado, si aplicamos poco calor, se puede realizar una soldadura "fría", la cual a simple vista es opaca, y tendrá poca resistencia mecánica y baja conductividad eléctrica.

DESOLDADO

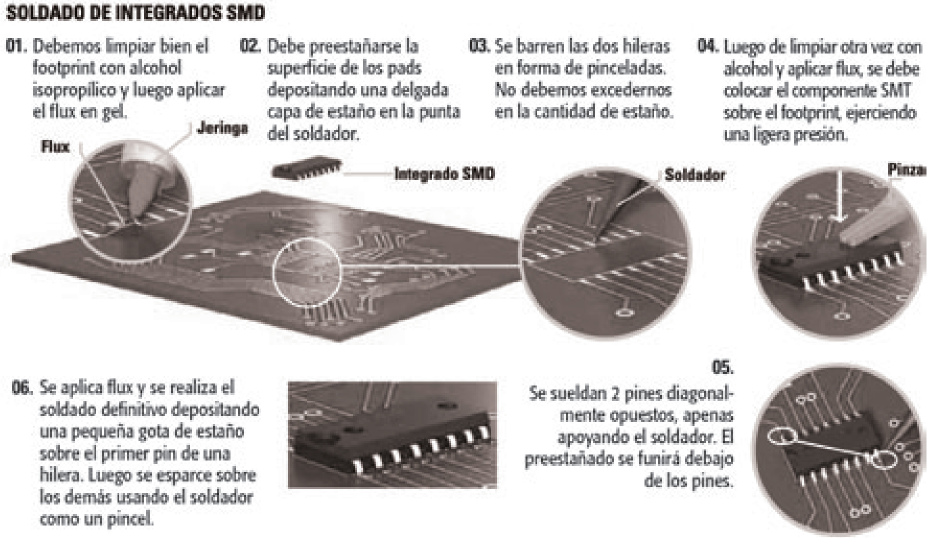
Existen varios métodos para desoldar componentes electrónicos. Uno de ellos es mediante el uso de un **desoldador** (**chupador de estaño**). Este dispositivo es básicamente una bomba de succión, formada en general por un cilindro de aluminio el cual tiene en su interior un émbolo accionado por un resorte.

Posee una punta por la cual se succiona el estaño y un pulsador que libera el resorte que desplaza el émbolo y produce la succión.

El procedimiento de uso es bastante simple. Primero se prepara el desoldador, accionando el émbolo. Luego se apoya la punta del desoldador sobre el estaño que necesita ser quitado. Seguidamente, se apoya la punta del soldador sobre el área a ser desoldada. (**Figura 16**)

Luego de unos pocos segundos, cuando se funde el estaño, se acciona el pulsador del desoldador, para producir la succión del estaño. Este proceso se deberá repetir si aún quedan restos de estaño.

En este capítulo, aprendimos cómo realizar circuitos impresos y sus características. Además hicimos las primeras conexiones en el protoboard, valiéndonos de las ventajas que aporta trabajar sobre este. También, analizamos todo sobre el proceso de soldado.



SOLDADO DE INTEGRADOS SMD

01. Debemos limpiar bien el footprint con alcohol isopropílico y luego aplicar el flux en gel.

02. Debe preestañarse la superficie de los pads depositando una delgada capa de estaño en la punta del soldador.

03. Se barren las dos hileras en forma de pinceladas. No debemos excedernos en la cantidad de estaño.

04. Luego de limpiar otra vez con alcohol y aplicar flux, se debe colocar el componente SMT sobre el footprint, ejerciendo una ligera presión.

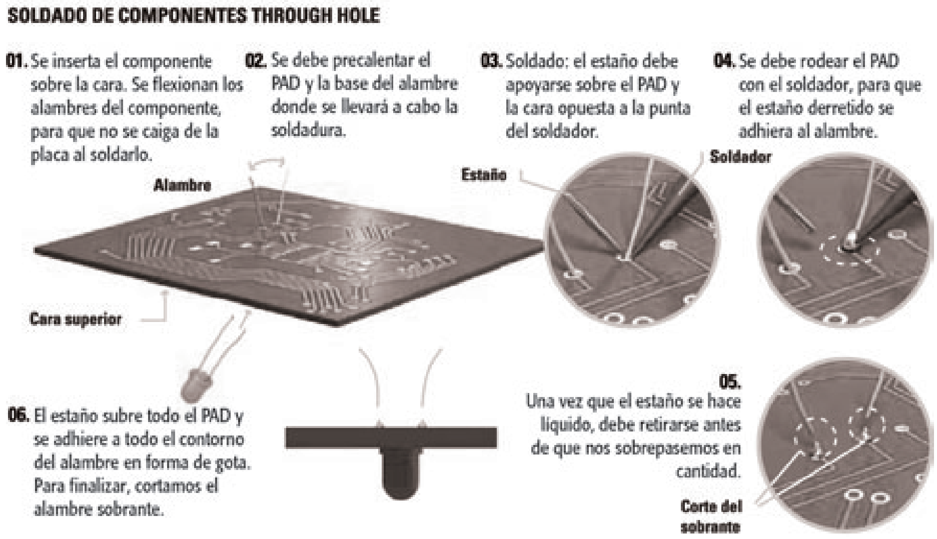
05. Se sueldan 2 pines diagonalmente opuestos, apenas apoyando el soldador. El preestañado se funirá debajo de los pines.

06. Se aplica flux y se realiza el soldado definitivo depositando una pequeña gota de estaño sobre el primer pin de una hilera. Luego se esparce sobre los demás usando el soldador como un pincel.

FIGURA 13. En esta infografía, encontramos las diferentes técnicas de desoldado.

www.FreeLibros.me

ELECTR_Cap2_xxx_xxx_ajustado.qxp 04/07/2011 16:32 PÆgina 54



SOLDADO DE COMPONENTES THROUGH HOLE

01. Se inserta el componente sobre la cara. Se flexionan los alambres del componente, para que no se caiga de la placa al soldarlo.

02. Se debe precalentar el PAD y la base del alambre donde se llevará a cabo la soldadura.

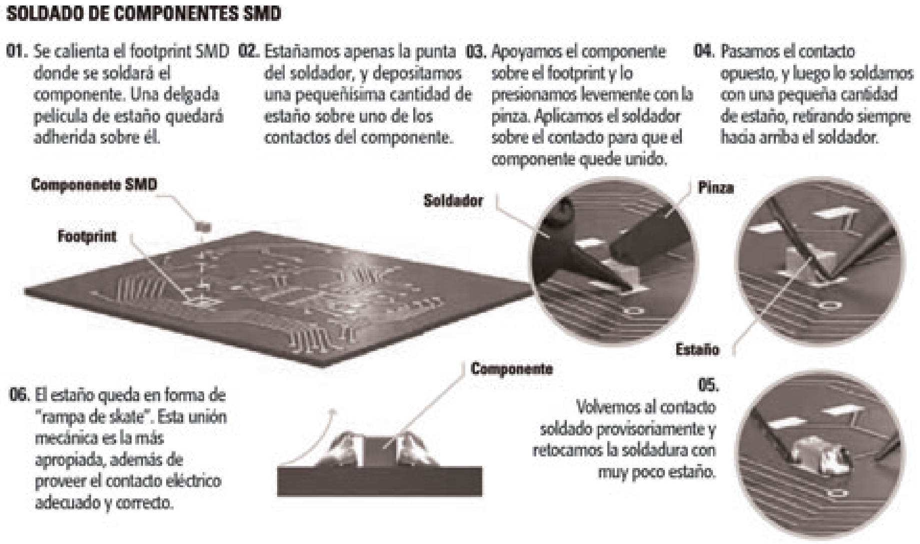
03. Soldado: el estaño debe apoyarse sobre el PAD y la cara opuesta a la punta del soldador.

04. Se debe rodear el PAD con el soldador, para que el estaño derretido se adhiera al alambre.

05. Una vez que el estaño se hace líquido, debe retirarse antes de que nos sobrepasemos en cantidad.

06. El estaño subre todo el PAD y se adhiere a todo el contorno del alambre en forma de gota. Para finalizar, cortamos el alambre sobrante.

FIGURA 14. **En estos pasos, analizamos cómo realizar el soldado de componentes through hole.**



SOLDADO DE COMPONENTES SMD

01. Se calienta el footprint SMD donde se soldará el componente. Una delgada película de estaño quedará adherida sobre él.

02. Estañamos apenas la punta del soldador, y depositamos una pequeñísima cantidad de estaño sobre uno de los contactos del componente.

03. Apoyamos el componente sobre el footprint y lo presionamos levemente con la pinza. Aplicamos el soldador sobre el contacto para que el componente quede unido.

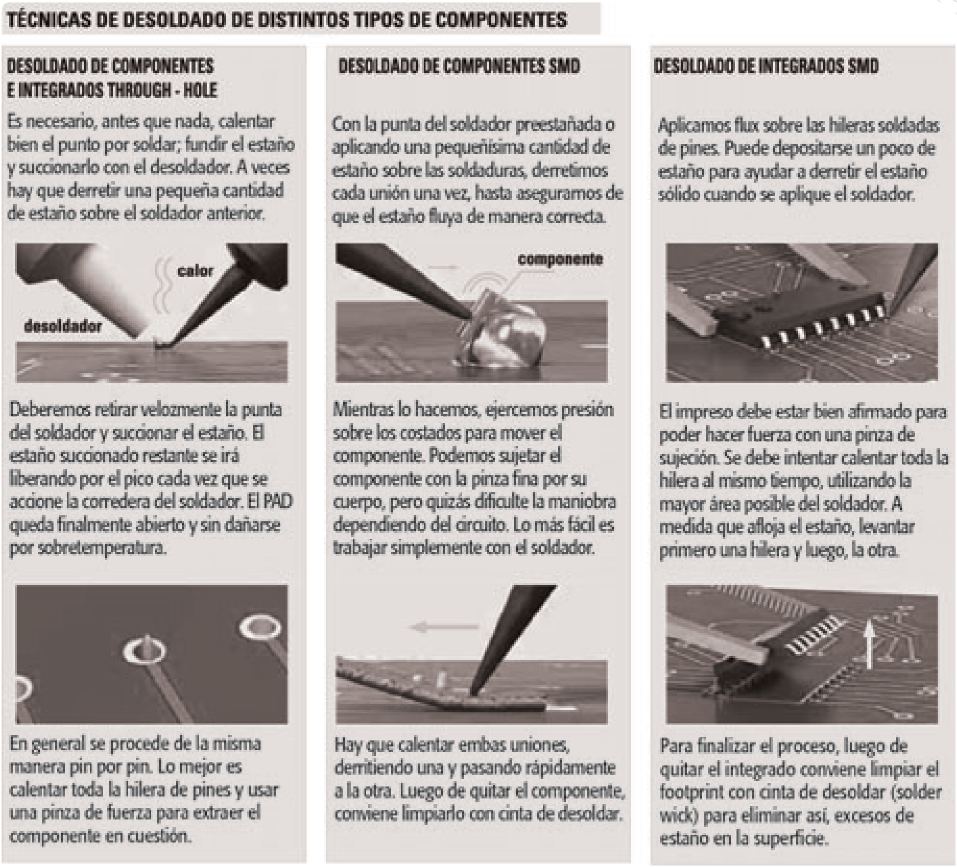
04. Pasamos el contacto opuesto, y luego lo soldamos con una pequeña cantidad de estaño, retirando siempre hacia arriba el soldador.

05. Volvemos al contacto soldado provisoriamente y retocamos la soldadura con muy poco estaño.

06. El estaño queda en forma de "rampa de skate". Esta unión mecánica es la más apropiada, además de proveer el contacto eléctrico adecuado y correcto.

FIGURA 15. **Al seguir este procedimiento, aprenderemos a soldar componentes SMD.**

www.FreeLibros.me



TÉCNICAS DE DESOLDADO DE DISTINTOS TIPOS DE COMPONENTES

DESOLDADO DE COMPONENTES E INTEGRADOS THROUGH - HOLE

Es necesario, antes que nada, calentar bien el punto por soldar; fundir el estaño y succionarlo con el desoldador. A veces hay que derretir una pequeña cantidad de estaño sobre el soldador anterior.

Deberemos retirar velozmente la punta del soldador y succionar el estaño. El estaño succionado restante se irá liberando por el pico cada vez que se accione la corredera del soldador. El PAD queda finalmente abierto y sin dañarse por sobretemperatura.

En general se procede de la misma manera pin por pin. Lo mejor es calentar toda la hilera de pines y usar una pinza de fuerza para extraer el componente en cuestión.

DESOLDADO DE COMPONENTES SMD

Con la punta del soldador preestañada o aplicando una pequeñísima cantidad de estaño sobre las soldaduras, derretimos cada unión una vez, hasta asegurarnos de que el estaño fluya de manera correcta.

Mientras lo hacemos, ejercemos presión sobre los costados para mover el componente. Podemos sujetar el componente con la pinza fina por su cuerpo, pero quizás dificulte la maniobra dependiendo del circuito. Lo más fácil es trabajar simplemente con el soldador.

Hay que calentar embas uniones, derritiendo una y pasando rápidamente a la otra. Luego de quitar el componente, conviene limpiarlo con cinta de desoldar.

DESOLDADO DE INTEGRADOS SMD

Aplicamos flux sobre las hileras soldadas de pines. Puede depositarse un poco de estaño para ayudar a derretir el estaño sólido cuando se aplique el soldador.

El impreso debe estar bien afirmado para poder hacer fuerza con una pinza de sujeción. Se debe intentar calentar toda la hilera al mismo tiempo, utilizando la mayor área posible del soldador. A medida que afloja el estaño, levantar primero una hilera y luego, la otra.

Para finalizar el proceso, luego de quitar el integrado conviene limpiar el footprint con cinta de desoldar (solder wick) para eliminar así, excesos de estaño en la superficie.

FIGURA 16. **Vemos de qué manera realizar el soldado de integrados SMD.**

HISTORIA DEL PROCESO DEL SOLDADO

El primer proceso de soldadura fue la **soldadura de fragua**, que predominó hasta el siglo XIX. Se desarrollaron luego la **soldadura por arco** y la **soldadura a gas**, seguidas por la **soldadura por resistencia**. A principios del siglo XX, las técnicas de soldado se multiplicaron.

Instrumentos de medición

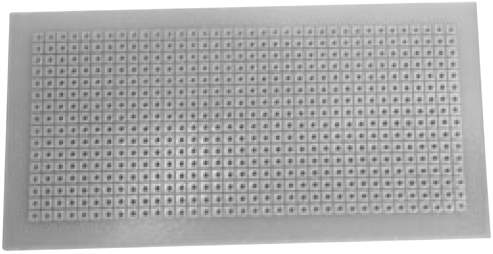
En esta capítulo explicaremos cuáles son las medidas que podemos realizar sobre un circuito, cuál es la manera apropiada de hacerlo y qué instrumentos necesitamos.

Tomar una medida es comparar dos cantidades de una determinada magnitud física. Para esto, podemos contar con instrumentos digitales o analógicos. Los primeros –por definición de la norma **IEC 485** (*International Electrotecnic Comission*)– son aquellos donde la indicación aparece en forma numérica.

Los segundos –por definición de la norma **IEC 51**– son aquellos en los cuales la indicación resulta de relacionar la posición de un índice respecto de una escala graduada. Lo que diferencia a un instrumento analógico de uno digital son los procesos que se realizan en la adquisición de la señal a medir. Para el caso de estos últimos, los procedimientos involucran técnicas de conversión analógico-digital de la señal de entrada. Los analógicos, en cambio, proporcionan una salida de naturaleza continua, ante una entrada del mismo tipo.



Instrumentos analógicos

En este apartado, conoceremos las nociones elementales inherentes a los instrumentos analógicos. Analizaremos sus parámetros y especificaciones más relevantes. La presencia de una escala graduada y de un índice o aguja para la indicación de resultados son datos más que suficientes para reconocer, en forma inmediata, un instrumento analógico. El corazón de todo instrumento de medición analógico en continua es el elemento de imán permanente y bobina móvil, también conocido como **D´Arsonval**.

Los analógicos son instrumentos en los que se establece un campo magnético en el espacio existente (entrehierro) entre la bobina móvil y el imán permanente (**Figura 1**). La bobina móvil es solidaria con el índice (aguja de indicación) que se desplaza sobre la escala graduada. Dicho campo magnético tiene dirección radial y uniforme. Esto conlleva a una relación matemática entre la **cupla** (par de fuerzas que genera el movimiento del índice) y la **señal** que se detecta.

ALCANCE DE TENSIÓN DEL INSTRUMENTO ANALÓGICO

Describiremos a continuación cómo se utiliza en los voltímetros analógicos, el instrumento de D´Arsonval como núcleo. Si llamamos **Im** a la intensidad de corriente máxima que circula por la bobina del galvanómetro, y **Rg** a la resistencia eléctrica que presenta dicha bobina, al aplicar la ley de Ohm, podemos determinar el alcance de tensión **Um** del instrumento básico. Se denomina alcance de un instrumento al máximo valor de medida –valor de fondo de escala–

www.FreeLibros.me

que puede indicar bajo una determinada configuración. Ahora bien, ¿qué pasaría si necesitáramos realizar medidas de tensiones mayores a las que permite el instrumento básico de D´Arsonval?

Para resolver esto, es necesario intercalar otra resistencia **Rs** (denominada resistencia multiplicadora) en serie con la bobina. También tendremos que aplicar una tensión **Us** mayor, para establecer una corriente **Im** que produzca la misma deflexión del índice. De este modo, hemos cambiado el alcance de tensión del instrumento de **Um** a **Us**.

Todo voltímetro analógico de continua incorpora el instrumento de D´Arsonval como núcleo

CIFRA EN OHM/VOLT

Cuando se habla de **cifra en Ohm/Volt**, se hace referencia a la indicación de la sensibilidad del instrumento. Recordemos que **Im** es la intensidad de

corriente máxima admisible por el instrumento de **D´Arsonval**. Para el voltímetro se cumple la siguiente ecuación: **Im = Um / Rg = Us / Ri = cte,** donde **Ri** es la resistencia interna del voltímetro para un determinado alcance.

Llamaremos resistencia interna de un voltímetro a la suma de las resistencias **Rs** (multiplicadora) y **Rg** (del devanado de la bobina): Ri = Rs + Rg.

Al cociente **Ri / Us** se lo denomina **cifra en Ohm/Volt** y es una indicación de la sensibilidad del instrumento. A mayor cifra en Ohm/Volt, estaremos en presencia de un instrumento de mayor calidad.

AMPERÍMETRO ANALÓGICO

Un razonamiento similar al anterior se emplea para utilizar el instrumento de D´Arsonval cómo **amperímetro** de distintos alcances. En estos casos, se hace uso de una resistencia derivadora **Rshunt** (denominada resistencia de Shunt) en paralelo con el instrumento básico, conformando un divisor de corriente. Ante la excitación de una corriente **Is**, la resistencia derivadora Rshunt se elige de manera que, a través de la bobina de resistencia **Rg**, circule **Im**, por la simple aplicación de la **Ley de Ohm**.

Otro índice o parámetro de fabricación característico de los instrumentos analógicos es el denominado índice de clase C

ÍNDICE DE CLASE DE UN INSTRUMENTO ANALÓGICO

Otro índice o parámetro de fabricación característico de los instrumentos analógicos es el denominado **índice de clase C**, el cual nos permite calcular el error intrínseco del instrumento. Se define así al error que se comete sistemáticamente por la utilización del instrumento en la obtención de una medida. Es propio del instrumento. Dado el índice de **clase C**, el error intrínseco (**Ei**) del instrumento se obtiene al despejar la siguiente ecuación: **Ei = C x (Valor de fondo de escala)** (**Figura 2**).

FIGURA 2. **Los instrumentos analógicos son precisos, pero debemos saber que siempre hay un margen de error en la medición.**

www.FreeLibros.me

EL MULTÍMETRO DIGITAL

Se denomina multímetro a aquel instrumento que nos permite configurarlo como **voltímetro**, **amperímetro** y **óhmetro** (instrumento de medición de valores de resistencia). Las versiones digitales incorporan funciones de **capacímetro**, **frecuencímetro** (hasta 20 **KHz**), de medición de **hfe** (ganancia), de transistores y de termocuplas, para medir temperaturas sobre superficies. A estas funciones extra se les suman las utilidades de comprobación de **continuidad eléctrica** y **prueba de diodos**.

Podemos destacar también que con multímetros digitales es posible realizar medidas, no solo de **voltajes** y de **corrientes continuas**, sino también de **señales alternas** que se ajusten a los alcances del instrumento (**Figura 3**). Algunos multímetros más completos incorporan la función "**autorango**", es decir, el instrumento selecciona automáticamente el rango, sin necesidad de intervención de la persona.

PRINCIPIO DE FUNCIONAMIENTO

Un multímetro digital está formado por distintos bloques funcionales que conforman las etapas de tratamiento de la señal a medir. La primera etapa está compuesta por un amplificador atenuador construido a partir de amplificadores operacionales.

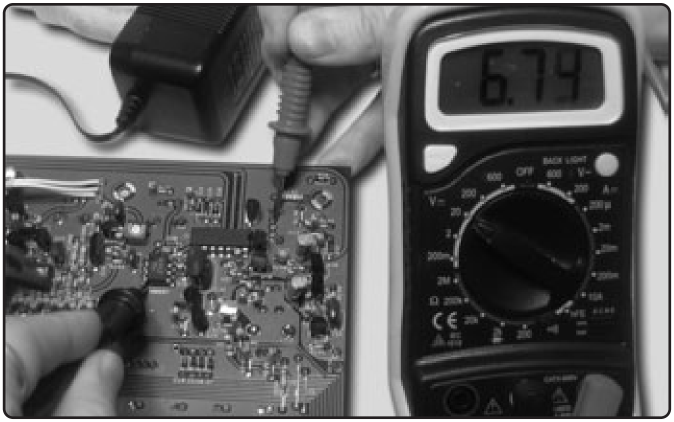

FIGURA 3.
Un multímetro digital **nos permitirá realizar la mayoría de las mediciones necesarias en la práctica: medidas de** tensión AC y DC, corriente AC y DC, capacidad, resistencia y comprobación de continuidad.

CONSEJO PARA INSTRUMENTOS ANALÓGICOS

Siempre conviene medir lo más próximo posible al fondo de escala, para que el error relativo tenga menor peso. El error relativo mínimo que podemos obtener es el que se comete cuando se mide a fondo de escala.

www.FreeLibros.me

El bloque atenuador, además de actuar como selector de rango, proporciona una elevada resistencia de entrada, para minimizar el error de inserción en las medidas de voltaje (**Figura 4**).

El bloque siguiente corresponde a un acondicionador de señal, que adapta la salida del amplificador atenuador al rango de trabajo del conversor A/D (generalmente, de **12 bits** y del tipo doble-rampa). Para mediciones de alterna, se deriva la entrada a circuitos rectificadores que convierten la señal a un valor de continua. Lo que resta, simplemente, es la etapa de procesamiento de la salida digital del conversor A/D, que permite la visualización del resultado en el display numérico (**Figura 5**).

USO DEL MULTÍMETRO DIGITAL

Aprenderemos a realizar dos mediciones sobre un circuito: la medida de diferencia de tensión entre dos puntos y la intensidad de corriente por una rama.

El multímetro es el instrumento que permite realizar la mayoría de las mediciones de un circuito

Antes de empezar, realizaremos unas comprobaciones de rutina. Primero, nos aseguraremos de que el **tester** tenga buena carga de batería. Algunos testers muestran el nivel de batería en el display. Pero también podemos darnos cuenta de que la batería está baja, porque el pitido que genera el instrumento –cuando medimos continuidad– es débil.

Verificaremos, también, que el **fusible** de protección del multímetro no se encuentre cortado. Generalmente, el fusible queda expuesto cuando retiramos la tapa trasera del tester. Además, controlaremos que las puntas y los cables de las puntas estén en buenas condiciones. Por último, al realizar las medidas, tomaremos la precaución de no tocar con nuestros dedos las partes metálicas de las puntas de medición; Las tomaremos siempre por su mango plástico, para no afectar las medidas y también por seguridad. De todas maneras, en este caso, los valores de tensión y corriente manejados son completamente

inocuos. El circuito en cuestión se puede armar sencillamente con una **batería** de **9 V** y dos **resistencias comerciales** de **3,3 KOhm**.

Para medir una diferencia de tensión, ubicamos en el circuito los bornes de la **resistencia R2**. Debemos asegurarnos, previo a la medición, de que el alcance seleccionado sea el adecuado, para no dañar al tester y poder registrar la medida. La tensión a medir será aproximadamente de **4,5 V**. Luego, el alcance que se deberá seleccionar con la rueda será el de **20 V** para la "sección de continua".

www.FreeLibros.me

Para medir una diferencia de **tensión positiva**, debemos ubicar la **punta roja** del tester digital sobre el borne superior de la resistencia **R2**. Debido al sentido de la circulación de corriente, este borne será el de valor tensión positivo. La masa o retorno del multímetro (**COM**) se ubicará sobre el otro borne, que corresponde a la tierra del circuito, es decir, nos "colgamos" en paralelo de la resistencia **R2** (**Figura 6**).

El tester configurado como voltímetro en su condición ideal actúa como un circuito abierto. Presenta, de este modo, una impedancia infinita cuando se conectan las puntas en paralelo con los bornes a medir. Esto no es así en la realidad. La resistencia interna (Ri) del tester tiene un valor definido que derivará corriente para sí, disminuirá la caída sobre R2 y afectará, así, la medida.

A esto se lo llama error de inserción. Por suerte, se los puede calcular en forma exacta. Para nuestro caso, hacemos las cuentas como se ve en la **Figura 7**.

Para realizar una medición de corriente, ahora configuraremos el multímetro como amperímetro. La primera diferencia con respecto a la medición de voltaje es que el tester deberá colocarse en serie con la corriente a medir. Así, nos vemos obligados a abrir el circuito para intercalar el multímetro. La corriente por medir será de **1,36 mA**.

Luego, el alcance a seleccionar será el de **2 mA** para la sección de corriente continua. Para efectuar la medición, debemos cambiar la posición del cable de **punta rojo** (**vivo**). Ahora, se ubicará en la entrada (**mA**) del tester, protegida por el fusible de **200 mA**.

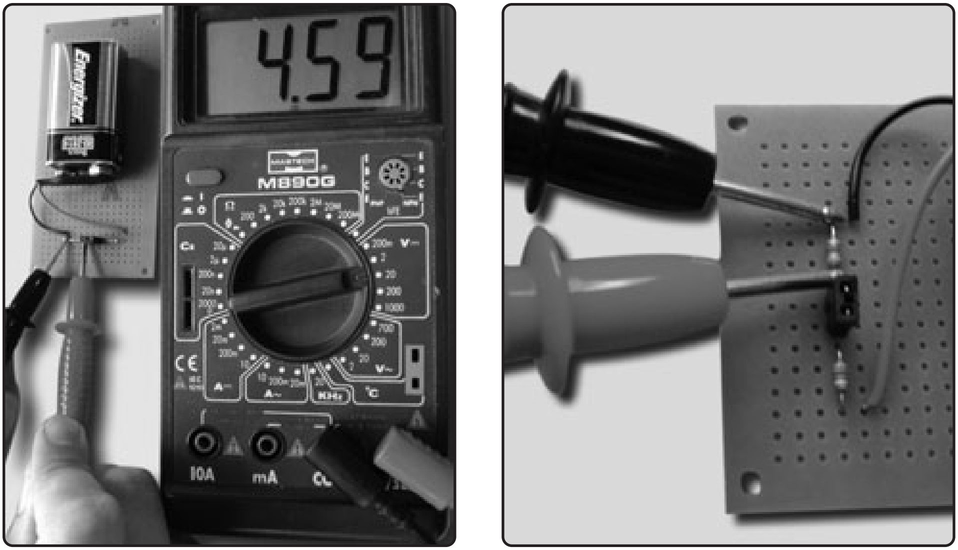

FIGURA 6. Al colocar las puntas al revés, la medida arrojará un valor negativo en el multímetro.

www.FreeLibros.me

Algunos testers muestran el nivel de batería en el display

Las puntas del tester deben colocarse de manera tal que la roja se conecte con la entrada de corriente a medir, y la negra, con el punto de salida. Registraremos así un valor positivo de corriente. Si invirtiéramos las puntas, el signo de la indicación en el display cambiaría. El amperímetro ideal es visto como un cortocircuito (**resistencia cero**) por el circuito. Pero la resistencia interna del amperímetro, aunque muy pequeña, se suma a la equivalente del circuito, y se opone también al paso de la corriente. Por lo tanto, la corriente medida tiene un valor menor al real. El cálculo de dicho error de inserción se ve en la **Figura 8**.

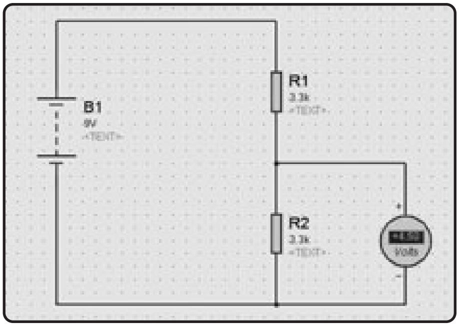

FIGURA 7.
Rinterna voltímetro = 1 Mohm
Vverdadero = 9 V * [(3.3 k + 3.3 k) / 3.3 k] = 4.5 V
Vmedida = [9 V / (R1 + R2 // Ri)] * (R2 // Ri) = [9 V / (3.3 k + 3.289 k)] * (3.289 k) = 4.4925
%error = (Verdadero–Vmedido)/Verdadero = 0.75% Menor al 1%.!!!

Cargador de baterías Ni-Cd

En este apartado realizaremos la comprobación de continuidad, y la medición de parámetros de componentes, voltajes y corrientes en funcionamiento normal. Haremos las mediciones pertinentes para la comprobación del funcionamiento del circuito cargador de baterías de Ni-Cd. Para tal tarea, utilizaremos un multímetro digital típico, de **3 ½ dígitos**. Todas las mediciones que llevaremos a cabo serán de continua, ya que el circuito no posee tensiones ni corrientes de alterna, salvo en el circuito de fuente, que no analizaremos aquí.

Primero, haremos ciertas comprobaciones sin alimentación, relacionadas con la seguridad eléctrica,

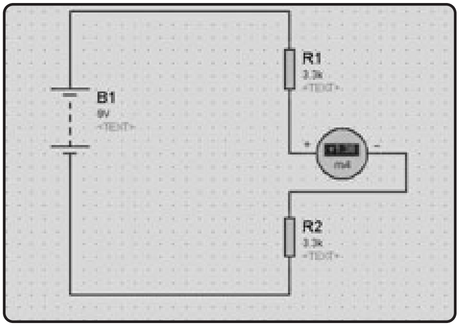

FIGURA 8.
Rinterna amperímetro = 100 Ohm (ejemplo)
Iverdadera = 9 V * [(3.3 k + 3.3 k)] = 1.3636 A
Imedida = [9 V / (R1 + R2 + Ri)] = 9 V / (3.3 k + 3.3 k + 100 Ohm) = 1.3433
%error = (Iverdadera–Imedida)/Iverdadera = 1.49 %

www.FreeLibros.me

ELECTR_Cap3_xxx_xxx_ajustado.qxp 04/07/2011 16:33 PÆgina 68

conexionado y buen funcionamiento de los componentes del circuito. Las otras mediciones se harán con el circuito cargador alimentado a **12 V de continua** (**Figura 9**).

No importa el orden con que se conecten las puntas sobre el circuito para medir continuidad

COMPROBACIONES DE CONTINUIDAD

Realizaremos una comprobación de rutina, para la cual se empleará el multímetro en el modo **detección de continuidad**. En este modo, no importa la posición de las puntas. Mientras haya conexión, la alarma sonora se activará indicando que existe continuidad eléctrica. La punta de medición roja debe conectarse al borne **V/Ohm** del multímetro y, la negra, a la tierra **(COM)**. La comprobación consiste en asegurarnos de que haya continuidad eléctrica en los bornes que deben estar conectados a la masa del circuito.

Tomando como referencia la **Figura 9**, hacemos base en **C** (GND a la entrada del circuito) con cualquier punta, y recorremos los puntos **D** (borne a masa de la resistencia de 10k) y **F** (borne negativo de la batería sobre el circuito). La alarma sonora indicará la existencia de continuidad eléctrica.

PARÁMETROS DE COMPONENTES

Ahora, vamos a medir ciertos parámetros de los componentes utilizados, que nos indicarán si se encuentran en buen estado. Salvo la medición del **hfe** (ganancia) del transistor **PNP**, las otras dos se pueden realizar con el circuito ensamblado. Las mediciones son las siguientes:

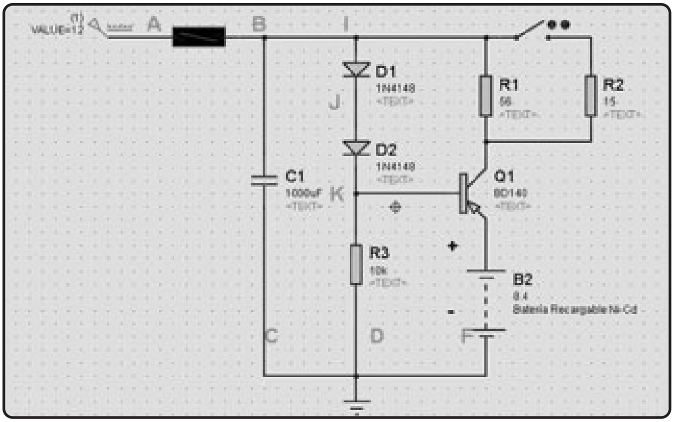

FIGURA 9. **Observamos el diseño del circuito donde se marcan los puntos de referencia para las mediciones.**

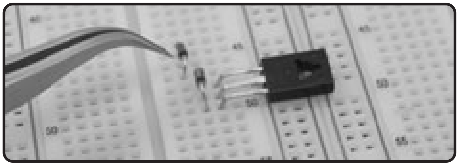
www.FreeLibros.me

- Medición del umbral de los diodos (I y J de la **Figura 9**, en la página anterior).
- Medición de las resistencias de selección de velocidad de carga.
- Medición del hfe (ganancia) del transistor PNP.

La utilidad de comprobación de diodos se encuentra casi siempre en la misma posición de la rueda que la detección de continuidad. Al posicionar la punta roja **V/Ohm** sobre el ánodo del diodo (**I**) y la punta **COM** sobre el cátodo (**J**), observaremos, en pantalla del multímetro, un valor en **mVolts**, que indicará la tensión umbral del diodo (**cercano a los 600 mV**).

Si invertimos las puntas de medición, el tester deberá indicar infinito, mostrando el número 1 en el bit más significativo. Esto es así ya que, ahora, la corriente que inyecta el tester para realizar la medición se encuentra con el diodo en inversa. Luego, el multímetro ve un circuito abierto y la medición no se efectúa por no poder establecerse la corriente.

A continuación, pasaremos a medir las resistencias de conmutación, cuyos valores se encuentran calculados para el establecimiento de dos intensidades de corriente fijas: **15 mA** y **45 mA**. Para llevar a cabo estas mediciones, emplearemos el multímetro digital como **óhmetro**. Siempre con la punta roja en el borne **V/Ohm** y la negra en la tierra común **COM**, medimos a ambos extremos de las resistencias del circuito. Es suficiente la selección del alcance más bajo de **200 Ohm**. La medición del hfe del transistor bipolar es muy sencilla de realizar, aunque no todos los multímetros incorporan esa funcionalidad.



Una vez insertado el componente en el zócalo, se visualiza en pantalla la ganancia del transistor. El **BD140** es un transistor bipolar PNP, por lo que debe insertarse en el zócalo correspondiente. Esta es una función que mide el parámetro **hfe** de transistores bipolares. No debe usarse para hacer medidas de transistores del tipo **FET**, ya que puede dañarse (**Figura 10**).

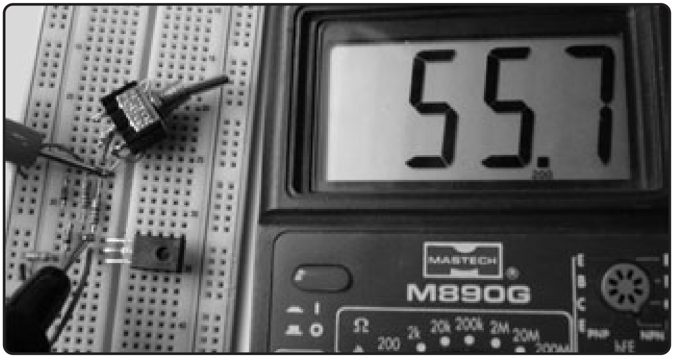


FIGURA 10.
Con el circuito sin alimentar, es posible utilizar el multímetro como óhmetro y estimar el valor de las resistencias.

www.FreeLibros.me

Mediciones con el circuito **alimentado**

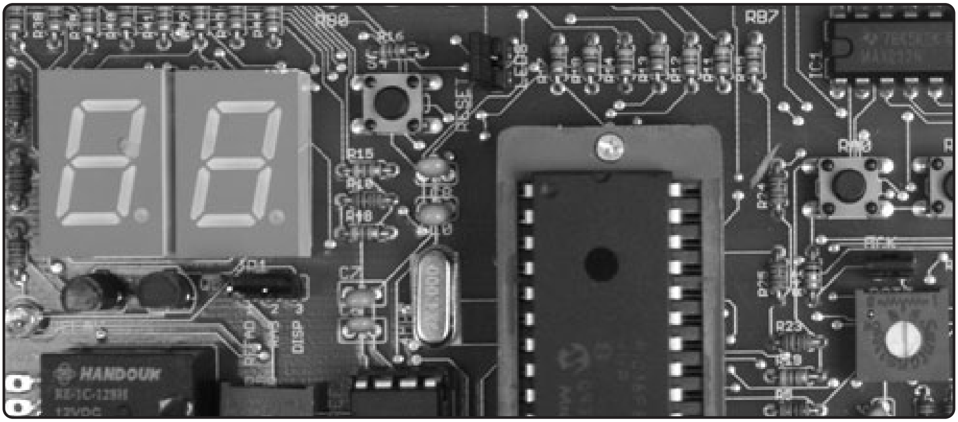
Hasta el momento, aprendimos a tomar medidas. Ahora, realizaremos algunas mediciones elementales pero, en esta ocasión, lo haremos con el circuito alimentado con 12 V.

Realizaremos una medición de voltaje sobre los diodos **D1 y D2**. Una vez que se han realizado todas las mediciones anteriores, podemos proseguir a alimentar el circuito con los **12 V de continua**. Mediremos, ahora, la caída de tensión de "**on**" de ambos diodos en conducción. Estos diodos tienen como función polarizar, en forma permanente, la juntura **Emisor-Base** del transistor **PNP**.

Como todos sabemos, establecida **IB**, **IC** queda unívocamente determinada a través de la ganancia **hfe** del transistor de **unión bipola**r: **IC = hfe x IB**. Vamos a verificar, mediante dos rápidas medidas, que efectivamente encontremos 1,2 V sobre los diodos, polarizando la juntura del PNP. También veremos qué valor de tensión encontramos sobre la **juntura E-B**.

Como primer paso, seleccionaremos el alcance de **2 V** del instrumento, corriendo la rueda de selección hacia la posición indicada. Luego, colocaremos la punta roja sobre el **ánodo (I)** del diodo 1. Efectuaremos la medida, posicionando ahora la **punta COM** sobre el **cátodo** (**K**) correspondiente al diodo 2. Como era previsto, la medida arrojará un valor de tensión fijo cercano a los **+1,2 V**.

Para medir la corriente, ponemos el cable rojo en el borne (mA) del tester



www.FreeLibros.me

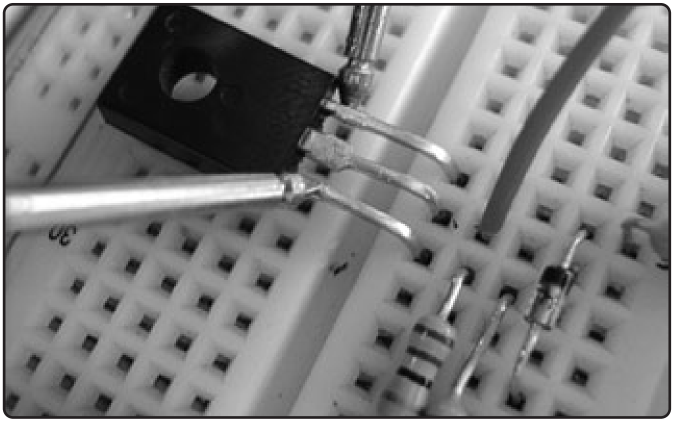


FIGURA 11.
Los diodos polarizan la juntura del transistor en forma permanente. Con esta configuración del tester, podremos medir la caída de tensión sobre la juntura E-B (emisor-base).

Si procedemos de la misma manera, pero ahora ubicamos las puntas para medir la diferencia de **tensión E-B** (**emisor-base**), comprobamos una caída cercana a **1 V**. Notemos que colocamos las puntas siguiendo el sentido de la corriente de base, es decir, saliendo de la misma. Por eso se ubica la punta negra **COM (-)** del tester sobre la base y la roja sobre el emisor que está a un potencial superior (**Figura 11**).

MEDICIÓN DE LA CORRIENTE DE CARGA IC

A continuación, pasemos a la medición de la corriente **Ic** de carga del circuito, que es la correspondiente al colector del transistor **PNP** y es la que se utilizará para cargar la batería cuando se la conecte en los bornes indicados. Como el transistor **BD140** se comporta como una fuente de corriente, siempre entregará por su colector una intensidad de carga constante, independientemente de la tensión que exista en bornes de la batería. Por cálculo, se estima que esta será de **15 mA** con la llave abierta y de **45 mA** con la llave en cortocircuito.

Ahora, necesitaremos dos alcances de continua para completar las mediciones.

Para realizar una medición de corriente, debemos desconectar el cable de punta roja del borne **(V/Ω/f)** del multímetro y posicionarlo en el borne marcado como **(mA)**, por el que pueden circular hasta **200 mA** sin destruir el fusible de protección. Si necesitáramos medir una corriente mayor a este valor, colocaríamos el cable de punta roja en el borne marcado **20 A**, lo que indica la máxima corriente que soporta el instrumento en esa conexión que, por otra parte, no está protegida por fusible.

Debido a que la resistencia interna **Ri** del tester en modo amperímetro es muy pequeña, no debe apreciarse un cambio radical en la corriente de colector o de carga. Procediendo así, tomamos la lectura del instrumento para ambas posiciones de la llave y usamos el alcance apropiado para cada una. Vale destacar que debemos posicionar las puntas del multímetro de manera que coincida la punta roja

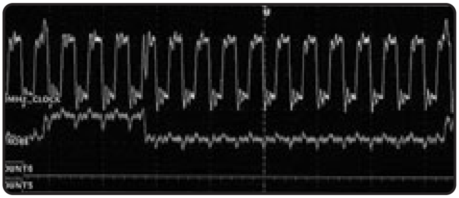
www.FreeLibros.me

con el borne de entrada de corriente (**+**), y el negro COM con el de salida (**-**).

MEDICIÓN SOBRE LA BATERÍA DURANTE LA CARGA

Por último, debemos monitorear el valor de tensión en carga que toma la batería a medida que transcurre el tiempo. Para ello, posicionaremos el tester en paralelo con la batería en carga cada 15 minutos.

El tiempo de carga dependerá, principalmente, del parámetro **mA/h** de la batería en cuestión, pudiendo llegar a varias horas. Espaciaremos la toma de muestras en el tiempo, para no reiterar demasiado las mediciones. Siempre tenemos que comprobar que la tensión registrada no se escape del valor nominal **+10%** que establecimos como límite. Cuando detectemos que el valor de tensión alcanzó el **10%** del valor nominal de entrega de tensión de la batería, desconectaremos el circuito y consideraremos que la carga se ha realizado.



Para medir la corriente, debemos desconectar el cable rojo del borne (V/Ω/f) **y colocarlo en el borne** (mA)

El **osciloscopio**

Es uno de los instrumentos de medición más utilizados por los profesionales. Veamos de qué se trata y cuáles son las claves que necesitamos saber para emplearlo. El osciloscopio es un instrumento que permite reproducir gráficamente las variaciones de señales de tensión a través del tiempo, en una pantalla. De este modo, es posible analizar, con gran detalle, distintas formas de onda y comprender el funcionamiento de un circuito (**Figura 12**). Este elemento es una herramienta esencial en cualquier laboratorio o taller de electrónica y en otras áreas también, por ejemplo, la militar y la médica.

MEDICIONES CON OSCILOSCOPIO

El concepto básico de este instrumento es que representa formas de onda en dos dimensiones.

OSCILOSCOPIO DE MUESTREO

Es un instrumento utilizado para analizar señales periódicas de muy alta frecuencia, mayor aún que el ancho de banda (osciloscopio analógico) o la tasa de muestreo (osciloscopio digital), y de muy baja amplitud, generalmente, de hasta 3 V pico a pico.

www.FreeLibros.me

5mV
mV
CH 2

FIGURA 12.
Es posible utilizar el osciloscopio para analizar distintas formas de onda individualmente, o también para observar y comparar dos o más, y ver el modo en el que interactúan entre sí.

El eje vertical, o **eje Y**, se usa en general para representar la tensión de entrada, mientras que el horizontal, o **eje X**, se emplea usualmente como eje de tiempo. Así, tendremos en pantalla una representación temporal de la señal de tensión aplicada a la entrada. En los osciloscopios duales y en los multicanales, es factible representar dos o más señales en pantalla en forma simultánea, lo cual resulta práctico para comparar distintas formas de onda y analizar su interacción.

Aunque la representación temporal de formas de onda es la aplicación más común en los osciloscopios, también es posible representar de manera gráfica el comportamiento de una variable respecto de otra, o funciones paramétricas. Un aplicación de este último caso son las **figuras de Lissajous**, mediante las cuales podemos determinar gráficamente algunos parámetros y relaciones de dos formas de onda de manera simultánea.

TIPOS DE OSCILOSCOPIOS

Más allá de que la filosofía de funcionamiento de estos instrumentos es la misma, existen diferentes tipos, lo que nos permite clasificarlos en categorías. Una de las más importantes es si son analógicos o digitales. A su vez, dentro de estos, tenemos subcategorías, como por ejemplo, los osciloscopios con persistencia y los de muestreo.

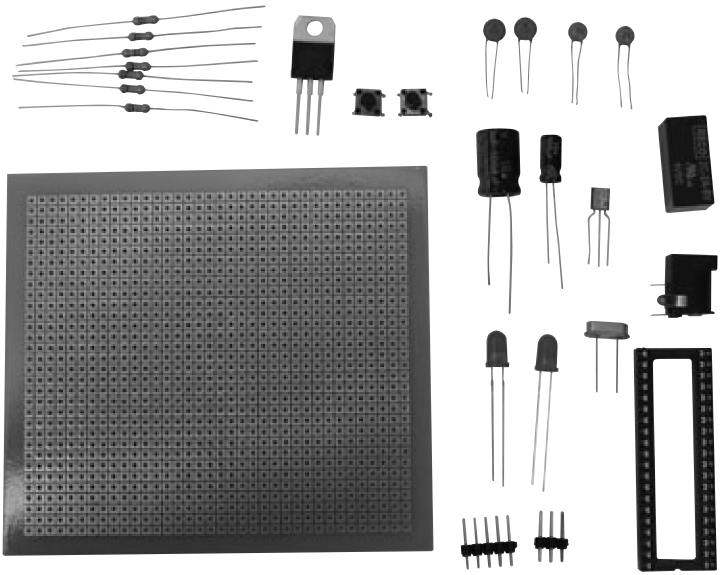
OSCILOSCOPIO ANALÓGICO

Utiliza el principio de deflexión electrostática de un haz de electrones, para crear las gráficas en un Tubo de Rayos Catódicos (TRC). Aquí, las tensiones aplicadas a las placas deflectoras X e Y producen un punto que se mueve en la pantalla. En el eje horizontal, esto es controlado por una base de tiempos, mientras que, en el eje vertical, la deflexión es proporcional a la amplitud de la señal de entrada.

OSCILOSCOPIO DE ALMACENAMIENTO DIGITAL (DSO)

Es la forma convencional de los osciloscopios digitales y emplea pantallas del tipo raster, como las usadas en los monitores de PC para representar las gráficas. El equipo convierte la señal de entrada a un formato digital, por medio de técnicas de conversión

www.FreeLibros.me



analógico-digital, para luego guardar esta información y procesar la señal. La limitante está en la velocidad de la conversión.

OSCILOSCOPIO DE FÓSFORO DIGITAL (DPO)

Con poco más de una década en el mercado, es una variación muy versátil del DSO, que utiliza una arquitectura de procesamiento en paralelo para permitir el análisis de señales que resultarían prácticamente imposibles con un DSO. Se especializa en el muestreo de fenómenos transitorios que ocurren en el inicio de los sistemas digitales (pulsos, glitches y errores de transición).

Las puntas de prueba son las encargadas de entregarnos la mejor señal

Funcionamiento del osciloscopio

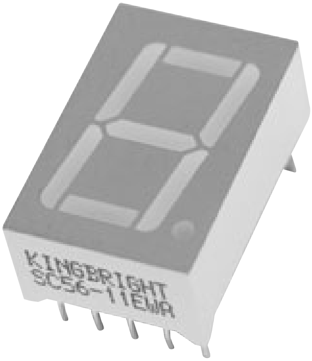
Hasta el momento hemos conocido las características principales del osciloscopio. En este apartado, veremos los principios elementales de su funcionamiento. En el osciloscopio, una señal con forma de rampa proveniente de la base de tiempos, produce

www.FreeLibros.me

el movimiento del haz en el sentido horizontal. La señal a medir, convenientemente acondicionada, ocasiona el movimiento en sentido vertical. La base de tiempos se sincroniza con un instante de la señal a medir y está calibrada de modo de hacer corresponder el desplazamiento del haz con una medida temporal y visualizar la señal en la pantalla.

ANCHO DE BANDA

En un **osciloscopio analógico**, la respuesta en frecuencia del amplificador vertical ocasiona una atenuación gradual de las señales de alta frecuencia. Por ejemplo, un osciloscopio de 20 MHz puede visualizar correctamente una señal senoidal de 20 MHz, pero puede mostrar señales de mayor frecuencia, solo que serán atenuadas por el amplificador vertical.



En el caso de un **osciloscopio digital**, existe una frecuencia de muestreo, que es la que determina la cantidad de muestras de la señal que el osciloscopio toma para reconstruirla. El fabricante especifica además el ancho de banda de forma similar al osciloscopio analógico. Para poder visualizar de manera correcta una señal, debemos garantizar que sus componentes más importantes entren en el ancho de banda que puede mostrar el osciloscopio.

DISPARO

La base de tiempos debe sincronizarse con la señal a visualizar para que siempre arranque la visualización en el mismo instante. Para esto, el osciloscopio incorpora un circuito de comparación que genera un pulso de sincronismo interno basado en la observación del nivel de la señal y el sentido (ascendente o descendente) en el que lo cruza. Esta comparación puede hacerse además con una señal externa. Existen, también, otros modos de trabajo en los que se fuerza un disparo aún sin señal, para ver señales sin variaciones, o se lo demora por un cierto tiempo, para evitar redisparos no deseados en señales complejas.

LOS OJOS DEL OSCILOSCOPIO

Las puntas de prueba son las encargadas de entregarnos la mejor señal. Veamos, entonces, cuáles son las características que deben tener para arrojar resultados precisos.

KARL FERDINAND BRAUN

El físico alemán Karl Ferdinand Braun fue el inventor del osciloscopio de rayos catódicos. Lo realizó en el año 1897, y también descubrió que ciertos cristales actuaban como rectificadores, convirtiendo la corriente alterna en continua.

www.FreeLibros.me

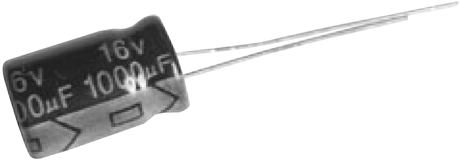
Muchas veces, perdemos de vista la importancia que tienen las puntas de prueba, cuando evaluamos integralmente las condiciones de medición.

Debemos tener presente que ellas conforman los "ojos" de nuestro osciloscopio. Si no son capaces de entregarnos la mejor calidad de señal posible, resulta poco probable que obtengamos buenos resultados de la señal bajo prueba. Idealmente, las puntas deberían ser "transparentes" para el equipo, queriendo significar con esto que la señal presente en el punto de prueba del circuito es "vista" por el osciloscopio, sin ningún tipo de interferencia o distorsión, tanto para el instrumento como para el circuito bajo prueba.

CALIBRACIÓN

Aunque no siempre lo hacemos, para garantizar una buena medición es fundamental efectuar una calibración de las puntas antes de ser usadas. De este modo, obtendremos una respuesta plana dentro del espectro de frecuencias (es decir, todo el espectro es tratado de igual forma).

Para ello, es posible utilizar la señal de calibración del osciloscopio, midiéndola con la punta a calibrar. Esta es una onda cuadrada de una amplitud y frecuencia estable y conocida. Debemos ajustar el pequeño potenciómetro incluido en la punta de prueba, hasta que la señal se vea perfectamente cuadrada: sus bordes no deben aparecer redondeados o con sobreimpulsos. Las puntas de prueba pueden tener una atenuación fija, o contener una llave conmutadora para seleccionarla. Estas atenuaciones vienen prefijadas en valores **x1** (sin atenuación) y **x10** (con atenuación). Veremos, aquí, la manera en que estas señales son presentadas en la pantalla de nuestro osciloscopio y la forma de interpretarlas.



La atenuación x10 de las puntas lógicas se emplea para disminuir el efecto de carga de la punta sobre el circuito

Los osciloscopios digitales tienen características que ayudan a la interpretación de la señal, tal como la indicación automática de la frecuencia y el nivel de tensión de la señal mostrada.

Primero, observemos cómo está configurada la pantalla del instrumento. Se ve que está dividida, formando una retícula de **10x8** cm, con dos ejes centrales subdivididos cada **2 mm**. Los circuitos internos del osciloscopio están calibrados de manera tal que la representación gráfica de la amplitud y el tiempo de la señal en pantalla pueden leerse directamente a través de la retícula, contando simplemente la cantidad de divisiones que ocupa.

Esto es posible porque los mandos de amplitud (**eje vertical**) y base de tiempos (**eje horizontal**) están

www.FreeLibros.me

ajustados a ganancias prefijadas, relativas a cada división. Están expresadas en V por división (**V/div**) y, en segundos por división (**s/div**), respectivamente. Algunos osciloscopios incluyen también, en uno de los costados de la pantalla, una escala expresada en porcentaje. Particularmente, se indican los valores **0%**, **10%**, **90%** y **100%**. Estas marcas están para facilitar una lectura directa del tiempo de los flancos de subida y bajada de una determinada señal. Recordemos que estos parámetros se miden, justamente, entre el **10%** y el **90%** del valor pico a pico de la señal.

Entonces, si ajustamos la amplitud de la señal para que su valor pico a pico coincida con las marcas **0%** y **100%**, podremos obtener una lectura del tiempo de dichos parámetros directamente desde donde la señal cruza las marcas **10%** y **90%**. Solamente debemos contar las divisiones que ocupa y multiplicar por la base de tiempo seleccionada (**Figura 13**).

Cualquiera sea el tipo de osciloscopio que utilicemos, debemos tener presente que se trata de un instrumento de precisión que tiene sus limitaciones. Si bien para cada área de especialización existe un osciloscopio que se adapta mejor, la mayoría de las aplicaciones no profesionales pueden resolverse mediante uno analógico de **20 MHz**, siendo un **DSO** de **100 MHz** apropiado para gran cantidad de tareas profesionales.

CLIPS DE MASA

Las puntas del osciloscopio vienen con un clip de puesta a masa que es removible. Este será conectado a un punto de prueba del circuito para proveer la referencia común a ambos. En muchos casos no existe mayor inconveniente, pero cuando trabajamos con potencias o señales de muy alta frecuencia, deberemos tener el menor camino posible desde la señal hasta la punta de prueba, por lo que el clip de masa se conecta directamente al punto de masa más próximo al elemento a medir. Esto nos asegurará una muy buena performance desde el punto de vista eléctrico.

Cabe destacar que la masa del osciloscopio está vinculada al terminal de tierra del enchufe, y suele ser además un punto de puesta a tierra.

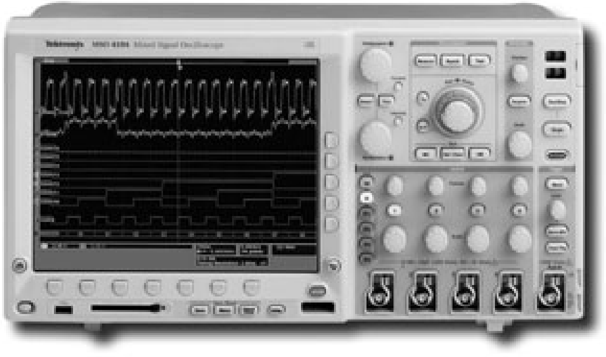


FIGURA 13.
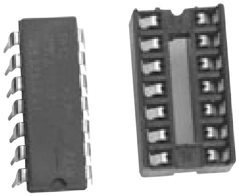
Los circuitos internos del osciloscopio están calibrados de forma tal que la gráfica mostrada puede ser interpretada a través de las divisiones y marcas que posee la pantalla.

www.FreeLibros.me

MEDICIONES DE FORMAS DE ONDA

Toda señal que se repite en el tiempo es periódica. Posee parámetros que la definen y que son inherentes a su naturaleza: la amplitud, la frecuencia o el período y su fase. Veamos cada una de ellas:

- **Amplitud**: es la diferencia entre el valor máximo de la señal (positivo o negativo) y el valor tomado como referencia (masa del circuito). Su unidad es el Volt (**V**) o el Ampere (**A**), dependiendo de si estamos analizando formas de onda de tensión o de corriente, respectivamente.
- **Período y frecuencia**: la frecuencia de una señal se expresa con la letra **f** y la unidad que la representa es el Hertz (**Hz**). Indica la cantidad de ciclos u oscilaciones de una señal periódica que ocurren en un intervalo de tiempo de un segundo. El período se expresa con la letra **T** y su unidad es el segundo (**s**). Existe una relación unívoca entre ambos los parámetros: la frecuencia es la inversa del período. A continuación vemos la fase.
- **Fase**: este parámetro se define para señales periódicas, en donde un ciclo completo de la señal corresponde a 360° (**deg**) o 2 π radianes (**rad**). La fase de una señal en un determinado instante es la fracción de ciclo transcurrido desde su inicio. Cuando comparamos dos señales periódicas idénticas, puede ocurrir que no coincida en el tiempo el paso por dos puntos equivalentes de ambas señales.



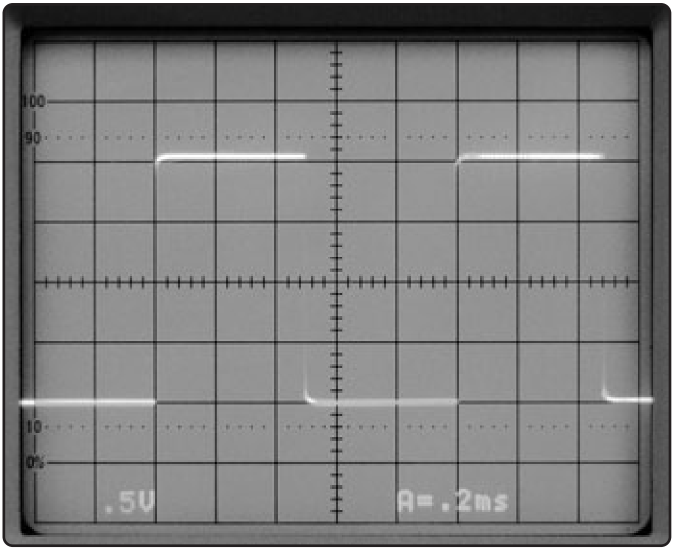


FIGURA 14.
Señal cuadrada bajo medición. Se utiliza la retícula calibrada para medir la amplitud y la frecuencia o período de la señal.

www.FreeLibros.me

ELECTR_Cap3_xxx_xxx_ajustado.qxp 04/07/2011 16:33 PÆgina 79

Medición de tensión y frecuencia

La medición de estos parámetros de la señal bajo análisis puede efectuarse a través de la retícula que posee la pantalla del osciloscopio. Hoy en día, la mayoría de los osciloscopios incorporan diversas funciones que nos ayudan a obtener una lectura más rápida y precisa de la señal en pantalla. Nos muestran información de la diferencia de tensión o de tiempo entre dos puntos, y otros datos relevantes de la señal (**Figura 14**).

MEDICIÓN DE TENSIÓN

En primer lugar, ajustamos la posición vertical del canal hasta que el piso o el techo de la señal coincidan con alguna división horizontal de la retícula, y contamos cuántas divisiones verticales ocupa.

A este valor, lo multiplicamos por el valor de ganancia del canal seleccionado y obtenemos, así, el valor de tensión pico a pico de la señal. En nuestro caso, la señal ocupa 4 divisiones verticales exactas, y como la ganancia del canal está en 0,5 V/div, tenemos:

$$V = 4\text{div} \,.\, 0{,}5\,\frac{V}{\text{div}} = 2\ \text{Volt}_{\text{picon pico}}$$

La amplitud es la diferencia entre el valor máximo de la señal y el valor tomado como referencia de masa

MEDICIÓN DE FRECUENCIA

Procedemos de forma similar a la medición de tensión. Ajustamos la posición horizontal del canal hasta que uno de los flancos (puede ser el ascendente o el descendente) coincida con alguna división vertical de la retícula. Luego, contamos cuántas divisiones horizontales ocupa un período de la señal.

A este valor, lo multiplicamos por la base de tiempo seleccionada y obtenemos, así, el período. Si hacemos la inversa del período, podemos inferir el valor de la frecuencia de la señal. En nuestro caso, la señal ocupa 5 divisiones horizontales exactas y, como la base de tiempo del canal está en 0,2 ms/div, tenemos:

$$T = 5\text{div} \,.\, 0{,}2\,\frac{\text{ms}}{\text{div}} = 1\ \text{ms}$$

$$\Rightarrow\ f = \frac{1}{T} = \frac{1}{1\,.\,10^{-3}\,\text{s}} = 1000\,\frac{1}{\text{s}} = 1\text{kHz}$$

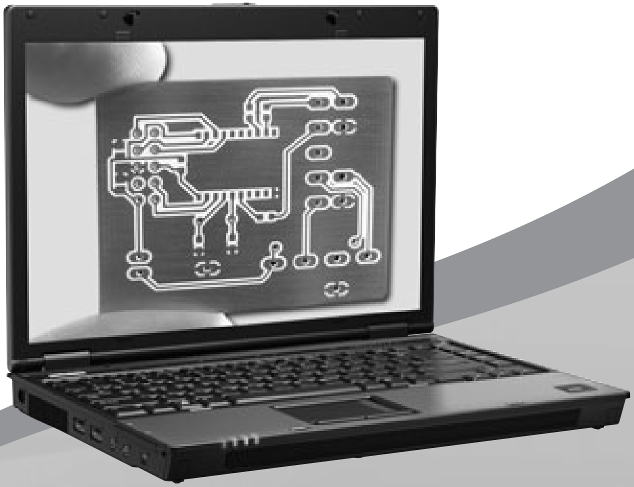
Diseño de circuitos impresos



Conoceremos las características
del software para la creación, edición
y gestión de proyectos electrónicos.

RedUSERS.com

www.FreeLibros.me

Diseño de circuitos **impresos en la PC**

Conoceremos las características, funciones y limitaciones de algunos de los paquetes de diseño asistido por computadora para la creación, edición y gestión de proyectos electrónicos.

En esta clase, abordaremos los conceptos teóricos y prácticos que nos introducirán por completo en el mundo de la creación de diseños de circuitos impresos. Además, conoceremos las ventajas que existen sobre el método tradicional de trabajo, y los diferentes módulos, herramientas y áreas de trabajo que forman parte del paquete **CadSoft EAGLE**. Haremos hincapié en las bibliotecas de símbolos que vienen incluidas, en la edición y creación de nuevos componentes y en la generación de **PCBs** mediante métodos manuales, automáticos y mixtos. A modo informativo, conoceremos las limitaciones de la versión gratuita, el uso de reglas de ruteo y los diseños mediante capas. Culminaremos esta clase con un proyecto que nos guiará paso a paso hacia la creación de una placa correspondiente a un cargador de baterías Ni-Cd.

Un circuito impreso sirve como soporte físico y base de conexión para los componentes electrónicos

Recordemos que un circuito impreso es una placa o plaqueta de material aislante, generalmente construida en Pertinax o material Epoxi. Posee, en una o en ambas de sus caras, láminas de cobre delgado que conectan los pines de los diferentes componentes que conforman un circuito electrónico. El montaje de los componentes se realiza a través de orificios practicados en la placa o, en el caso de la tecnología de montaje superficial, soldados directamente sobre las láminas conductoras (**Figura 1**).

En la actualidad, el diseño de placas de circuitos impresos avanzó a la par del crecimiento de la informática. Debido al grado de complejidad de los circuitos electrónicos, es necesario utilizar herramientas dedicadas que brinden asistencia completa durante el proceso de diseño. Para dichos fines, surgen los programas de **CAD** (*Computer Aided Design*, **Diseño Asistido por Computadora**), que permiten realizar la captura, es decir, llevar a nuestra pantalla el circuito esquemático y generar los archivos de soporte necesarios para finalizar con el proceso de creación del PCB (**Figura 2**).

MÉTODO DE DISEÑO TRADICIONAL

Tradicionalmente, realizar el diseño de una placa de circuito impreso era un proceso tedioso y artesanal. Era necesario disponer de paciencia, mucha atención y pericia para lograr un diseño sin errores y que cumpliera una serie de reglas acordes al esquema elegido para armar.

Para trabajar, se utilizaban elementos de dibujo técnico, como reglas, escuadras, plantillas, lápices y fibras. Primero, había que llevar a cabo un boceto o borrador para poder darle forma, y conocer la ubicación y el

tamaño de los componentes. El segundo paso consistía en diagramar las conexiones eléctricas. Una vez concluido esto, se pasaba el dibujo en limpio, preferentemente con papel vegetal y tinta china.

También se utilizaba un método en el cual se recortaban y pegaban trozos de pistas, curvas y terminales, previamente diseñados sobre mylar. Esto llevaba el nombre de su mayor fabricante: Bishop.

www.FreeLibros.me

Para terminar, el arte era transferido por métodos fotográficos al proceso de fabricación final (fotográfico, serigráfico).

ENTORNOS DE DISEÑO CAD

Los programas de diseño de circuitos impresos están conformados por un entorno que incluye varios módulos. Uno muy importante es el que permite realizar la captura del circuito esquemático. En los casos donde este no se incluya, es primordial que el entorno permita importar las listas de conexiones generadas a partir de archivos esquemáticos creados con otra aplicación de la misma empresa o de terceros.
Si no tenemos ninguna opción de captura o importación de esquemáticos, nos veremos obligados a dibujar la placa, colocando los componentes de forma manual y uniendo los respectivos terminales. Este método es, en esencia, similar al manual, con la diferencia de que lograremos mayor calidad de impresión y definición de los trazos o pistas de conexión. Hay que tomar ciertos recaudos a la hora de trabajar con esta clase de software, ya que generalmente no incluyen ninguna opción de chequeo de errores ni reglas de diseño.

Los entornos profesionales de última generación, como **Altium Designer** y **Cadence OrCAD**, incluyen todo lo necesario, y todavía más (**Figuras 3** y **4**).

Los programas de diseño de circuitos impresos están conformados por un entorno que incluye varios módulos

Las diferencias entre el diseño manual y el diseño asistido por computadora son varias y muy importantes. La reducción del tiempo empleado en el diseño y la calidad final son las primeras en destacarse. Sin embargo, la optimización toma importancia a la hora de realizar el posicionamiento y el conexionado de los componentes. Esto reduce drásticamente los errores que se pueden llegar a producir.

Otras características que incorporan las aplicaciones de CAD son las que permiten la industrialización o producción en serie. Es posible exportar diferentes archivos para operar máquinas de taladrado y de corte por control numérico.

EL MÓDULO DE CAPTURA DE ESQUEMÁTICOS

Este es el módulo encargado de llevar a cabo la captura del diagrama eléctrico, es decir, el proceso de

SOBRE LOS ENTORNOS DE TRABAJO

Los entornos ideales para trabajar son los que permiten dibujar el diagrama esquemático (proceso de captura), generar los listados de conexiones y de componentes utilizados y, por último, exportar todo al módulo PCB.

www.FreeLibros.me

dibujo del circuito. Para ello, el software proporciona herramientas y funciones que permiten seleccionar los símbolos de los diferentes componentes que forman parte de él, realizar las conexiones eléctricas, asignar valores y nombres a los objetos utilizados, aplicar comandos de edición como borrar, copiar y pegar, e indicar conectores, fuentes de alimentación y puntos de prueba. Además, una vez concluido el proceso de captura, es posible exportar diferentes archivos, en general de texto en **formato ASCII**, con

Entorno de diseño KiCAD. Es un completo set de herramientas de software libre, aplicado a la creación, edición y gestión de proyectos de diseño.

www.FreeLibros.me

datos útiles para otros programas de diseño. Usualmente, es posible exportar listados de materiales, listados con indicación de todas las conexiones y listados con errores, entre otros.

EL MÓDULO DE CAD

Una vez que el esquema está concluido, se debe pasar a la parte de diseño. Cada paquete de software de diseño de PCB cuenta con el **editor CAD**. Este módulo permite importar el diagrama capturado, convertir los símbolos en encapsulados y realizar las pistas de conexión. Este proceso puede ser manual, automático o una mezcla de ambos (**Figura 5**).

> Es preciso que el software de diseño cuente con un sistema de control que evite errores

EL CONTROL DE ERRORES

Todo buen programa de diseño de circuitos impresos permite controlar posibles errores cometidos durante el proceso de captura o de creación del PCB.

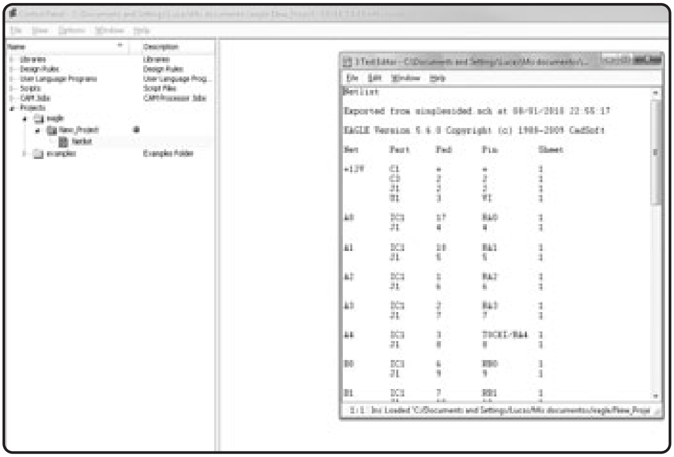

FIGURA 5.
El archivo netlist **realizado con** CadSoft EAGLE. **En él, se encuentran detallados todos los componentes que forman el circuito, con sus valores, pines y nodos de conexión.**

ARCHIVOS NETLIST

Es una lista de los nodos (nets). Un nodo se define como un punto de conexión común entre dos o más elementos. Según el archivo netlist, este puede incluir información variada, como el formato físico de los trazos de circuito impreso y las propiedades de cada componente.

www.FreeLibros.me

Por ejemplo, conexiones hechas entre los polos positivo y negativo de la fuente de alimentación o pines sin conexión eléctrica (**Figura 6**). Generalmente, se encuentran disponibles dos tipos de verificación: **ERC** (*Electrical Rules Check* - **Chequeo de Reglas Eléctricas**) y **DRC** (*Design Rule Checking* - **Chequeo de Reglas de Diseño**).

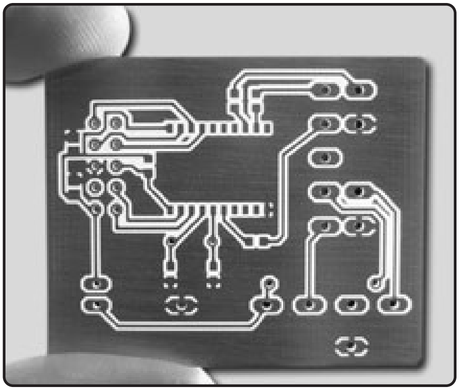

FIGURA 6. **Una vez diseñado y probado en la computadora, el circuito deja de ser virtual para pasar a ser real.**

CADSOFT EAGLE

Para iniciarnos en el manejo, la creación y la gestión de diseños simples, podemos descargar desde la página web **www.cadsoftusa.com** una versión gratuita para aplicaciones no comerciales. Una vez descargada e instalada, nos encontraremos con una potente aplicación de diseño.

El software posee un **Panel de control** (*Control Panel*) desde donde se gestionan todos los proyectos. Desde allí, se pueden generar o editar circuitos esquemáticos (archivos **.SCH**), **diseños de circuitos impresos** (archivos **.PCB**), librerías de componentes (archivos **.LBR**), scripts (archivos **.SCR**) y programas en lenguaje de usuario (archivos **.ULP**).

El Panel de control utiliza la vista en estructura de árbol para navegar a través de los archivos del sistema: librerías, scripts, proyectos, programas escritos en lenguaje de usuario y trabajos **CAM** (*Computer Aided Manufacturing* - **Fabricación asistida por computadora**). A la derecha de la estructura, se visualiza la descripción del ítem seleccionado (**Figura 7**).

FIGURA 7. **El** Panel de control **de** EAGLE **permite gestionar todos los archivos generados por sus distintos módulos, gracias al uso de una estructura de árbol.**

www.FreeLibros.me

Además del panel de control, **EAGLE** dispone de varios subprogramas o módulos para realizar cada tarea. Por ejemplo, **Schematic**, para la edición y captura de diagramas esquemáticos; **Board**, una herramienta de trabajo sobre circuitos impresos, y **Library**, un completo editor de librerías (**Figura 8**).

También posee un editor de textos para crear los archivos script o programas **ULP** y un procesador **CAM**. Este último módulo permite generar los datos necesarios para realizar la fabricación de las placas de circuito impreso. Puede producir archivos, por ejemplo, para controlar estaciones de taladrado, impresoras, plotters (máquina impresora lineal) y máquinas postscript.

Interfaz de los módulos

El usuario de EAGLE dispone de una barra de **Menú** donde se encuentran las funciones de cada módulo: utilidades de **zoom**, acceso a programas ULP y acceso directo a las otras aplicaciones del entorno. Debajo de esta barra de menú encontramos una barra de **Parámetros**. En este espacio, aparecerán distintas funciones y propiedades de acuerdo con la herramienta elegida. Una de las barras más importantes es **Herramientas**. Desde ella, es posible acceder a los botones que nos permitirán realizar y editar los esquemas y diseños de circuito impreso.

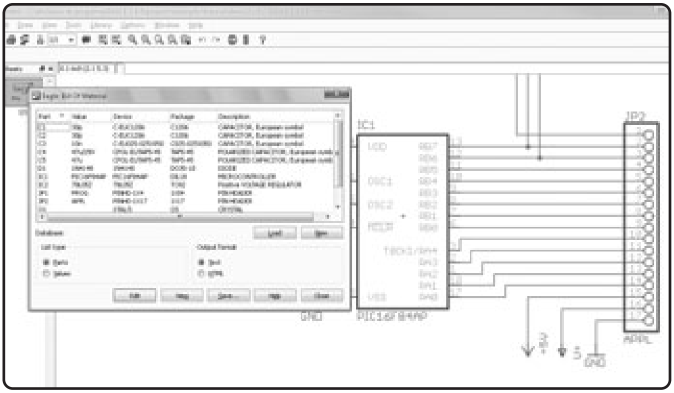

FIGURA 8. El módulo de captura Schematic **ejecutando una aplicación realizada en el** lenguaje ULP**. En este caso, se trata de un generador de listados de componentes con posibilidades de exportación a formato** HTML**.**

SOBRE ULP

EAGLE incorpora un lenguaje de programación llamado **ULP**. Se trata de una herramienta flexible, que permite tener un completo acceso a las estructuras de datos internas y escribir pequeños programas para añadir funcionalidades que resuelvan todo tipo de situaciones.

www.FreeLibros.me

ELECTR_Cap4_xxx_xxx_ajustado.qxp 04/07/2011 16:39 PÆgina 89

También es posible acceder a todos los comandos mediante órdenes de texto (con la línea de comandos). Asimismo, se encuentra disponible una **barra de Estado** que muestra informaciones y descripciones útiles sobre los comandos que están siendo utilizados. Además de las diferentes barras, cada módulo integra un **área de trabajo**. Dicha sección es el lugar de edición de los esquemas o librerías. Está delimitada por un rectángulo que equivale a la clásica hoja de papel en donde, de forma manual, antiguamente se dibujaban los circuitos.

COMPONENTES DISPONIBLES

EAGLE cuenta con una extensa librería de componentes por defecto, que se hallan organizados por fabricantes de dispositivos electrónicos, familias de productos y funciones (**Figura 9**). Estos símbolos generalmente se encuentran normalizados, es decir que respetan las medidas y los formatos físicos de los componentes, pero CadSoft no asegura que esto sea realmente así.

El usuario de EAGLE dispone de una barra de Menú donde se encuentran las funciones de cada módulo

Es un punto a tener en cuenta, ya que puede haber diferencias de tamaño con la vida real. También es posible agregar nuevas librerías desde el sitio de Internet de CadSoft, en la sección de descargas **www.cadsoftusa.com**, o utilizar el editor de librerías para crear nuevos componentes.

DISEÑO DE UN CIRCUITO ESQUEMÁTICO

El primer paso a seguir para crear un circuito impreso es la captura del diagrama esquemático. Como ya sabemos, EAGLE dispone de la herramienta

Explorando las librerías. Al utilizar la función Add**, se ejecuta un diálogo que permite escoger un componente. Podemos ver el nombre, la descripción, el símbolo eléctrico, y el correspondiente encapsulado.**

www.FreeLibros.me

`Schematic` para realizar el dibujo. La abrimos desde **`Control Panel/File/New/Schematic`**. A continuación, se desplegará en pantalla la ventana del Editor de esquemas, en la cual podemos empezar a dibujar nuestro circuito.

El primer paso es escoger los componentes que utilizaremos. En la barra de **`Herramientas`**, disponemos del botón **`Add`**, que permite explorar las librerías, elegir uno a uno los símbolos y arrastrarlos hasta el área de dibujo (**Figura 10**).

El segundo paso consiste en ubicar los componentes en el lugar apropiado mediante el botón **`Move`**. También puede ser necesario emplear el botón **`Group`**, en caso de querer agrupar varios componentes para moverlos juntos. Para rotar objetos o cambiar su orientación, contamos con los botones **`Mirror`** y **`Rotate`**.

Una vez ubicados los componentes, deberemos llevar a cabo las conexiones eléctricas entre ellos. Escogemos de la barra de **`Herramientas`** el botón **`Net`**; en este modo nos posicionamos en cada pin de cada componente con el puntero del mouse y, al hacer clic, aparecerá el alambre que permitirá realizar la conexión. Este paso deberemos repetirlo hasta concluir con todos los componentes.

Por último, será necesario nombrar cada componente y configurar el valor correspondiente. Con los botones **`Name`** y **`Value`**, respectivamente, podremos realizar estas acciones.

FIGURA 10.
A través del botón `Add` **accedemos a la ventana de** `Selección de componentes`**. En ella podemos navegar una por una las librerías instaladas en el sistema, ver los componentes y escoger el adecuado para utilizar en nuestro esquema.**

VERIFICACIÓN DE ERRORES

EAGLE cuenta con una poderosa herramienta para detección de errores de diseño y eléctricos. Tenemos dos botones: **`ERC`** permite aplicar las reglas de diseño eléctrico, y el segundo botón, **`Errors`**, se utiliza para mostrar los errores encontrados.

www.FreeLibros.me

Creación **de librerías**

Para acceder al Editor de librerías, tenemos que dirigirnos a **`Control Panel/File/New/Library`** y se desplegará en nuestra pantalla la ventana del Editor. Lo primero que debemos hacer es crear una nueva librería vacía: vamos a **`New/File`**. Un punto a considerar es que dentro de una librería se guardan los dispositivos, y que cada uno de estos posee un símbolo y un encapsulado. En la **`barra de Herramientas`** disponemos de los botones que permiten acceder a la creación y edición de cada dispositivo, con su símbolo y su encapsulado.

Mediante el botón **`Symbol`**, tendremos la posibilidad de crear el símbolo que representará al dispositivo en el módulo de captura del esquemático. Lo pulsamos, le damos un nombre y, al presionar el botón **`Ok`**, podremos empezar a editarlo. Una vez creado el símbolo, deberemos agregar y posicionar los pines que forman parte de él. Para ello, nos valemos del botón **`Pin`**.

Los pines poseen propiedades que podemos modificar si hacemos clic con el botón derecho del mouse sobre cada uno. Es posible editar el nombre, la posición, el ángulo de inclinación, la dirección, la función y la longitud, entre varias funciones más.

Con los pines creados, posicionados y nombrados, podremos dibujar el componente

Una vez creados todos los pines, es necesario nombrarlos. Si bien esta opción se encuentra en el cuadro de propiedades, también disponemos del botón **`Name`** para realizarla. Al seleccionar y hacer clic sobre cada pin se nos habilitará dicha opción. La elección del nombre del pin generalmente tiene que ver con la función que cumple y es recomendable respetar este método.

Con los pines creados, posicionados y nombrados, podremos dibujar el componente. En la barra de **`Herramientas`**, pulsamos el botón **`Wire`**, seleccionamos la capa **94Symbols** y le damos forma al símbolo.

También es posible agregar texto con nombres y valores. Disponemos de la herramienta **`Text`** para hacerlo. Hay que tener en cuenta la capa en la que estamos trabajando, ya que cada tipo de texto posee una específica, como por ejemplo, **95Names**, **96Values**, **97Info**, entre otras.

¿QUÉ ES UN PAD?

Se llama **PAD** a la isla de soldadura o superficie de contacto entre los pines de un componente electrónico y las láminas de cobre. EAGLE permite configurar varios parámetros de los pads, como formato, diámetro, tamaño del orificio y ángulo de orientación.

www.FreeLibros.me

El segundo paso en la creación de una nueva librería es la realización del encapsulado (**Figura 11**). Este tipo de símbolo es la representación de cada componente que se utilizará en el **Editor de PCB** (**Board**) y reemplaza a cada símbolo eléctrico empleado en los diagramas esquemáticos.

En la barra de **Herramientas**, se encuentra disponible un botón llamado **Package** que, al ser presionado, desplegará una ventana donde podremos nombrar y crear el símbolo del encapsulado. Acto seguido, podremos agregar los pads correspondientes, editar sus propiedades y, por último, dibujar el encapsulado mediante la herramienta **Wire**.

Para finalizar con la creación de nuestra librería, tendremos que llevar a cabo un dispositivo nuevo. Presionamos el botón **Device** para que se despliegue la ventana en la cual podremos darle un nombre y confirmar su creación.

En la barra de **Herramientas**, encontramos el botón **Add**, que permite añadir un símbolo a nuestro dispositivo. Al pulsarlo, se desplegará una ventana donde veremos el símbolo creado anteriormente. Una vez finalizado este proceso, deberemos agregar el encapsulado correspondiente. Pulsamos el botón **New** para que se despliegue la ventana de diálogo con el encapsulado creado anteriormente.

Con el Editor de librerías**, es posible crear y editar librerías de componentes, símbolos y encapsulados.**

El último paso es hacer coincidir los pines del símbolo con los pads del encapsulado. Para esto, disponemos del botón **Connect**. Deberemos realizar estos pasos repetidas veces, hasta que estén todos los pines conectados. También es posible agregar una descripción general, que será visualizada en el explorador de librerías cada vez que busquemos un componente. Es recomendable completar este campo.

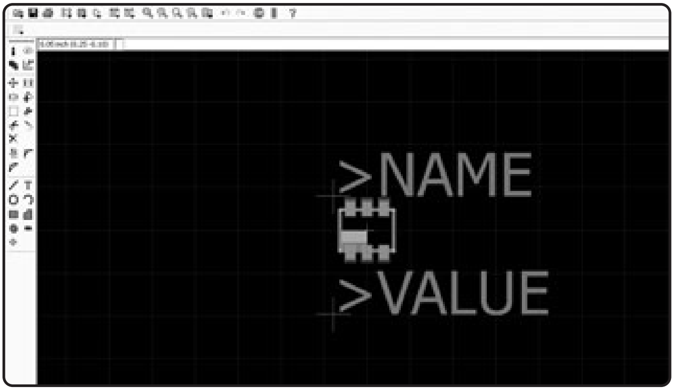

FIGURA 11. Mediante el Editor de encapsulados **es posible crear o modificar el encapsulado correspondiente.**

www.FreeLibros.me

Generación del **circuito impreso**

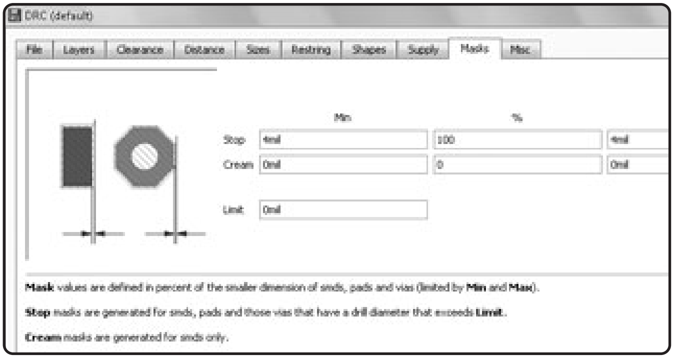
El editor de PCB puede lanzarse tanto desde el **`Panel de Control`** como desde el editor de esquemáticos, al pulsar el botón **`Board`**. En este último caso, una ventana nos preguntará si deseamos crear un nuevo diseño de circuito impreso a partir del diagrama esquemático. Veremos más adelante, al crear el PCB para nuestro cargador de baterías Ni-Cd, que aparecerán todos los componentes utilizados en el esquema, desorganizados y fuera del espacio definido para la placa (indicado por un rectángulo de color blanco). Las líneas de color amarillo indican las conexiones eléctricas entre ellos.

Podemos seleccionar los componentes por medio del botón **`Group`** y realizar cualquier acción, por ejemplo, moverlos con el botón **`Move`**.

Hay que tener en cuenta que, cuando el diseño parte de una captura de esquemático (realizada con el módulo **`Schematic`**), el programa no permite la inclusión de nuevos componentes ni conexiones que no figuren en el esquema. En el caso de tener que realizar modificaciones, habrá que hacerlas desde el módulo de captura.

Para transformar las líneas de conexión (*ratsnest* – **nido de ratas**) en pistas de circuito impreso, tarea que recibe el nombre de ruteo, disponemos del botón **`Route`**, que nos permitirá ir dibujando las pistas una a una. Solo basta con hacer clic con el puntero del mouse sobre uno de los pads a rutear y mover la pista a nuestra conveniencia. Al llegar al pad de destino, volvemos a hacer clic y el trazo queda terminado. Si nos equivocamos en el trazado, podremos volver a la pista anterior mediante el botón **`Ripup`**.

Al utilizar el botón **`Route`**, se despliega una nueva barra de Herramientas que permite configurar varios parámetros disponibles para las pistas. Es posible elegir el ángulo de los codos, el tipo de codo (rectangular o curvo), y hasta el ancho de las pistas. Por último, tenemos la posibilidad de agregar texto en cualquiera de las caras mediante el botón **`Text`**, y corregir aspectos de la serigrafía a través de **`Smash`** (**Figura 12**).



Stop 4mil 100 4mil
Cream 0mil 0 0mil
Limit 0mil

Mask values are defined in percent of the smaller dimension of smds, pads and vias (limited by **Min** and **Max**).

Stop masks are generated for smds, pads and those vias that have a drill diameter that exceeds **Limit**.

Cream masks are generated for smds only.

FIGURA 12.
Configuración de las reglas de diseño (DRC). Con este diálogo, es posible definir todos los parámetros referentes al diseño: tamaños, separaciones, distancias y terminación de las figuras son algunos de los disponibles.

www.FreeLibros.me

FUNCIÓN DE RUTEO AUTOMÁTICO

Esto permite que EAGLE realice el trabajo de ruteo de forma automática. Es posible utilizar el autoruteo en cualquier momento, sin importar la existencia de pistas trazadas de forma manual. Si existen, no se verán afectadas.

Al invocar el modo de autoruteo mediante el botón **`Auto`** de la barra de **`Herramientas`**, se despliega en pantalla una ventana con varias pestañas de configuración. En la pestaña **`General`**, es posible definir la cantidad de capas a emplear. En la versión gratuita, el máximo es de dos capas: superior (*Top*) e inferior (*Bottom*). En el caso de utilizar una única capa, también se puede decidir si será la que pertenece al lado de los componentes o al de las soldaduras. En esta pestaña, disponemos de dos opciones y cada una posee una lista desplegable que permite elegir uno de los parámetros disponibles (**"-"**, "**|**", "**/**", "\", "*****" y "**`N/A`**"). La opción "**`N/A`**" posibilita desactivar una de las capas, mientras que los otros símbolos indican la dirección que predomina en los trazos de cada capa: horizontal, vertical, diagonales y automático.

Una vez hecha la configuración, presionamos el botón **`Ok`** y veremos cómo EAGLE empieza a buscar todas las combinaciones posibles de trazado de pistas para realizar el ruteo. Dependiendo de la complejidad del esquema, será el tiempo que tarde en lograr el objetivo (**Figuras 13** y **14**).

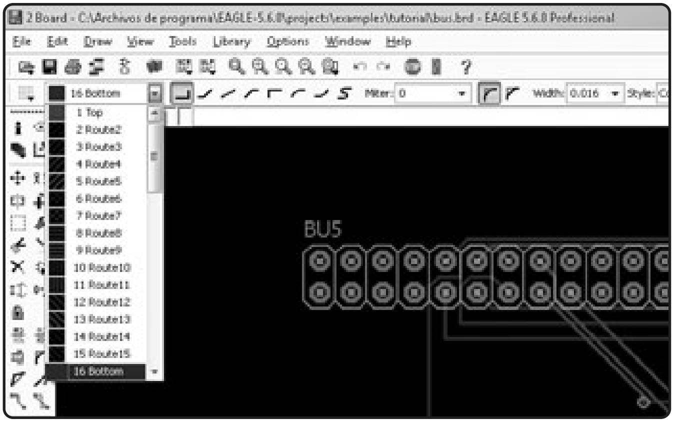
FIGURA 13. **Ventana de configuración del sistema de autoruteo. Si bien cuenta con varias pestañas con opciones, podemos lograr resultados satisfactorios si escogemos algunos parámetros únicamente desde el menú** `General`**.**

REGLAS DE DISEÑO (DRC)

Es muy importante utilizar y configurar las reglas de diseño (DRC). Mediante un correcto uso de esta función, es posible reducir los errores, como por ejemplo, pistas solapadas, violaciones de distancias mínimas y objetos fuera del área de trabajo.

www.FreeLibros.me



2 Board - C:\Archivos de programa\EAGLE-5.6.0\projects\examples\tutorial\bus.brd - EAGLE 5.6.0 Professional

Width: 0.016

FIGURA 14.
Placa generada mediante la función de autoruteo utilizando dos capas, superior e inferior. Para realizar las conexiones entre pistas de diferentes capas, se emplean las `Vías`**.**

MANEJO DE CAPAS

EAGLE utiliza diferentes capas para trabajar con los objetos que forman parte de un esquema. El resultado final es parte de una combinación de las capas.

Por ejemplo, para imprimir el arte que será transferido a la lámina de cobre de una placa de una sola cara se deberán activar las capas **`Bottom`** y **`Pad`** con el botón **`Display`**. Es posible realizar diferentes combinaciones para los trabajos de impresión o para limpiar el área de trabajo cuando los diseños son complejos y se dificulta seguir al ratsnest.

CÓMO UTILIZAR CADSOFT EAGLE

La idea de este **Paso a paso 1** es familiarizarnos con las opciones principales del programa, para poder orientarnos en la utilización de sus aplicaciones fundamentales. Como hemos visto en páginas anteriores, hay dos secciones importantes dentro del programa. Una de ellas es la que emplearemos para la confección del esquema del circuito (modo **`Schematic`**). Con este modo, seleccionaremos los componentes necesarios e indicaremos las conexiones entre ellos. La otra sección de relevancia es la que nos servirá para realizar el esquema de la placa (modo **`Board`**). Con este modo, trazaremos las rutas del circuito que unirán los componentes. Finalmente, podremos imprimir el esquema del circuito PCB.

DISEÑO DE UN PCB

Veremos un ejemplo de cómo utilizar EAGLE para la construcción de un esquema de circuito sencillo y práctico, correspondiente al conocido cargador de baterías (**Paso a paso 2**).

Realizaremos el diseño de una placa de circuito impreso (**PCB** - *Printed Circuit Board*) para el cargador de pilas Ni-Cd, que desarrollamos en el **Capítulo 2**. Para ello, en primer lugar, llevaremos a cabo el esquemático y, luego, lo transferiremos al módulo de diseño de PCB. Ubicaremos los componentes, haremos algunos trazados en forma manual y, finalmente, pediremos a EAGLE que realice el ruteo en forma automática.

Use the context menu to create new schematic or board files within this project.

Una vez creado el nuevo proyecto, el cursor se posicionará sobre la carpeta en cuestión. Puede cambiarle el nombre o eliminarlo. Haga clic con el botón derecho del mouse sobre el proyecto y se desplegará un menú de diálogo. Seleccione la opción **New** y, luego, **Schematic**, que le servirá para crear un nuevo esquema del circuito.

RESISTOR, American symbol

Package: 0207/12

RESISTOR

type 0207, grid 12 mm

Ahora, seleccione los componentes necesarios para el circuito. Como vio anteriormente, debe agregarlos mediante la opción **Add**. Tiene que adicionar tres resistores, entonces, busque por resistor y seleccione aquél que se acerca mejor a lo que tiene, en este caso, en **R-US, R-US_207/12**. Repita esta operación para el capacitor electrolítico y los diodos **1N4148**.

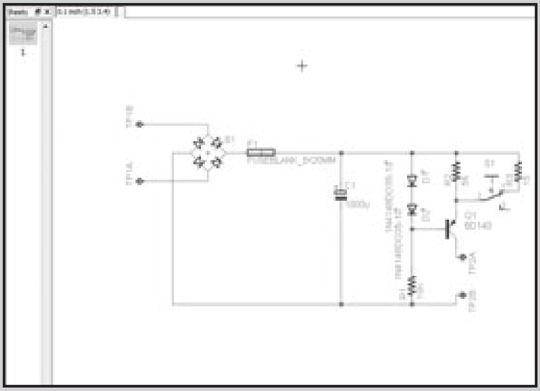
Molded Package

grid 2.3 mm

A continuación, necesita seleccionar el transistor BD140, que encontrará dentro de la sección de transistores de potencia. Para seleccionarlo, tiene que seguir el mismo procedimiento del paso anterior. Recuerde que la opción **`Add`** le permite adicionar el componente elegido.

5

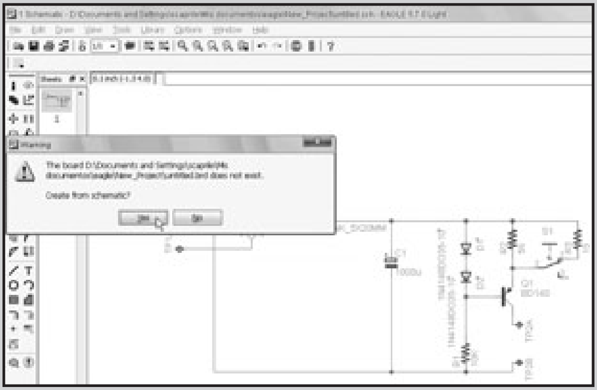


Realice el esquema del circuito. Para girar los componentes, utilice la herramienta **`Rotate`**, ubicada en la barra de la izquierda de la pantalla. Para trazar las líneas use la opción **`Net`**; de este modo, unirá cada uno de los componentes, formando la configuración deseada del circuito.

www.FreeLibros.me

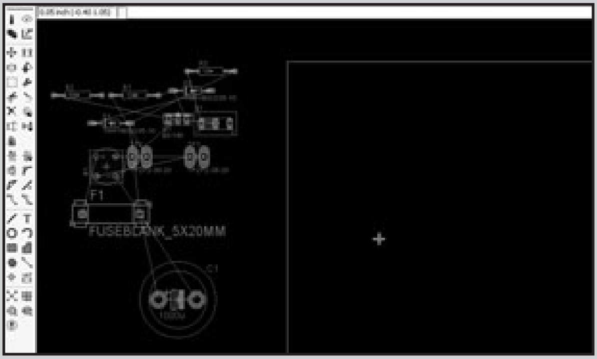
PASO A PASO /2 (cont.)

6



Una vez que haya terminado el dibujo del esquema, proceda seleccionar la opción **`Board`**, ubicada en la barra debajo del menú. Aparecerá un mensaje informativo que le preguntará si desea generar una placa a partir del esquemático del circuito. Haga clic en **`Yes`**.

7



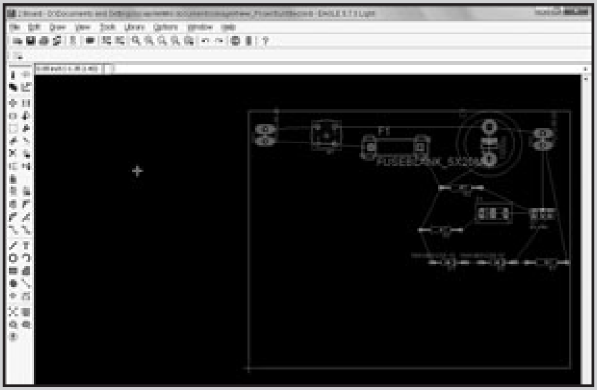
Ahora, se encuentra en el modo **`Board`**. En él, podrá observar, por un lado, los componentes y, por el otro, la placa a diseñar. Lo que tiene que hacer es mover los componentes dentro de la placa. Para ello, utilice la herramienta **`Move`**. Las líneas amarillas indican las conexiones que se transformarán en pistas (ratsnest).

www.FreeLibros.me

ELECTR_Cap4_xxx_xxx_ajustado.qxp 04/07/2011 16:39 PÆgina 102

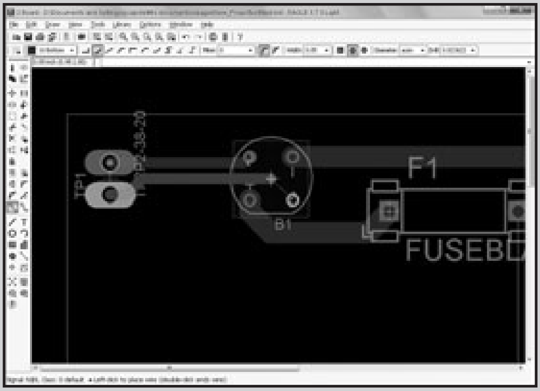
PASO A PASO /2 (cont.)

8



Queda acomodar de manera óptima los componentes. El posicionamiento deberá responder a la manera natural de seguir las pistas, lo cual se ve en el ratsnest, agrupando de forma de minimizar sus vueltas y recorridos. Luego, podrá comenzar a realizar el ruteo.

9



Con la herramienta **`Route`**, haga clic sobre las líneas amarillas, que servirán como guías para el trazado de las pistas. El zoom puede resultar útil para observar mejor la tarea. Debe rutear con pistas gruesas aquéllas que, por ejemplo, transportan mayor corriente.

Limitaciones de la **versión freeware**

La versión freeware de EAGLE es suficiente para la confección de un circuito PCB, sin embargo, no tiene toda la potencia de la versión comercial.

Explicamos, anteriormente, cuáles son los usos que podemos darle al programa EAGLE en su versión freeware, es decir, sin costo y con uso ilimitado. En general, cuenta casi con la misma funcionalidad que la versión de pago, salvo algunas excepciones que veremos a continuación.

- El área de las placas que puede ser utilizada es de solo 100 x 80 milímetros.
- Únicamente puede crearse una sola hoja dentro del editor de esquema del circuito.
- Solamente podemos emplear dos capas para el diseño de la placa, denominadas top y bottom. No podemos usar capas internas.
- No incluye la posibilidad de soporte técnico vía telefónica o fax.

De todas maneras, para nuestros propósitos, la versión freeware es muy completa, ya que nos permitirá abordar toda clase de proyectos a nivel educativo y nos será más que suficiente para estudiar los contenidos que se desarrollan en esta obra.

La versión freeware del programa solamente se puede utilizar con fines educativos, no comerciales

Además de la versión freeware, el programa ofrece una profesional, sin limitaciones y con soporte permanente. Es importante destacar que este programa no tiene una versión en castellano, solamente se lo puede conseguir en inglés. Sin embargo, cuenta con la ventaja de ser compatible con varios sistemas operativos:

- **Microsoft**: Windows 2000, XP, Vista y Windows 7.
- **Linux**: solo compatible con Linux Kernel versión 2.6.
- **Mac**: Mac OS X 10.4

Para más información acerca del programa, podemos visitar el sitio web del fabricante del software (**www.cadsoftusa.com**), donde tendremos la posibilidad de profundizar nuestros conocimientos.

ACTUALIZACIONES

Una de las ventajas que ofrece la versión profesional de EAGLE es la posibilidad de realizar actualizaciones desde su web oficial, en **www.cadsoftusa.com/upload.htm**. Esto es importante, ya que existen sitios no oficiales que ofrecen este programa sin el soporte necesario.

www.FreeLibros.me

También podemos descargarlo desde la sección de Download dentro de la página y acceder a los foros de usuarios del programa, que nos serán de suma utilidad ante cualquier duda o problema que tengamos (**Figura 15**). La dirección del sitio es **www.eaglecentral.ca/forums**.

REGLAS DE RUTEO

La finalidad de las reglas de ruteo tiene que ver con la minimización del área utilizada, la disminución de posibilidades de interferencias y de ruidos, y una apropiada distribución de los componentes. Veamos algunas reglas elementales (**Figura 16**).

- **Posición de capacitores de desacople**: deben colocarse lo más cerca posible de la alimentación de los circuitos integrados que desean desacoplarse.
- **Separación mínima de pistas**: si se trabaja con tensiones bajas, el mínimo debe ser de 0,3 mm, pero tiene que aumentarse para tensiones mayores. Si más de dos pistas son paralelas entre sí, su separación debe ser uniforme.
- **Separación entre los bordes de la placa y las pistas**: como mínimo, de entre 2 y 3 mm.
- **Ancho de las pistas**: entre otros factores, dependerá de la corriente que pasará por ellas. A mayor corriente, mayor ancho de pistas. Las pistas de alimentación deberán tener un mínimo de anchura de 1 o 2 mm, independientemente de la corriente que consuma el circuito.
- **Largo de las pistas**: tenemos que tratar que sean lo más cortas posibles, con el fin de hacer un diseño simple y reducir el tamaño final del PCB.
- **Trazado de intersecciones**: debe evitarse que, en la intersección de dos pistas, se formen ángulos de 90 grados. Lo ideal es 45º.
- **Conectores de entrada y salida**: tienen que colocarse alejados entre sí, en lo posible, ubicados en extremos opuestos, para evitar que se produzca un acoplamiento entre ellos.
- **Líneas de masa**: en caso de que el circuito cuente con una parte analógica y otra digital, debe haber dos líneas de masa diferentes para cada una, las cuales se unirán en un solo punto.

EAGLE permite configurar diversos parámetros para las reglas de ruteo y puede testear su cumplimiento mediante la opción **[DRC]** (*Design Rule Check*).

EAGLE

Version 5.7

Now with interactive Follow-me Router!

Take our Guided Tour and discover EAGLE. You will be surprised!

You can test drive EAGLE with our Freeware version!

Call our US office toll free at 1-800-858-8355.

FIGURA 15.

El programa no tiene una versión en castellano, pero sí encontraremos versiones disponibles para diferentes sistemas operativos.

www.FreeLibros.me

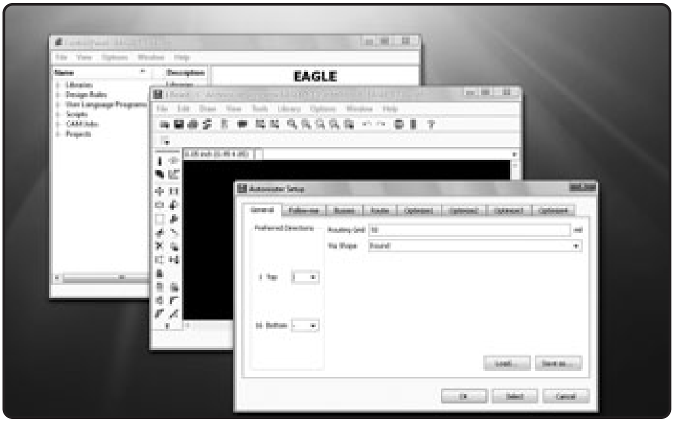

FIGURA 16. **Panel con diversas opciones para configurar el ruteo automático. Los parámetros pueden guardarse en un archivo y, posteriormente, cargarse desde allí.**

Sistema métrico y mils

Haremos una comparación entre dos sistemas de unidades, que nos servirán como herramientas para distintas mediciones de las partes de un circuito.

El sistema métrico es el que normalmente utilizamos porque la mayoría de los países lo eligió para representar medidas de longitud. Utiliza el metro como unidad y es parte de un sistema de unidades mucho más complejo denominado Sistema Internacional de Unidades. Un metro es la longitud de una barra llamada **metro patrón**, que se guarda en la Oficina de Pesos y Medidas en París. Hoy en día, hay formas más modernas de definir el metro, y la más actual es "la distancia que recorre la luz en el vacío durante un intervalo de 1/299792458 de segundo", lo cual se desprende de que la velocidad de la luz ha sido determinada en 299792458 m/s y elimina la necesidad de mantener dicha barra a temperatura constante. Un milímetro es la milésima parte de un metro (mili metro).

AUTORUTEO O RUTEO AUTOMÁTICO

Una de las opciones interesantes es la del autoruteo. Una vez que nosotros hayamos completado el diseño del circuito en la placa, esta opción nos optimizará la posición de los diversos componentes en base a los parámetros establecidos previamente como reglas de ruteo.

www.FreeLibros.me

Hablar de mils significa referirse a la milésima de una pulgada

Muchos de los países de habla inglesa utilizan el llamado sistema anglosajón o imperial. En este sistema, una unidad de longitud es la pulgada, equivalente a 25,4 mm. Cuando hablamos de **mils**, nos estamos refiriendo a la milésima de pulgada, algo así como el equivalente del milímetro en el sistema imperial. Un mil es, entonces, 0,0254 milímetros o 25,4 micrones. Por las actuales dimensiones de los componentes electrónicos y como muchos de los encapsulados tienen sus dimensiones dadas por el sistema imperial, el mil resulta mucho más conveniente que otras alternativas. La equivalencia sería:
1 mil = $25{,}4\times10^{-6}$ m = 1×10^{-3} inches (pulgadas) = $25{,}4\times10^{-3}$ mm = 25,4 µ

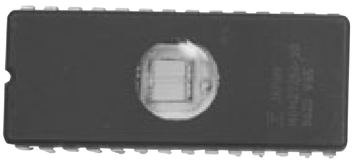
Recordemos que, en notación científica, el exponente del número 10 determinará los lugares que se correrá la coma. Si es negativo, hacia la izquierda y, si es positivo, hacia la derecha.

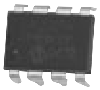
TIPOS DE ENCAPSULADOS MÁS COMUNES

La palabra encapsulado hace referencia a la cavidad en la cual podemos encerrar algún objeto. En nuestro caso, lo que encerramos son componentes electrónicos. Si bien el encierro es mayormente hermético, permitimos una forma de conexión con el exterior, para poder acceder a este y hacer que cumpla su función en nuestro circuito. La finalidad de los encapsulados es: protección del componente, accesibilidad, comodidad y facilidad para el montaje y desmontaje, y disipación de calor, entre otras.

Algunos de los encapsulados más comunes para circuitos integrados son los siguientes:

- **DIP (*Dual Inline Package*)**: es un encapsulado que cuenta con dos filas de pines (o patitas), las cuales se insertan dentro de un zócalo de la placa del circuito. El integrado es más pequeño que el encapsulado exterior. Si bien esto puede ser visto como una desventaja en términos de tamaño ocupado, es cierto, también, que facilita su instalación en una placa.
- **SOP (*Small Outline Package*)**: se diferencian de los DIP en la terminación de los pines y en su menor tamaño. En los SOP, los pines están doblados de forma tal que no se incrustan en un zócalo, sino que se son soldados en la placa, lo cual implica una dificultad mayor para removerlos o instalarlos.
- **PLCC (*Plastic Leaded Chip Carrier*) o QFJ (*Quad-Flat-J-Leg Chipcarrier*):** ambos nombres refieren al mismo tipo de encapsulado. Su forma puede ser cuadrada o rectangular y los pines se disponen a sus cuatro lados. La ventaja principal de estos encapsulados es que se aprovechan los cuatro costados para realizar conexiones.





www.FreeLibros.me

Multiple **choice**

1 ¿Cuál es el primer paso que debemos seguir para crear un circuito impreso?

a- Agrupar los elementos.
b- Generar las conexiones.
c- Capturar el diagrama esquemático.
d- Ubicar los componentes.

2 ¿Cómo se llama la herramienta para dibujar nuestro circuito?

a- **Schematic**.
b- **Move**.
c- **Net**.
d- **Erc**.

3 ¿Qué botón nos permite explorar las librerías?

Capítulo 5

Simulación de circuitos en la PC

En este capítulo, explicaremos qué es la simulación de circuitos y su utilidad en el proceso de diseño.

RedUSERS.com

www.FreeLibros.me

Diseño y simulación

La simulación de circuitos permite evaluar su comportamiento real y predecir sus características

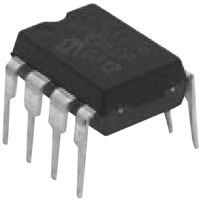
En este capítulo explicaremos qué es la simulación de circuitos, su utilidad en el proceso de diseño y cómo simular un circuito visto en el **Capítulo 2**, utilizando el software ISIS. Un paso necesario en el proceso de diseño de un circuito es asegurarnos de que este se comporte de acuerdo con las especificaciones dadas. Estas pruebas se llevan a cabo modificando la señal de entrada o variando las condiciones de operación, como la temperatura.

Todo el proceso requiere de un tiempo considerable y es costoso, ya que involucra diversos equipos de laboratorio. Afortunadamente, podemos realizar estas pruebas usando la simulación de circuitos por computadora. De este modo, se reducen los costos y el tiempo empleado en las pruebas. Para nuestro caso, se trata, más que nada, de validar, mediante la simulación, el funcionamiento elemental del circuito para, luego, abocarse a la construcción de un prototipo.

Veremos las herramientas de simulación de circuitos electrónicos que nos permitirán observar su funcionamiento sin construirlo físicamente. Los circuitos electrónicos se vuelven cada día más complejos, pero también más eficientes. El proceso de diseño puede llegar a ser muy complicado. En la actualidad, existen sistemas electrónicos que poseen miles y hasta millones de transistores, por lo que el análisis de su funcionamiento sería imposible de realizar manualmente. Por esta razón, se crearon herramientas de simulación de circuitos por computadora, tales como SPICE (*Simulation Program with Integrated Circuit Emphasis*), que permite al diseñador simular el comportamiento real de dichos circuitos y predecir sus características. Gracias a ellas, se acortan drásticamente los tiempos de diseño y se disminuyen los costos (**Figura 1**).

PROCESO DE DISEÑO

El proceso se inicia con el enunciado del problema y las especificaciones, etapa en la cual el diseñador comienza con el desarrollo de una solución abstracta que se transformará en un circuito. El diseño se evalúa mediante un modelo que simula su operación, para verificar la respuesta del circuito frente a diversos estímulos de entrada. El modelo se simula y se revisa las veces que sean necesarias, hasta obtener los resultados deseados. También se evalúan las diferentes opciones de diseño y la manera en que cada una incide en los costos.



www.FreeLibros.me

Una vez validado el diseño, se desarrolla e implementa el diseño físico. Por último, se prueba el circuito terminado, y los resultados de la prueba se comparan con el comportamiento modelado para detectar posibles fallas (**Figura 2**).

VENTAJAS DE LA SIMULACIÓN DE CIRCUITOS

La simulación de circuitos por computadora nos permitirá realizar las siguientes acciones:

- En primer lugar, podemos observar el funcionamiento del circuito antes de construirlo.
- Realizar mediciones difíciles (debido al ruido eléctrico), no factibles (por no disponer del equipamiento adecuado) o inapropiadas (el circuito de prueba podría dañarse).
- Emplear componentes ideales para realizar una aproximación a un circuito electrónico, proporcionando una respuesta más simple de calcular.
- Cambiar los parámetros de los modelos de los dispositivos semiconductores para efectuar simulaciones en distintas condiciones, como análisis de corriente continua o alterna.
- Por último, podemos observar la dependencia de la temperatura, la generación de ruido, el efecto de capacitancias intrínsecas y las propiedades físicas del disposi-tivo por simular.

MODELADO DE CIRCUITOS ELECTRÓNICOS

Los programas de simulación de circuitos electrónicos utilizan modelos matemáticos para predecir el comportamiento real de un dispositivo o circuito.

El modelo es la representación de un sistema con un grado de abstracción determinado, en tanto que la abstracción es el proceso por el cual se aísla conceptualmente una propiedad de un objeto: comportamiento, entrada/salida y estructura.

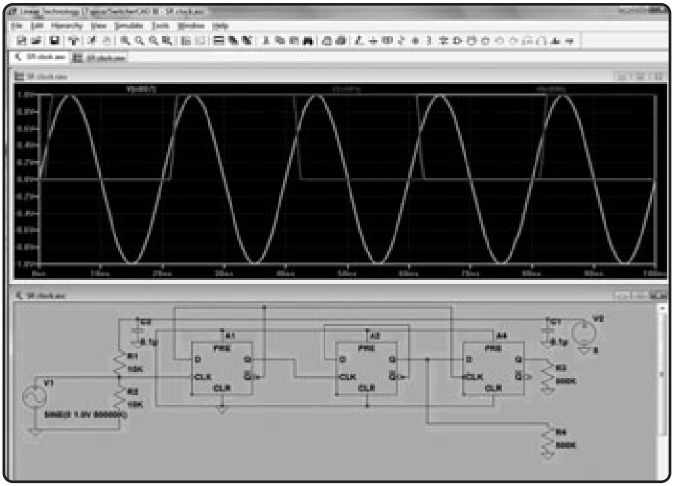

FIGURA 2.
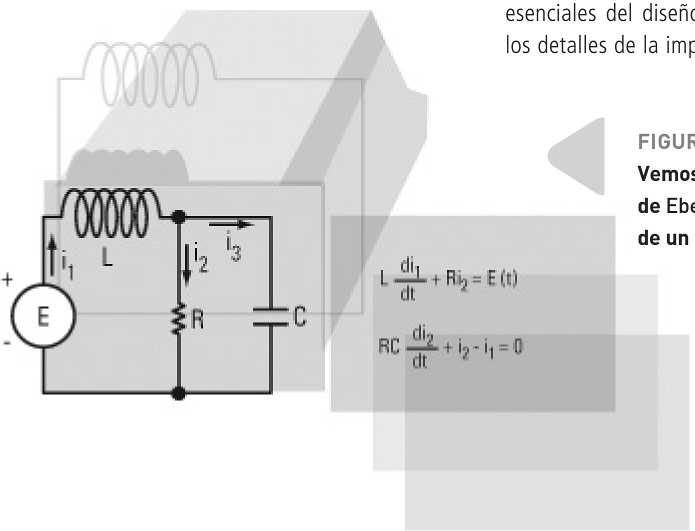
Captura de un software de simulación. Cuando no disponemos de las herramientas de medición, como el osciloscopio o el generador de funciones, la simulación resulta de gran utilidad.

www.FreeLibros.me

> El modelo se simula y se revisa las veces que sean necesarias

Para realizar el modelo matemático, un dispositivo es reemplazado por un bloque que contiene expresiones matemáticas capaces de describir su funcionamiento. Estas pueden estar, por ejemplo, en función de la corriente o de las tensiones del circuito. Un modelo matemático muy utilizado es el de la función transferencia, en el cual, a través de un cociente, se relaciona la respuesta de un sistema a una señal de entrada. A partir de los modelos matemáticos, las suposiciones en el comportamiento de cada componente y sus interconexiones (nodos), el programa realiza la simulación (**Figura 3**).



Simulación lógica **funcional**

En este apartado veremos en qué consiste el proceso de simulación y cómo el software emplea los modelos matemáticos de los componentes para realizarlo. La simulación de un circuito electrónico tiene tres propósitos: la verificación lógica, el análisis de desempeño y el desarrollo de pruebas. El proceso de diseño comienza con un modelo abstracto que solo describe el comportamiento o la función deseada del circuito, sin especificar sus componentes reales. En esta parte se utiliza la simulación funcional, que es el proceso de simular la relación entre las entradas y las salidas del circuito sin hacer referencia a la implementación, es decir, reflejando solo la funcionalidad de sus módulos. Esto permite deducir las características esenciales del diseño, sin tener que ocuparse de los detalles de la implementación.

FIGURA 3.
Vemos aquí el modelo matemático de Ebers Moll **y sus ecuaciones de un** transistor TBJ **de** unión NPN.

www.FreeLibros.me

LA LISTA DE RED

En los programas de captura de esquemático, el modelo del circuito es tomado por el simulador en forma de lista de red (*netlist*). La **netlist** es un archivo de texto generado por el software de captura de esquemático que posee información relativa a los dispositivos integrantes del diseño y sus interconexiones.

La netlist se basa en el proceso de reemplazo de todos los módulos del circuito no primitivos, por las redes de elementos primitivos que representan. Se denomina componente primitivo a aquel que no se forma con elementos menores. De esta manera, cada dispositivo se representa por un símbolo gráfico, que se usará para dibujar el esquema, y un modelo asociado, que describe su comportamiento (**Figuras 4** y **5**).

La simulación lógica consiste en simular los componentes del circuito que se expresan en ecuaciones

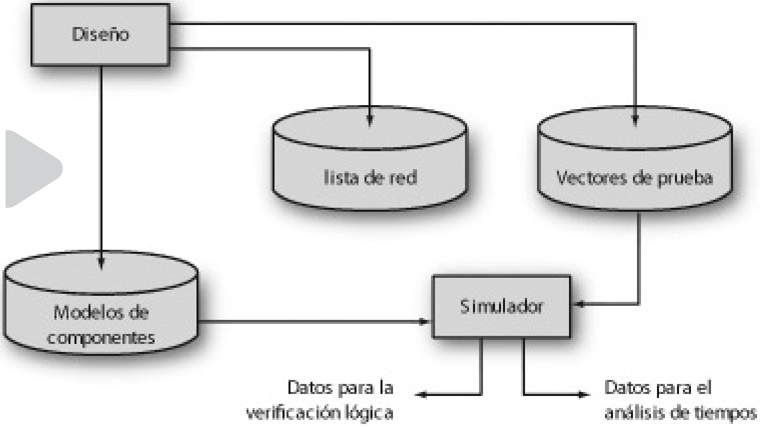


FIGURA 4. **Un diagrama en bloques del entorno del proceso de simulación lógica.**

SIMULACIÓN DE COMPONENTES DIGITALES

En los circuitos que involucran componentes digitales, la información se utiliza para realizar la simulación lógica. Esta simula los componentes del circuito que se expresan en términos de ecuaciones lógicas, utilizando los modelos obtenidos en las librerías del software.

PROGRAMAS DE SIMULACIÓN

Los programas de simulación de circuitos para PC parten de un software de captura de esquemas. Se trata de una herramienta gráfica interactiva con la que un diseñador dibuja un diagrama de circuito que debe ser procesado por el motor de simulación. Poseen librerías de los modelos matemáticos que describen a los componentes. Veamos los más populares.

PROTEUS

Es un entorno integrado para el diseño y el desarrollo de circuitos electrónicos. Es de licencia propietaria, pero posee una versión de prueba con limitaciones. Para la elaboración de esquemáticos, cuenta con el software ISIS, que incorpora una librería de más de 6000 modelos de dispositivos digitales y analógicos (**Figura 6**). Una vez dibujado el diagrama, podemos hacer la simulación a través del módulo **ProSPICE**, basado en el conocido estándar de simulación **SPICE** (**Figura 7**). A diferencia de los tradicionales simuladores de circuitos basados en gráficos, ProSPICE ofrece una completa animación interactiva. Permite emplear componentes interactivos tales como LEDs, displays de siete segmentos y motores.

FIGURA 6.
Captura de ISIS**, el editor de esquemáticos de** Proteus**. En cuanto a la edición, el usuario puede seleccionar el ancho de las líneas, los estilos de relleno, los colores y las fuentes.**

Incluye, además, varios instrumentos virtuales: amperímetros, voltímetros, osciloscopios y generadores de señales, que funcionan de manera similar a los que se pueden encontrar en el mundo real.

Para esquemas electrónicos grandes, ProSPICE permite la simulación parcial de un diseño, para no tener que dividir y probar un esquema por partes. Una característica que se destaca en él es la inclusión de modelos de simulación **VSM** (*Virtual System Modeling*). Esta técnica permite la simulación completa de esquemas electrónicos con microcontroladores, incluida toda la electrónica asociada y con velocidades cercanas al tiempo real.

ORCAD

El paquete de diseño y desarrollo de circuitos electrónicos del software **OrCAD** incluye el módulo **PSPICE A/D** para los procesos de simulación. Es también de licencia propietaria. Mediante el programa **OrCAD Capture** es posible dibujar el esquemático del circuito para luego simularlo en **PSPICE A/D** (**Figura 8**). Incluye simulación de componentes, tanto electrónicos como digitales. El software de captura de esquemático posee un servicio opcional llamado **CIS** (*Component Information System*), el cual otorga acceso a las librerías de componentes de las compañías de semiconductores más importantes.

El módulo PSPICE A/D posee una gran cantidad de modelos, tales como **IGBTs** (*Insulated Gate Bipolar Transistor*), conversores A/D y D/C y moduladores de ancho de pulso. Además, permite diseñar y generar modelos de transformadores e inductores. Tiene integración con el software de simulación **Simulink**, de **Matlab**.

El módulo PSPICE A/D posee una gran cantidad de modelos

ALTIUM DESIGNER

Es un conjunto de programas para el diseño electrónico en todas sus fases. No se trata de un grupo de paquetes sueltos, como una suite, sino de un solo programa. Su versión **Device Intelligence** incluye un simulador **SPICE** compatible con los modelos

OTROS PROGRAMAS I

Además de los mencionados, existen otros programas de simulación. Uno de ellos es **GEDA**, para Linux, de licencia GNU, que actualmente no cuenta con compatibilidad para Windows. Utiliza un motor de simulación llamado **NGSPICE**.

www.FreeLibros.me

habitualmente proporcionados por el fabricante. Permite simular cualquier tipo de dispositivos, incluyendo microcontroladores, aunque está orientado al desarrollo y la simulación de **FPGAs** (*Field Programmable Gate Array*). Es de licencia propietaria y no cuenta con soporte en español (**Figura 9**).

ISIS es un software para el diseño y la simulación de circuitos impresos por computadora

Software **ISIS**

En este apartado describiremos el uso del módulo ISIS, correspondiente a la versión **Proteus 6**, en la confección de esquemas circuitales. El software ISIS forma parte del paquete de productos de software Proteus, de la empresa Labcenter Electronics.

Se trata de una aplicación CAD (*Computer Aided Design*) que ofrece una solución completa para el diseño, la simulación y la elaboración de circuitos impresos. El paquete Proteus está compuesto de los siguientes módulos:

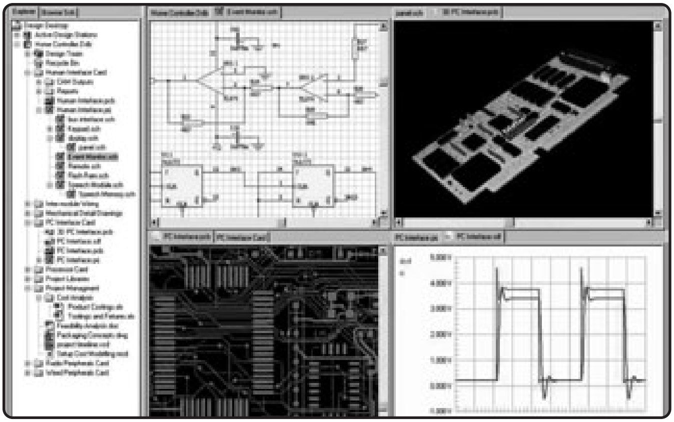

FIGURA 9.

Captura del software Altium Designer. **Por un lado, vemos el esquemático y las señales involucradas. Por el otro, las pistas de** PCB **y la** placa **en tres dimensiones.**

OTROS PROGRAMAS II

Electronic Workbench Multisim, de la empresa **National Instruments**, es muy popular. Su estética se asemeja a la de un laboratorio virtual y se utiliza frecuentemente como una herramienta para la enseñanza y el aprendizaje de la teoría de circuitos electrónicos.

www.FreeLibros.me

ELECTR_Cap5_xxx_xxx.qxp 04/07/2011 16:40 PÆgina 119

- **ISIS** (***Intelligent Schematic Input System***): diseña los esquemáticos de los circuitos.
- **VSM** (***Virtual System Modeling***): es el módulo de simulación funcional de los circuitos.
- **ARES** (***Advanced Routing Modeling***): se ocupa del diseño de los circuitos impresos (PCBs).

ENTORNO ISIS

El entorno ISIS es una herramienta gráfica de diseño de esquemáticos para circuitos impresos, que también incorpora funciones de simulación. Como podemos imaginar, ya sea para simular con el entorno **VSM** o para confeccionar un impreso con **Ares**, primero necesitamos crear un esquemático a partir de los componentes seleccionados para el diseño.

También es posible crear nuestros propios componentes, asignando pines y seleccionando encapsulados para el diseño de impresos, así como su modelización para simulación (**Figura 10**).

Otra característica importante es que se cuenta con la posibilidad de gestionar proyectos jerárquicos. Es decir, que un componente creado puede representar un circuito completo en su interior, conformando un proyecto con varios niveles jerárquicos. Además, admite anidar múltiples hojas de esquemáticos. Resulta cómodo trabajar de esta manera con proyectos de mayor complejidad. Por último, con ISIS podemos simular nuestros diseños en tiempo real mediante su menú de funciones **Debug**, de la barra de herramientas, o desde la barra de simulación ubicada en la parte inferior de la pantalla.

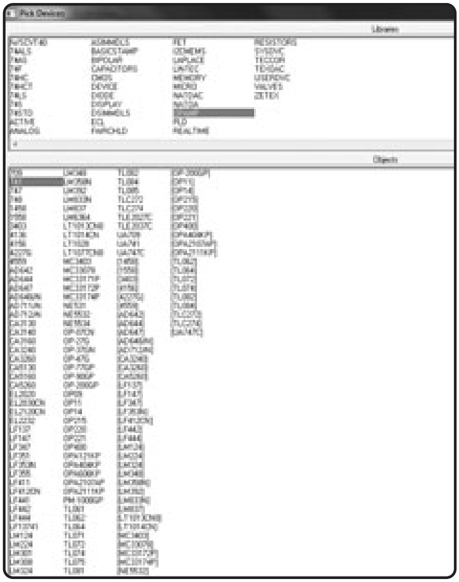

FIGURA 10. Vemos aquí el conjunto de librerías que ofrece la suite para simulación y confección de impresos.

LOS COMPONENTES DE ISIS

Encontramos varios tipos de fuentes de señal, conectores, switches, llaves, relés y demás elementos necesarios en la confección de un circuito. Elementos como voltímetros, amperímetros, osciloscopios y simuladores de interfaces nos brindan una excelente versatilidad.

www.FreeLibros.me

ELECTR_Cap5_xxx_xxx.qxp 04/07/2011 16:40 PÆgina 120

Área **de trabajo**

Vamos a conocer a fondo cómo configurar y movernos en nuestra área de trabajo, la distribución de las barras de herramientas y las ventanas auxiliares para el diseño. Una vez que abrimos ISIS, nos encontramos con la hoja de diseño, que será nuestro lugar de trabajo. Notamos, en primer lugar, la presencia de una **grilla,** cuyo espaciado es configurable, y que nos permitirá trabajar con un "paso" más fino o más grueso a la hora de mover componentes o trazar líneas de conexión. Desde el menú principal podemos realizar las siguientes configuraciones:

- Configuración del tamaño del área de trabajo: **`System/Set sheet sizes`**.
- Cambiar el espaciado de la grilla: **`View/Snap`**.
- Activar/desactivar la visualización de las distintas barras: **`View/Toolbars`**.

Las barras lateral y superior poseen los accesos a las diferentes herramientas para agilizar el trabajo

BARRAS DE ACCESO RÁPIDO

En la parte superior de la pantalla están el **`Menú principal`** y las **`Barras de acceso rápido`** para funciones de visualización, impresión y herramientas varias. Sobre la izquierda, se ubican las ventanas y las barras de botones para el diseño. Las barras de botones y ventanas ubicadas a la izquierda de la pantalla nos ofrecen varias funciones importantes para confeccionar circuitos.

Las **`Barra de funciones`** y **`ventanas`** se ubican en la parte superior de la hoja de trabajo, y contienen funciones generales, opciones y herramientas de proyecto. Veamos en detalle cada una de estas opciones en las **Guías Visuales 1 y 2**.

SOBRE NETLIST

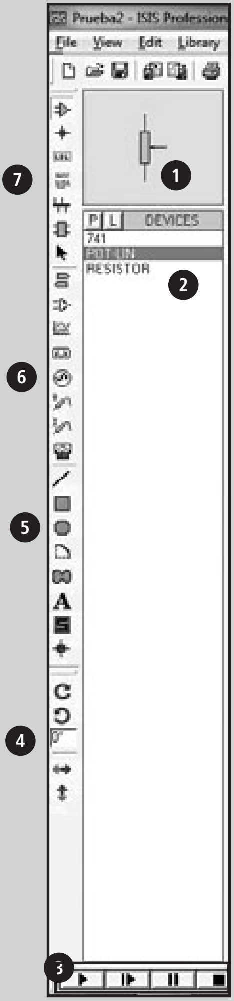
La **Netlist** es el archivo con el detalle de conexión entre los componentes de un diseño que Ares debe interpretar. Su información ayuda con el diseño del PCB al unir automáticamente los componentes del esquemático confeccionado en ISIS, a través de líneas de guía virtuales.

www.FreeLibros.me

ELECTR_Cap5_xxx_xxx.qxp 04/07/2011 16:40 PÆgina 121

GUÍA VISUAL /1

Barra de funciones y ventanas



① **`Ventana de vista completa`**: desde aquí podremos visualizar la totalidad del proyecto y movernos sobre toda la hoja, haciendo clic sobre el punto donde queremos centrar la vista.

② **`Ventana de componentes y librerías`**: en ella aparecen las opciones correspondientes a cada menú de trabajo. Por ejemplo, el menú **`Component`** explora las librerías y muestra los dispositivos del proyecto.

③ **`Barra de simulación`**: contiene las teclas **`Run`**, **`Step`**, **`Pause`** y **`Stop`** para la simulación temporal de los circuitos.

④ **`Barra de rotación de componentes`**: se utiliza para modificar la orientación de los componentes con el fin de facilitar su posicionamiento e inserción en los circuitos que se diseñen. Podemos rotar a derecha e izquierda y espejar los dispositivos en forma vertical y horizontal.

⑤ **`Barra de dibujo`**: permite agregar figuras 2D a nuestros diagramas. También podemos incluir texto con los distintos estilos de formato asignados para referencias, indicadores y dispositivos de las librerías.

⑥ **`Barra de diseño electrónico`**: está destinada a la inserción de dispositivos, tales como generadores de señal de todo tipo, instrumentos de medición para simulación en tiempo real, puntas de medición de corriente/tensión y terminales de conexión entre distintas hojas de trabajo, entre otras.

⑦ **`Barra de modos de trabajo`**: esta barra contiene algunas de las opciones más utilizadas. El botón **`Component`**, para listado de los componentes del proyecto y la exploración de librerías; la opción **`Wire Label`**, para darles nombre a las líneas de conexión; **`Buses Mode`**, para la inserción de buses, y el modo instantáneo de configuración de los dispositivos.

1. **`Barra de manejo de archivos`**: aquí podemos encontrar las funciones típicas para crear un nuevo proyecto, guardar información, importar y exportar, y las opciones de impresión.
2. **`Barra de visualización`**: ofrece las opciones de zoom, centrado de la hoja de trabajo, vista de hoja completa y selección del área por visualizar. También podemos habilitar/deshabilitar la grilla y el botón de actualización de vista.
3. **`Barra de edición`**: incluye las funciones de **`Undo`** y **`Redo`**, **`Copy`**, **`Cut`** y **`Paste`** de elementos individuales. También, las opciones de copiado, movimiento, desbloqueo y eliminación de objetos agrupados (opciones tagged). Además, vemos la función de conversión de un grupo en elemento de librería y el botón **`Pick/Update Device Symbol`**, para búsqueda de componentes.
4. **`Barra de proyecto`**: incluye el botón de búsqueda de dispositivos por propiedades internas (**`Matched property`**) y todas las opciones relacionadas con proyectos multihoja y jerárquicos: retorno y cambio de hoja de diseño, movimiento por la estructura jerárquica y eliminación de hojas. También están los botones de acceso rápido a la confección del reporte de materiales (**`Bill of materials`**), chequeo de conexión eléctrica (**`Electrical rules check`**) y generación de la Netlist para el diseño de impreso en Ares.

DESPLAZAMIENTO POR EL ÁREA DE TRABAJO

Para movernos sobre el área de trabajo disponemos de varias opciones, que detallamos a continuación:

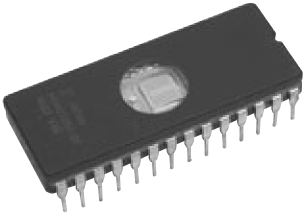
- **`Herramienta Re*centre Display`**
  Es el botón marcado con una **X** que se encuentra en la barra de acceso rápido. Al presionarlo, el cursor toma la forma de una mira telescópica. Moviéndonos hasta el lugar donde centraremos la vista, presionamos el botón izquierdo para realizar el trabajo.

- **`Herramienta Zoom`**
  Utilizando el scroll del mouse, podemos acercar o alejar la vista de la región centrada en la posición del puntero. También podemos hacerlo con la

www.FreeLibros.me

opción **Zoom to Area**, de la solapa **View** del menú principal, o desde la barra de acceso rápido, con la opción **View selected Area**.

- **Ventana de vista completa**
  La ventana de vista completa muestra, en forma minimizada, el aspecto de todo el diseño. Haciendo clic con el puntero del mouse sobre la zona donde queremos centrar la visualización, lograremos movernos por la hoja. El recuadro verde muestra la zona visible en la hoja de trabajo. Esta puede modificarse haciendo zoom con el scroll del mouse o mediante **View selected Area**, de la barra de visualización, en la parte superior (**Figura 11**).



- **Tecla Shift y mouse**
  Si combinamos esa tecla con el movimiento del mouse, lograremos un desplazamiento muy veloz. Esta combinación funciona cuando tenemos maximizada la visualización y el área de trabajo no entra en la pantalla del monitor. Es la forma más rápida de movernos por el proyecto.

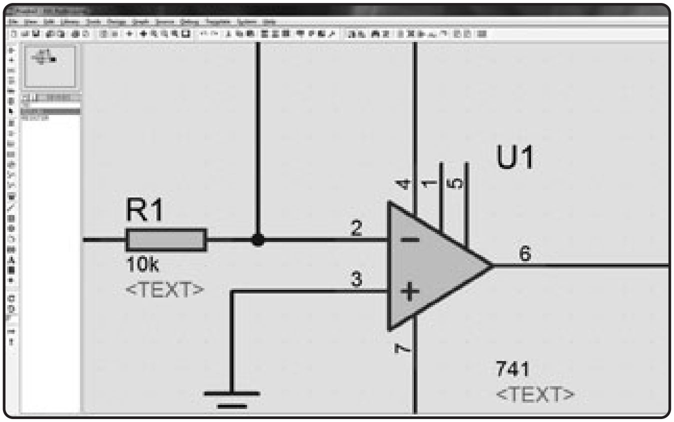


FIGURA 11. Observamos un recuadro de color verde en la ventana de vista completa, que demarca la zona visualizada en la hoja de trabajo.

MEDICIÓN DE DISTANCIAS

Es posible medir distancias relocalizando el origen de la hoja por medio del botón Enable/Disable Manual Origin Specification, de la barra de visualización de acceso rápido ubicada en la parte superior de la hoja.

www.FreeLibros.me

ELECTR_Cap5_xxx_xxx.qxp 04/07/2011 16:40 PÆgina 124

Diseño **en ISIS**

Luego de explorar el área de trabajo, pasaremos a explicar el proceso de inserción de componentes desde las librerías de ISIS y las distintas formas de hacerlo.

Este programa cuenta con una gran librería de componentes donde, además de la forma esquemática tradicional, se muestra la forma física o footprint del elemento seleccionado. Además, ISIS ofrece la aplicación **ProSPICE,** que permite el uso de instrumentos virtuales para la visualización del comportamiento de las señales de los circuitos.

Para la construcción del esquemático del amplificador inversor, vamos a seleccionar los componentes dentro de las librerías de ISIS. Luego, los colocamos en la ventana de trabajo y realizamos la unión entre ellos por medio de las pistas. Finalmente, dejamos conectado un **osciloscopio** para visualizar la señal de salida.

LIBRERÍAS DE COMPONENTES

ISIS nos ofrece unas completas librerías, no solo para confección de impresos, sino también para simulación (**Figura 12**). Entre ellas, podemos encontrar componentes estándar, como resistencias, capacitores, transistores, diodos, etc. Además, se incluyen diversos integrados clasificados por fabricante: microcontroladores, memorias, amplificadores operacionales, **ICs** varios y **CPLDs**, entre otros.

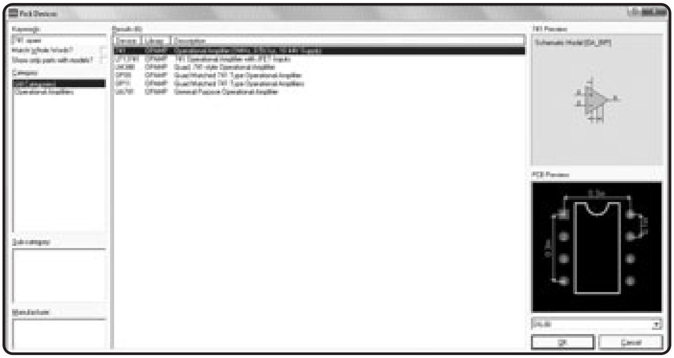

FIGURA 12.
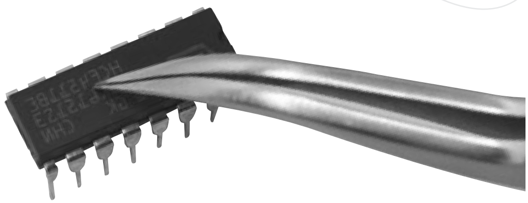
A la derecha se observa la ventana de librerías, el esquemático del amplificador 741 **y su correspondiente** footprint **para el diseño de impresos.**

ESQUEMÁTICO Y FOOTPRINT

El esquemático hace referencia al símbolo normalizado que se utiliza para representar gráficamente componentes electrónicos: el footprint del componente electrónico, la forma física que este ocupará en una placa electrónica, y la disposición de perforaciones y pads.

www.FreeLibros.me

> ProSPICE permite el uso de instrumentos virtuales para visualizar las señales de los circuitos



INSERCIÓN DE COMPONENTES

Desde la barra de modos de trabajo, presionamos el primer botón, que corresponde a la opción **`Component`**. Haciendo clic sobre **`Pick Device`**, se abrirá el menú de librerías, con los distintos componentes disponibles.

Allí podemos seleccionar una categoría del menú **`Library`**. Una vez hecho esto, desde la lista **`Objects`** es posible elegir cuáles de los componentes que forman parte de ella utilizaremos.

Otra manera de acceder a las librerías es mediante el botón **`Pick or update device/symbol`** o desde el menú principal, desplegando la solapa **`Library`**, donde se ubica el comando denominado **`Pick Device/Symbol`** (**Figura 13**).

La ventana que se despliega, en ambos casos, corresponde a un buscador de texto por cadena de caracteres. Se debe seleccionar el tipo de componente o dispositivo por buscar y el modo de comparación: coincidencia exacta, solo del comienzo, que contenga el texto, solo fin del texto, etc. Luego, escribiendo en el campo el nombre del componente o texto correspondiente, las coincidencias aparecerán listadas en la ventana. Como en el caso anterior, al hacer doble clic sobre un componente, este se añadirá a la lista del proyecto.

Cerrando las ventanas de selección y volviendo a la hoja de trabajo, solo resta insertar el componente desde la lista de proyecto que fuimos armando. Para hacerlo, desde la lista de proyecto de la ventana de componentes, seleccionamos el dispositivo que

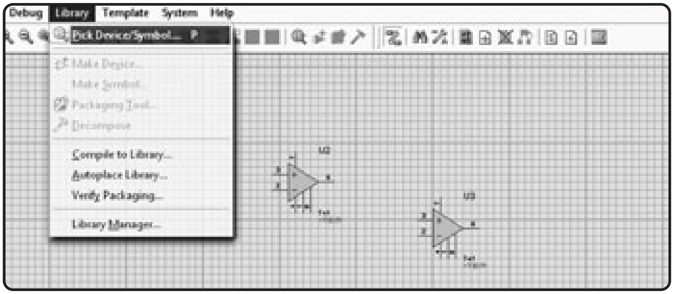


FIGURA 13.
Otra forma de realizar la búsqueda e inserción de componentes es accediendo al menú `Library/Pick Device Symbol`**.**

www.FreeLibros.me

queremos insertar usando el botón izquierdo del mouse. Lo veremos en la ventana principal, pero para insertarlo en la hoja, debemos hacer clic con el botón izquierdo del mouse en algún punto del área de trabajo.

Para eliminar un componente, hacemos doble clic con el botón derecho del mouse. Con el primer clic, el componente se selecciona y se marca en rojo. Si volvemos a hacer otro clic derecho, este se quitará de la hoja, pero no de la lista de proyecto.

Por último, contamos con la posibilidad de rotar el componente y espejarlo a nuestra comodidad, utilizando las opciones de la barra de rotación, sobre la izquierda de la pantalla. Observamos cinco posibilidades: rotar 90º a la derecha, rotar 90º a la izquierda, rotar un ángulo específico, reflejar horizontalmente y reflejar verticalmente.

Podemos utilizarlas antes de posicionar el componente sobre la hoja o una vez que este ya fue insertado, marcándolo en rojo con el botón derecho del mouse y presionando el botón de la rotación deseada (**Figura 14).**

Diseño de un circuito

Estamos en condiciones de diseñar nuestro primer circuito con ISIS. Para el ejemplo, elegimos una etapa de ganancia a amplificador operacional con un sencillo LM741.

Utilizando los conceptos anteriormente descriptos, presionamos el botón **`Components`** y, luego, con el botón **`P`** de la herramienta **`Pick`**, seleccionamos los dispositivos que usaremos en el proyecto. Estos son:

- El **componente 741** de la librería **OPAMP**.
- Un resistor de la librería **ASSIMDLS**.
- Un potenciómetro **POT-LIN** de la librería **Active**.

FIGURA 14.
Con el botón derecho del mouse, es posible seleccionar los componentes para realizar distintas acciones. En este caso, elegimos `Delete Objet`**, para eliminarlo.**

www.FreeLibros.me

ELECTR_Cap5_xxx_xxx.qxp 04/07/2011 16:40 PÆgina 127

Primero debemos configurar nuestros componentes. En este caso, asignamos al resistor y al potenciómetro un valor de **10 K?**. Para hacerlo, podemos utilizar el botón de configuración instantánea de la barra de modos de trabajo. También podemos presionar el botón derecho del mouse sobre el cuerpo del componente y, luego, el botón izquierdo sobre el mismo marcado de rojo.

INSERCIÓN DE MASA Y ALIMENTACIÓN

Desde la barra de diseño electrónico, presionamos el botón **`Inter-sheet Terminal`**. Sobre la ventana de componentes, aparecerán varias opciones, entre ellas, el conector de **`Ground`**. Sobre la ventana, seleccionamos esta opción con el botón izquierdo del mouse. Por último, con el puntero del mouse nos dirigimos hacia algún lugar de la hoja de trabajo y, presionando el botón izquierdo del mouse, insertamos la masa del circuito.

Necesitamos también alimentación para el circuito y para simular la entrada de señal que queremos amplificar/atenuar. Sobre la misma barra de diseño electrónico, ahora presionamos el botón **`Generator`**. Seleccionando la opción **`DC`** y presionando el botón izquierdo del mouse sobre la hoja de trabajo, insertamos dos fuentes de continua al proyecto. Para la señal de entrada, utilizamos el dispositivo **`SINE`**, que es una fuente sinusoidal (**Figura 15**).

Resta configurar cada uno de los dispositivos. Una vez más, marcándolos de rojo con el botón derecho del mouse, abrimos una ventana de configuración. Para las fuentes DC, configuramos los valores de tensión 5 V y -5 V para los pines del LM741 (7) y (4), respectivamente. La fuente sinusoidal tendrá una amplitud de 2 V y una frecuencia de 1 KHz (**Figura 16**).

> Necesitamos también alimentación para el circuito y para simular la entrada de señal

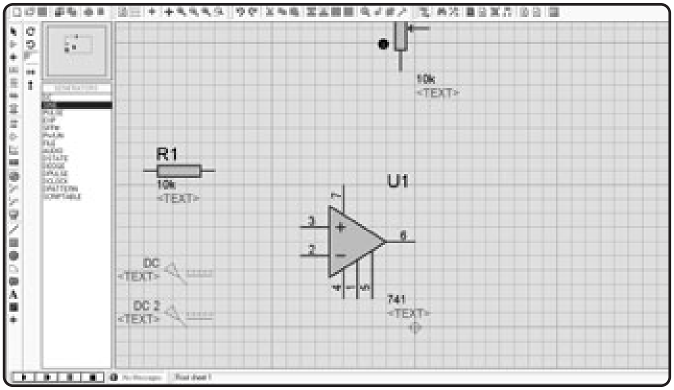

FIGURA 15.
Observamos las dos fuentes de alimentación de continua para el proyecto, denominadas DC1 y DC2.

FIGURA 16. Aquí se muestra la ventana de configuración de la fuente sinusoidal elegida para la entrada de señal del amplificador operacional. Esta tendrá una amplitud de 2 V **y una frecuencia de** 1 KHz.

CABLEADO DE DISPOSITIVOS

Ahora solo resta unir los componentes para conformar el circuito. Para hacerlo, trazaremos las líneas de conexión con el botón izquierdo del mouse, siempre partiendo de un pin.

Vamos a notar que el cursor cambia a una cruz cuando nos ubicamos con el puntero encima de un pin. Presionando una sola vez el botón izquierdo del mouse, comenzamos a trazar las líneas, desde ese punto hacia el pin destino del circuito. Volviendo a presionar el botón izquierdo sobre el pin destino, se realizará el trazado automático de la línea, siguiendo el camino más corto, pero sin pasar por encima de ningún componente u otra traza. Continuamos así hasta completar las conexiones y lograr que el circuito quede completamente armado.

Los instrumentos virtuales se seleccionan desde la opción INSTRUMENTS

INSTRUMENTOS DE SIMULACIÓN

Realizaremos una simulación de funcionamiento en tiempo real muy sencilla. Para este fin, utilizaremos un osciloscopio que debemos seleccionar desde el botón `Instruments`, de la barra de diseño electrónico (**Figura 17**).

Una vez insertado el osciloscopio, como cualquier otro dispositivo, conectamos su **Canal A** a la salida del amplificador operacional, es decir, en el pin (6). Luego, presionamos el botón **`Run`** de la barra de simulación y corremos nuestro diseño. Automáticamente se abrirá una ventana con la pantalla del osciloscopio virtual. Allí configuramos la sección vertical en 1 V/división, y la horizontal, en 500 us/división.
Manejando el potenciómetro insertado, veremos cómo amplificar la señal para valores mayores a 10 KOhm y atenuarla para valores inferiores, siguiendo la relación de amplificación: * RB / RA. Para este caso, RB = RV1 y RA=R2. Finalmente, presionando el botón **`Stop`** de la barra de simulación, la detenemos (**Figura 18**).

www.FreeLibros.me

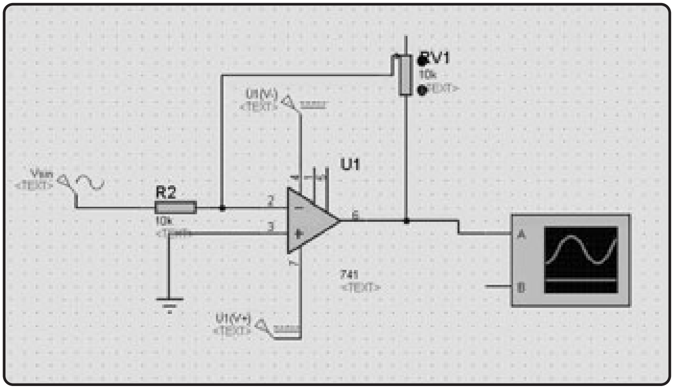

FIGURA 17.
Este es el circuito completo que debemos seguir para confeccionar el ejemplo.

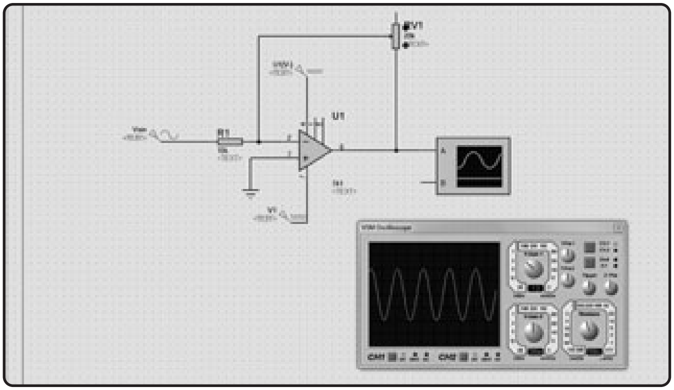

FIGURA 18.
Vemos aquí la simulación correspondiente al instrumento Osciloscopio de ISIS. Observamos cómo la señal de salida se amplifica para valores del potenciómetro mayores a 10 K, mediante la relación (- RV1 / R2).

SIMULADOR DEL CARGADOR DE BATERÍAS

En el **Paso a paso 1** aprenderemos paso a paso cómo realizar la simulación del cargador de baterías que se detalló en el **Capítulo 1**. Daremos nuestros primeros pasos en la simulación de circuitos electrónicos. Este proceso puede realizarse en ISIS, sin necesidad de abrir otro programa. Para efectuar este procedimiento, construiremos el esquemático del cargador de baterías, luego colocaremos los instrumentos de medición para ver su funcionamiento y, finalmente, realizaremos la simulación del circuito, para ver la curva de salida correspondiente.

El primer paso es crear un nuevo diseño. Puede realizarlo desde la pestaña **`File`**, ubicada en la Barra de menús, o también mediante la herramienta **`New File`**/**`From Default Template`**, que se encuentra en la Barra de archivos. En esta oportunidad, lo hará desde la opción **`File`**/**`New Design`**.

Al entrar en ese menú, se abre la ventana emergente **`Create New Design`**, donde se ofrecen varias plantillas para realizar el diseño. Estas se utilizan para hacer presentaciones de informes impresos con rótulos, como nombre de los archivos, día de presentación, nombre del diseño, autor, revisión y hora. Para su caso seleccione **`Default`** y presione **`Ok`**.

Una vez que ha generado un nuevo diseño, es recomendable crear una carpeta con el nombre del proyecto. Puede recurrir al comando `Save Design`, en la Barra de menús. Para este ejemplo, use `File`/`Save Design`. Aparece la ventana emergente `Save ISIS Design File`, que tiene las herramientas necesarias para crear la carpeta donde alojará el archivo de diseño. Cree la carpeta que se llamará **Cargador de baterías** y, dentro de ella, guarde el diseño; presione **ok**.

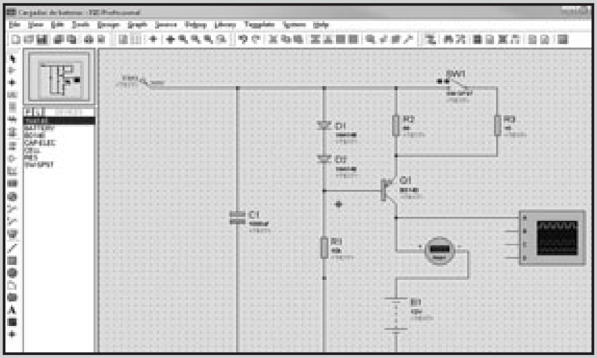
Batería

En este paso comparará el circuito original con el que va a simular. En el que simulará, no precisa el fusible, ya que en este caso no habrá ningún exceso de corriente. También va a reemplazar el puente rectificador y a colocar una fuente de corriente continua, lo que le permitirá ver el funcionamiento del cargador.

www.FreeLibros.me

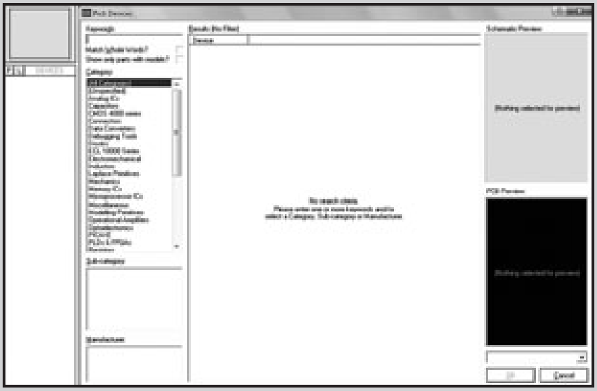
PASO A PASO /1 (cont.)

5



El circuito por simular no está conectado a la red domiciliaria, de modo que puede reemplazar el transformador, el circuito rectificador y el fusible. El puente rectificador se sustituye por una fuente de continua de **24 V**. Coloque una batería de **12 V** y saque el fusible, ya que no tiene modelo de simulación. Agregue el amperímetro y coloque un osciloscopio para visualizar la forma de la señal.

6

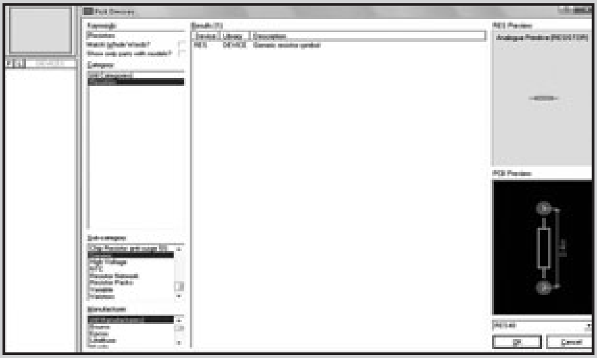


Debe ubicar los componentes que desea volcar. Presione el botón **`P`** para que se despliegue la ventana **`Pick Devices`**, en la cual tiene que buscar los distintos componentes del cargador de baterías.

www.FreeLibros.me

PASO A PASO /1 (cont.)

7



Ahora pondrá los resistores que lleva el circuito. Para hacerlo, coloque la clave **Resistor** en el cuadro de diálogo **`Keywords`** de la ventana **`Pick Devices`**. En **`Pick Devices`**/**`Category`** seleccione **`Resistors`**. En **`Sub-category`** elija **`Generic`**, y en **`Manufacturer`** deje la opción **`All Manufacturers`**. Presione **`Ok`** para colocar el componente en la ventana de trabajo.

Los comandos de simulación se encuentran en la barra del mismo nombre. Esta tiene cuatro comandos: **`Play`**, **`Step`**, **`Pause`** y **`Stop`**. **`Play`** corre la simulación sin pausas, en tanto que **`Step`** trabaja paso a paso en tramos de tiempo predefinidos y permite el uso de herramientas de depuración. Presione **`Play`** para comenzar con la simulación.

Simulación de código con ISIS

Con Proteus podemos simular código ensamblado de microprocesadores para visualizar el funcionamiento de un microcontrolador mientras se ejecuta el código correspondiente.

La simulación de código ensamblado es una de las herramientas que han facilitado el trabajo con los microcontroladores, ya que permite probar su comportamiento antes de implementar estos elementos en la protoboard o en la placa. Este proceso nos ahorra tiempo de desarrollo porque podemos depurar el circuito sin temor a equivocarnos, considerando que todo el desarrollo y la prueba de diseño se realiza en un programa de computadora. Recordemos que VSM (*Virtual System Modeling*) es capaz de trabajar con archivos de código Assembler de algunos de los siguientes fabricantes de microprocesadores: AVR, PIC, 8051, HC11, ARM/LPC200 y Basic Stamp. Además, integra la simulación de circuitos electrónicos tradicionales con modelos de animación de componentes electrónicos y microprocesadores que conforman el circuito.

> La simulación de código ensamblado permite depurar el circuito antes de su implementación real

Es importante destacar que la potencia de Proteus radica en que puede simular en un solo software todo el hardware necesario para un proyecto con microcontroladores. Por lo tanto, no solo posibilita el procesamiento del código Assembler, sino que también nos permite trabajar en tiempo real con su propio hardware, usando Display LCD, LEDs, teclados, puertos RS232, etc.

Todas estas opciones están incorporadas en ISIS a través de **Source** y **Debug** (**Figura 19**), ubicadas en

la barra de **Menú**. En la primera se incluyen las funciones que nos permiten cargar el código, el tipo de microcontrolador y la herramienta generadora de código. También se pueden cargar las herramientas destinadas a hacer el ensamble entre el código realizado y el microcontrolador, para su posterior compilación. En **Debug**, en cambio, se ofrecen las herramientas que nos permiten ver los registros del microcontrolador, el código fuente, la memoria de datos y la memoria EPROM, entre otras características que analizaremos más adelante.

Limitaciones de las versiones

Proteus ofrece diferentes versiones que presentan algunas limitaciones. Veamos cuáles son y sus características. La versión de Proteus que se distribuye sin costo es la denominada Lite, que incluye ISIS y Ares. El primero sirve para dibujar los esquemáticos de los circuitos, por lo que contiene todas las herramientas para tal fin; en tanto que el segundo se usa para desarrollar las placas electrónicas, con lo cual incorpora toda la librería de componentes y sus encapsulados con limitaciones en autoruteador de placas.

En Proteus es posible trabajar con instrumentos virtuales gracias a la implementación de ProSPICE Lite. Esta aplicación se utiliza para simular instrumentos que podemos tener en un taller, como el voltímetro, el amperímetro y el osciloscopio, entre otros. Veamos a continuación las diferencias principales entre la versión Profesional y la versión Lite de este programa:

- No hay integración entre ISIS y Ares en la versión Lite del software.
- ISIS Lite no implementa el verificador de las reglas de conexiones eléctricas (ERC).
- En la versión **Ares de Proteus Lite** no se pueden generar archivos Gerber o Excellon, necesarios para la producción de circuitos impresos.
- La versión de **Proteus Lite ProSPICE** no tiene limitaciones en cuanto a la complejidad de los circuitos que se analizan.
- Proteus Lite no incluye modelos VSM, sino que los necesarios deben comprarse aparte. A su vez, la simulación VSM está limitada a los ejemplos que vienen en esta versión. Es posible realizar cambios al código fuente suministrado en los ejemplos de Proteus Lite, el cual no debe superar 1k.

Más allá de estas restricciones, la versión Lite es una excelente herramienta para complementar nuestro estudio de la electrónica tanto analógica como digital.

MÁS SOBRE PROTEUS

En lo que respecta a la parte analógica, Proteus tiene toda la potencia necesaria para analizar circuitos con componentes pasivos, como resistores, capacitores e inductores; y activos, como diodos, transistores y amplificador operacional.

Capítulo 6

Fuentes de alimentación

Estudiaremos qué es y para qué sirve una fuente de alimentación y cuáles son los diferentes tipos.

www.FreeLibros.me

Las fuentes de alimentación

La fuente de alimentación es la encargada de proveer la tensión adecuada para el correcto funcionamiento de un circuito. Con diseño simple o complejo; reguladas, estabilizadas, lineales, conmutadas, fijas o variables; con circuitos integrados o con componentes discretos, las fuentes de alimentación están presentes en todos los aparatos electrónicos.
Algunas veces menospreciadas por su simpleza aparente, todo taller de este rubro debe contar con una. En particular, los modelos de laboratorio brindan tensión estabilizada y regulada, junto con protección y regulación de corriente. Con ellos, es posible limitar la corriente máxima que se le entregará al circuito, de modo que, aun bajo una falla grave, este se mantenga dentro de condiciones seguras para él y para los usuarios. En estas páginas veremos qué es y para qué sirve una fuente de alimentación, y cuáles son los diferentes tipos y especificaciones para alimentar cualquier circuito electrónico. Las fuentes son necesarias para alimentar los sistemas electrónicos. Es por eso que resulta clave conocerlas a fondo (**Figura 1**)

La energía eléctrica que llega a través de la red domiciliaria lo hace en forma de **corriente alterna**. Esto se debe a que los procesos de generación, transmisión y conversión de electricidad son más simples y eficientes en esta modalidad. En algunos países, se provee de una tensión alterna de **50 Hz**, cuyo valor eficaz es de **220 V**. En otros, se trabaja a **60 Hz** y **110 V**. Sin embargo, casi todos los circuitos electrónicos requieren una tensión

Las fuentes son necesarias para alimentar los sistemas electrónicos

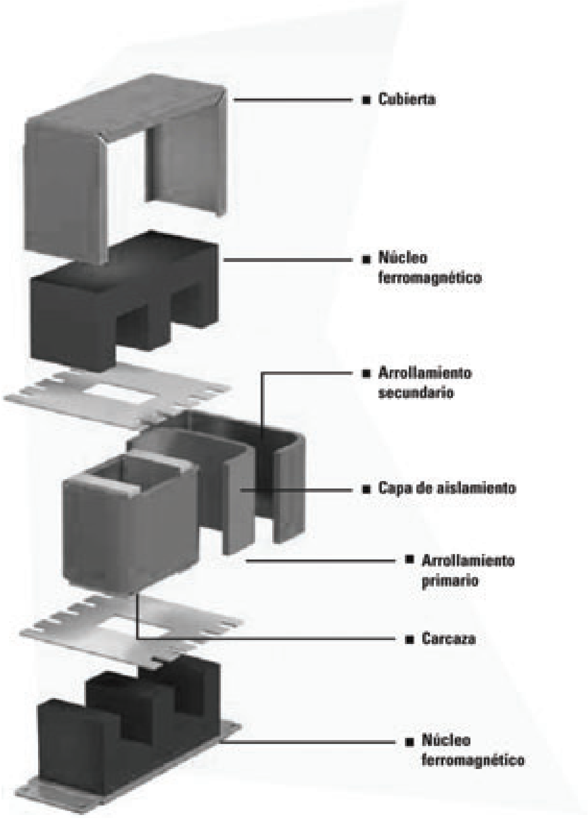

FIGURA 1. **Una fuente convierte energía** AC **en energía** DC. **Las tensiones** DC **logradas deben ser filtradas y reguladas.**

www.FreeLibros.me

continua para funcionar. La fuente de alimentación es, entonces, el dispositivo capaz de convertir la tensión alterna de la red de suministro en tensión continua. Las fuentes se clasifican, básicamente, en **lineales** y **conmutadas**, aunque también existen otras variantes. A continuación, haremos una introducción al tema para, luego, entrar en mayor detalle (**Figura 2**).

- **Fuentes lineales**: tienen un diseño simple, y su circuito posee las siguientes etapas: transformador, rectificador, filtro, regulación y salida. Más adelante estudiaremos en profundidad este tipo de fuentes.
- **Fuentes conmutadas** (switching): utilizan circuitos convertidores de nivel de tensión formados por bobinas y capacitores. La regulación se produce a través de dispositivos de estado sólido, como transistores y **MOSFETs**, entre otros, que operan como llaves. Una fuente de computadora es un ejemplo de fuente conmutada (**Figura 3**).

Una fuente convierte la tensión alterna de la red de suministro en tensión continua

FIGURA 3. **Una fuente de PC de tipo** ATX. **Es conmutada, y su circuito resulta bastante más complejo que el de una lineal.**

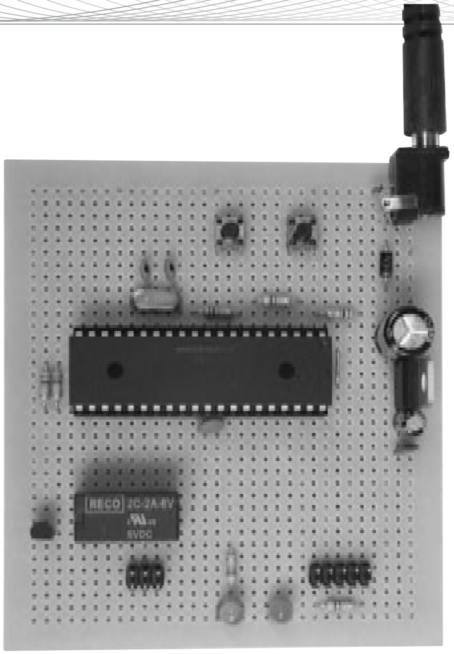
BATERÍAS

Son una fuente de alimentación lineal formada por celdas electroquímicas que almacenan la energía eléctrica suministrada para, luego, entregarla al dispositivo en cuestión. Los tipos de baterías más habituales son la de plomo y ácido sulfúrico y la de Ni-Cd.

www.FreeLibros.me

ESPECIFICACIONES DE LAS FUENTES

La primera especificación de una fuente es su tensión de salida, que suele ser de 12 V. La segunda, y prácticamente la más importante, es la corriente máxima de salida. Para entender esta característica, debemos pensar que el circuito o dispositivo electrónico que utilizará la fuente "demanda" la corriente necesaria para funcionar, y la fuente se la entrega. Si utilizamos una fuente que puede entregar una **corriente mayor** a la que el dispositivo precisa, éste funcionará correctamente. En cambio, si es menor, el funcionamiento del circuito se verá afectado, lo que se conoce como **sobrecarga**. La corriente máxima de salida multiplicada por el voltaje de salida da como resultado la potencia máxima que la fuente puede entregar, medida en Watts. Podemos ver otras especificaciones importantes en la **Tabla 1**.



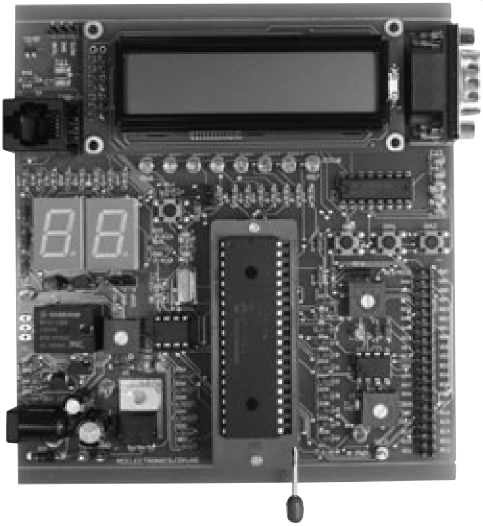
ESPECIFICACIÓN	DETALLES
`Ripple`	Es la ondulación residual que permanece luego del proceso de rectificación y filtrado.
`Regulación de línea`	Mide la variación en la salida nominal de la fuente cuando ocurre una variación en la tensión de entrada. Puede deberse a un cambio en la tensión alterna de la red o al ripple, en caso de un filtrado deficiente.
`Regulación de carga`	Mide la variación en la salida nominal de la fuente al estar sometida a variaciones en la carga conectada a ella.
`Estabilidad en temperatura`	Mide la variación de la tensión continua de salida respecto a las variaciones de temperatura, ya sea del ambiente o debido al calentamiento interno de la fuente.
`Eficiencia`	Es una medida de cuánta energía de la que utiliza la fuente para cumplir su función es realmente entregada a la carga. El resto se pierde en forma de calor.

TABLA 1. **Detallamos aquí otras especificaciones de las fuentes.**

www.FreeLibros.me

PROTECCIÓN

En caso de sobrecarga o cortocircuito, en circuitos sencillos, es común el empleo de un fusible: un finísimo cable dentro de un pequeño tubo de vidrio o plástico que interrumpe el funcionamiento de la fuente, ya que se funde si fluye una corriente peligrosa para la integridad del equipo. En aparatos más complejos, se utiliza un circuito de protección contra sobrecarga, que se activa solo si se intenta exceder el límite de corriente permitido. Una configuración frecuente es la de limitación de corriente **foldback**. Aquí, al ocurrir la sobrecarga, se disminuyen tanto la corriente como el voltaje de salida, con el fin de reducir la disipación de potencia del elemento regulador y de los otros componentes del circuito de la fuente.



Fuentes lineales y conmutadas

Analizaremos y compararemos los dos tipos de fuentes de alimentación, que se clasifican de acuerdo con la manera de transformar una tensión alterna en otra continua.

Las fuentes de alimentación son necesarias para alimentar casi todos los sistemas electrónicos

Las fuentes de alimentación son necesarias para alimentar casi todos los sistemas electrónicos, tanto digitales como analógicos. La mayoría se diseña para cumplir con alguno o con todos los requerimientos siguientes:

- **Regulación de salida**: la tensión de salida debe permanecer constante dentro de los límites prefijados. Las posibles causas de variación son los cambios en el voltaje de entrada o en la carga manejada por la salida de la fuente.
- **Aislación galvánica**: la salida debe estar eléctricamente aislada de la entrada. De este modo, se evita la interacción entre la salida de la fuente y la tensión de la red de distribución, y se aumenta la seguridad eléctrica.
- **Múltiples salidas**: generalmente se prefiere tener múltiples salidas (positivas y negativas) que difieran en cuanto a especificaciones de voltaje y corriente.

www.FreeLibros.me

Mod_Cap6_xxx_xxx.qxp 04/07/2011 16:41 PAgina 150

LA FUENTE LINEAL

Para llevar la tensión de línea al rango de tensión de salida deseado, y obtener aislamiento galvánico, la fuente lineal utiliza un transformador de **50 Hz** (**Figura 4**). La tensión alterna de salida del transformador ingresa en un circuito rectificador formado por diodos, para convertirse en una tensión continua pulsante. Luego, un circuito que actúa como filtro aplana la señal para que esta ingrese (o no) en un **regulador de tensión**. Este último proporciona una tensión continua y disminuye las variaciones que posee la señal que sale del filtro (ripple). Estas variaciones están directamente relacionadas con la frecuencia de **50 Hz** de la señal de línea. La regulación del voltaje de salida se logra a través de un sistema de control por realimentación; es decir, la salida es registrada y comparada con una referencia, que es, en general, el valor de tensión deseado. Según el resultado de esta comparación, el regulador ajusta la tensión de salida.

La aislación galvánica evita la interacción entre la salida de la fuente y la tensión de línea

LA FUENTE CONMUTADA

A diferencia de la fuente lineal, la conmutada utiliza las etapas en el siguiente orden: rectificador, conmutador, transformador, un segundo rectificador, filtro, regulador y salida. La tensión alterna de entrada se convierte en una tensión continua no regulada, empleando un rectificador similar al de la fuente lineal (**Figura 5**).

La transformación de tensión continua de un nivel a otro se logra por medio de circuitos convertidores como el **flyback**. Estos poseen dispositivos de estado sólido, como transistores y MOSFETs, entre otros, que operan como llaves, completamente encendidos o apagados.

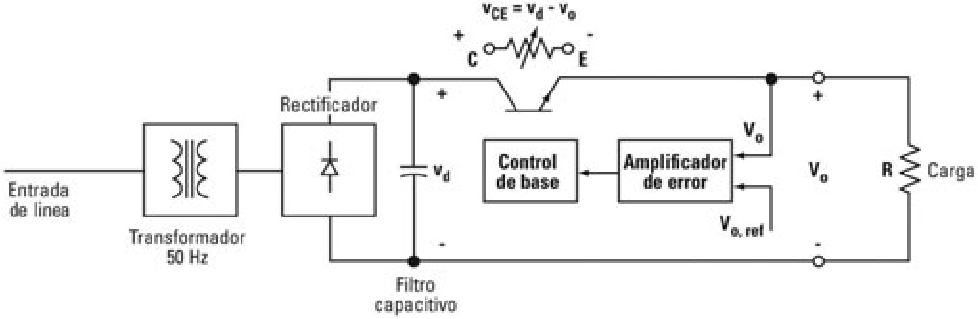


FIGURA 4. **Diagrama en bloques de una fuente lineal. Vemos cómo el transistor controla la tensión de salida de la fuente a través de una realimentación. Dependiendo de la salida, el transistor actúa como regulador ajustando su resistencia.**

FIGURA 5. Diagrama en bloques de una fuente conmutada con regulación. La rectificación se realiza antes de que la señal entre en el transformador.

Para obtener este comportamiento, se utiliza la técnica de **PWM** (*Pulse Width Modulation*), que consiste en conmutar una llave a una frecuencia constante (por lo tanto, a un período constante) y ajustar la fracción del período en que la llave permanece encendida, para lograr, así, controlar el voltaje promedio de salida.

Para obtener el **aislamiento galvánico**, los circuitos convertidores recurren a transformadores de alta frecuencia, ya que la conmutación se realiza a este nivel. La etapa final del convertidor consiste en otro rectificador, que, junto con un circuito integrador, formado por dispositivos que almacenan energía –como bobinas y capacitores–, produce una tensión continua a la salida.

Al igual que la fuente lineal, la regulación del voltaje de salida se consigue a través de una realimentación, porque la salida es registrada y comparada con una referencia, que es el valor de tensión deseado. Según el resultado de esta comparación, el controlador PWM ajusta la fracción de período que la llave permanece encendida para estabilizar la salida de la fuente.

Comparación entre **fuentes lineales y conmutadas**

Ahora que ya hemos estudiado el funcionamiento de ambos tipos de fuentes, analicemos sus ventajas y desventajas.

Las ventajas de las fuentes lineales tienen que ver con los siguientes aspectos:

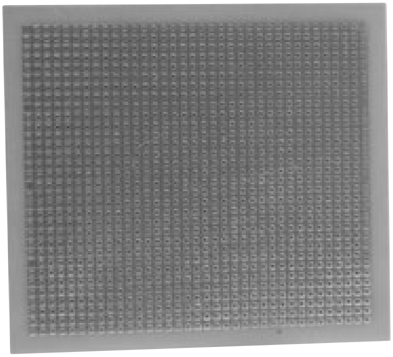
- Poseen un diseño simple, por lo que es viable construirlas de forma casera.
- Para aplicaciones que manejan potencias menores a 10 W, el costo de los componentes es menor que en las fuentes conmutadas.
- Tienen mejor inmunidad a las radiaciones electromagnéticas.
- No son un generador importante de EMI (*Electro Magnetic Interference*), por lo que no afectan el funcionamiento de otros equipos.

Como contrapartida, las **desventajas de las fuentes lineales** son:

- Poseen muy baja eficiencia en aplicaciones normales (entre 30% y 60%). Los valores se incrementan a medida que aumentemos la potencia de la fuente.
- Solo funcionan como reductor de tensión, dado que cada regulador lineal tiene una única salida.

Por otra parte, las **fuentes conmutadas** tienen sus ventajas, que se relacionan con los siguientes aspectos:

- Su eficiencia se encuentra entre un 70% y un 90%, porque el transistor de potencia funciona como llave y no trabaja en su zona activa.
- El transformador de aislación es de alta frecuencia (mayor a 15 KHz), por lo que su tamaño y peso se ven disminuidos de manera considerable.
- Pueden funcionar como reductor, elevador o inversor de tensión con múltiples salidas, porque la tensión de entrada es conmutada y ubicada en un elemento magnético. De este modo, permiten modificar la relación de transformación entre entrada y salida.



LA ELECCIÓN ADECUADA

Si queremos utilizar una fuente de pequeña potencia y bajos niveles de ruido, y además estamos interesados en realizarla nosotros mismos, la lineal es la mejor opción. Pero, si preferimos la eficiencia y la reducción de espacio, optaremos por una fuente conmutada.

www.FreeLibros.me

Finalmente, describiremos algunas desventajas de este tipo de fuentes:

- Tienen un diseño complejo, que requiere de amplios conocimientos y experiencia en electrónica de potencia. Su diseño, construcción y puesta a punto pueden demandar mucho tiempo.
- El ruido es mayor que en las fuentes lineales. Tanto la entrada como la salida producen radiaciones electromagnéticas, por lo que precisan filtros EMI.

Los aspectos detallados hasta el momento son las principales ventajas y desventajas de estas fuentes. Podemos completar esta información con el material complementario de la obra.

Etapas de una fuente de alimentación lineal

Hasta el momento hemos visto las características de una fuente de alimentación lineal. En estas páginas, estudiaremos en detalle sus tres primeras etapas: transformador, rectificador y filtro, a través de los cuales la tensión alterna de línea se convierte en continua.

EL TRANSFORMADOR
